Answer 13.14.3 The correct answer is “C.” In experienced hands, ultrasonography has greater than 95% sensitivity and specificity for pyloric stenosis. It has the additional advantage of avoiding radiation exposure. A pyloric muscle length, or thickness above the upper limits of normal, suggests the diagnosis. An UGI contrast study (“D”) may be used as a secondary test if physical exam and ultrasonography are nondiagnostic (or ultrasonography is not available). The “string sign” on an UGI study suggests pyloric stenosis, and it is formed when contrast material trickles through the elongated pyloric channel (and thus looks like a thin string on x-ray). “A” and “E” are not indicated (or useful) for diagnosing pyloric stenosis. Endoscopy (“B”) would only be indicated if other diagnostic studies were inconclusive and significant clinical suspicion remained. Palpation of the “olive” on physical exam is helpful if present; however, the diagnosis of infantile pyloric stenosis is increasingly being made by imaging studies before the olive becomes large enough to be palpable. Do an imaging study if you have any concern for pyloric stenosis.

HELPFUL TIP:

The definitive treatment for pyloric stenosis is surgical. However, it is an urgent, but not emergent, surgical indication. Make sure to take the time to correct fluid and electrolyte abnormalities prior to surgery.

You have a surgical consultant see the patient, pyloromyotomy is done, and everybody is happy.

► **Objectives: Did you learn to ...**

- Identify clinical manifestations of pyloric stenosis?
- Diagnose and manage pyloric stenosis?

QUICK QUIZ: PEDIATRIC BELLY PAIN

The treatment for midgut volvulus is:

- A) Watchful waiting
- B) Maneuver of Leopold
- C) Emergent surgery
- D) Air enema
- E) Nasogastric suction and bowel rest

The correct answer is “C.” Midgut volvulus is a surgical emergency. Midgut volvulus is an anatomical twisting of the bowel and needs to be surgically corrected. It presents with recurrent bilious vomiting; bilious vomiting in an infant should prompt you to rule

out midgut volvulus. None of the others is correct. Watchful waiting is dangerous and risks ischemic bowel with perforation, so “A” and “E” are wrong. Leopold maneuvers are used to move a breech pregnancy to vertex and have nothing to do with the bowel. “D,” air enema, can be used to reduce an intussusception but has no role in the treatment of midgut volvulus. “E” nasogastric suction and bowel rest are the treatment for a small bowel obstruction. Any bowel obstruction in a child demands investigation.

► **CASE 13.15**

A 5-year-old male who was recently diagnosed with influenza presents to your ED with complaints (via the parents) of intractable vomiting and mental status changes. On examination, the child is febrile and is vomiting but has neither meningeal signs nor focal neurologic findings. His liver is palpable. He takes no routine medications.

Question 13.15.1 Influenza is associated with which of the following complications?

- A) Pneumonia
- B) Rhabdomyolysis
- C) Myocarditis
- D) Encephalitis
- E) All of the above

Answer 13.15.1 The correct answer is “E.” All of the above can be a result of influenza. Pneumonia may be viral or due to a secondary bacterial superinfection. Patients may present with influenza-related severe leg pain secondary to rhabdomyolysis; the CK will be elevated. Myocarditis can present with CHF, arrhythmias, and sudden death; myocarditis can also be subclinical. Obviously, encephalitis will present with mental status changes.

You get labs on this patient. He is noted to be hypoglycemic and to have markedly elevated liver enzymes. His bilirubin is normal. The patient’s white blood cell count is normal, and the differential indicates a lymphocytic predominance.

Question 13.15.2 The MOST LIKELY diagnosis based on this patient’s history, physical, and laboratory findings is:

- A) Reye syndrome
- B) Bacterial meningitis
- C) Transverse myelitis
- D) Hepatic encephalopathy secondary to hepatitis
- E) Diabetes mellitus in the “honeymoon” period

Answer 13.15.2 The correct answer is “A.” This patient most likely has Reye syndrome (encephalopathy with fatty liver degeneration). Reye syndrome presents with intractable vomiting, elevated transaminases with a normal bilirubin level, hypoglycemia, and mental status changes (excitability, delirium, coma). Reye syndrome generally occurs in a genetically susceptible person who has been given aspirin in the setting of a viral illness such as influenza or chickenpox. This patient is

not likely to have meningitis, given the absence of an elevated white count and lack of meningeal signs. Also, he clearly does not have transverse myelitis, an autoimmune condition producing rapidly progressive weakness and sensory disturbance. “E” is incorrect since he is not on insulin.

Question 13.15.3 The medication MOST associated with Reye syndrome is:

- A) Ibuprofen
- B) Celecoxib (Celebrex)
- C) Aspirin
- D) Acetaminophen
- E) Naproxen

Answer 13.15.3 The correct answer is “C.” The use of aspirin in a child with a viral illness, classically influenza or chickenpox, has been associated with the development of Reye syndrome. There is likely some inborn error of metabolism that predisposes to Reye syndrome. Of note, the incidence of Reye syndrome has been steadily declining (currently, less than 1/1,000,000 children) now that parents are aware that they should avoid aspirin use in children. Reye syndrome is most commonly seen on board exams and not in real life (but, still you should know it!).

HELPFUL TIP:

The treatment of Reye syndrome is supportive and includes controlling hypoglycemia and treating cerebral edema. There is no specific treatment of this illness. The mortality rate remains high. Surviving patients should be screened for an inborn error of metabolism.

For some reason, you found heme-positive stool in this patient. You must have been thinking that every patient deserves at least one rectal examination.

Question 13.15.4 All of the following are relatively common causes of heme-positive stools in children 1 to 5 years of age EXCEPT:

- A) Colon polyps
- B) Ulcers
- C) Swallowed epistaxis
- D) Gangrenous bowel
- E) Intussusception

Answer 13.15.4 The correct answer is “D.” Gangrenous bowel (e.g., necrotizing enterocolitis) tends to be found in neonates and infants <1 year old as a result of necrotizing enterocolitis, midgut volvulus, etc. All of the others are correct. See Table 13-6 for more causes of occult GI blood loss in children.

► **Objectives: Did you learn to ...**

- Recognize sequelae of influenza infection?
- Describe Reye syndrome?
- Manage a patient with Reye syndrome (in the lottery-winning-chance that you'd ever really do that)?
- Identify some causes of heme-positive stools in children?

TABLE 13-6 CAUSES OF HEME-POSITIVE STOOLS IN CHILDREN

Less than 1 year: Swallowed maternal blood, anal fissure, intussusception, duodenal or gastric ulcers, gangrenous bowel (e.g., necrotizing enterocolitis), Meckel diverticulum, cow milk protein intolerance

More than 1 year: Juvenile colon polyps, ulcers, anal fissure, esophageal varices, intussusception, hemorrhoids, swallowed epistaxis, Mallory–Weiss tears, bacterial enteritis

► **CASE 13.16**

A mother comes to you with concerns about SIDS in her infant—not that her child has SIDS, which would be awful. Also, her sister had a child who died of SIDS, and she is concerned that her child is now at elevated risk.

Question 13.16.1 You can tell her which of the following?

- A) Twin concordance studies suggest SIDS is passed as chromosomal recessive disorder.
- B) Since her child is now 5 months old, there is no risk of SIDS as SIDS generally occurs before 3 months of age
- C) Siblings of an infant with SIDS have a fivefold increase in the risk of SIDS
- D) SIDS is more likely to occur in female infants
- E) Young maternal age (<20 years old) is associated with **reduced** risk of SIDS

Answer 13.16.1 The correct answer is “C.” A sibling of a child who died with SIDS has a fivefold increased risk of dying of SIDS (although the absolute risk is still less than 1%). “A” is incorrect. The cause of SIDS is unknown. Abnormal arousal from sleep may play a role with delayed brain maturation a factor. SIDS does not seem to be an isolated genetic disorder. “B” is incorrect. SIDS generally occurs between 2 and 4 months (median age 11 weeks). However, 90% of cases occur before 6 months of age, so a 5-month-old child is still at risk. “D” is incorrect as it is more common in males with a ratio of 3:2. Finally, the opposite of “E” is true: maternal age <20 years old is a risk factor as is maternal smoking and the infant's sleeping position.

Question 13.16.2 All of the following have been associated with an increased incidence of SIDS EXCEPT:

- A) Side-sleep positioning
- B) Prone-sleep positioning
- C) Early introduction of solid foods
- D) Premature birth
- E) Intrauterine exposure to drugs

Answer 13.16.2 The correct answer is “C.” The introduction of solid foods has nothing to do with the development of SIDS. All of the other factors increase the rate of SIDS including intrauterine environment. Of note, any nonsupine sleeping position is associated with an increased incidence of SIDS.

Question 13.16.3 The MOST important advice you can give to prevent SIDS is:

- A) Allow the child to sleep in bed with the parent(s) so they can closely monitor the child during sleep
- B) Bundle the child with blankets when sleeping
- C) Use a child alarm in the room to alert the parent(s) if something is wrong
- D) Place the child in the supine position (stomach and face up) when sleeping
- E) Use sheepskin or polystyrene bedding to prevent suffocation

Answer 13.16.3 The correct answer is “D.” Having the infant sleep in a supine position (“back to sleep”) reduces the risk of SIDS by up to 50%. “B” (swaddling) and “E” (polystyrene or sheepskin bedding) **increase the risk** of SIDS. Smoking cessation is important as smoking during pregnancy or after increases the risk of SIDS. Co-sleeping (“A”) should be discouraged as it increases the risk of SIDS. Home apnea monitors, oxygen monitors, etc. (“D”) are not shown to prevent SIDS and do not perform as well as the types of monitors used in a hospital setting.

HELPFUL TIP:

The use of pacifiers in bed may actually decrease the risk of SIDS as well. Give it to the child when he or she is put down for sleep. Do not reinsert it once the child is asleep if he/she spits it out.

HELPFUL (AND SCARY) TIP:

Nothing is free (especially the board examination ... how much are you paying for that?). Supine sleeping has increased the rate of positional plagiocephaly (flattening of the head, in this case in the occipital region). This risk can be minimized by placing the child in a **prone** position **while awake and supervised** (commonly referred to as “tummy time”). Helmets to reform the shape of the skull have been shown not to work (*BMJ*. 2014;348:g2741); and four out of five babies don't think they look very cool.

► **Objectives: Did you learn to ...**

- Identify risks of SIDS?
- Give advice on how to reduce the risk of SIDS?

► **CASE 13.17**

The parents of a 1-month-old female bring the infant for her routine check-up. They are first-time parents and are concerned about feeding. Evidently, one of the grandmothers is “from the old country.” Back in her day in the “old country,” they would start children on solid foods at 2 months of age—usually starting with strained liver (lots of vitamins and stuff, plus it is disgusting and the adults wouldn't eat it). This grandmother also cannot figure out why the couple is

wasting their money on formula when cow's milk (better yet, goat's milk when available) “worked just fine for me.” They would like your advice about feeding.

Question 13.17.1 You let them know that:

- A) Solid foods should be introduced at 3 months for all children. Two months of age is too soon. And grandma's right. Start with liver
- B) Cow's milk is considered adequate only after 6 months of age
- C) Early introduction of cow's milk has been irrefutably linked to type 1 diabetes mellitus
- D) The first foods introduced should be strained meats
- E) Children should have good head control before solid foods are introduced

Answer 13.17.1 The correct answer is “E.” Doesn't “E” just sound best? Even if you hadn't a clue, you would still pick “E,” right? Children should have good head control before starting solid foods. “A” is incorrect for a couple of reasons. First, solid foods are generally not recommended until 4 to 6 months of age. Second, note that the answer says “all children.” “B” is incorrect. Cow's milk should be avoided for the first year of life. Breastfeeding is optimal and infant formula is another good option if mom decides not to breastfeed; formula contains additional nutrients not found in cow's milk. In addition, the early use of cow's milk has been linked to an increase in gastrointestinal blood loss and iron deficiency anemia. “C” is incorrect. There has been some observational evidence to suggest a connection between diabetes type 1 and cow's milk, but the data are quite suspect. “D” is incorrect. Foods should be introduced one at a time, but there is no requirement as to what the first food should be. Usually, iron fortified cereals are introduced first.

HELPFUL TIP:

A word on introducing foods and food allergy... Contrary to what many of us were taught, the early introduction of allergens, such as peanuts, seems to *reduce* the risk of subsequent allergy (*N Engl J Med*. 2015;372:803–813). Whether this extends to other foods is not known. But it is at least reasonable to introduce possibly allergenic foods (peanuts, wheat) early. Early introduction of solids at 3 months does help sleep (*JAMA Pediatr* 2018 Aug; 172:e180739.)

HELPFUL TIP:

AAP guidelines recommend 400 IU/day of vitamin D from birth through the teenage years, no exceptions. This can come either from supplements or foods. Breast milk does not contain enough vitamin D. Supplement vitamin D in exclusively and partially breastfed infants, formula-fed infants receiving less than 1 L of fortified formula per day, and children and adolescents obtaining <400 IU/day through fortified milk and foods.

The parents manage to fend off this grandmother (quite an accomplishment, eh?). The child continues with formula feedings. However, the child gets somewhat fussy on occasion and has bouts of diarrhea. The family wants to know what to do.

Question 13.17.2 Your advice is to:

- A) Change formulas because this represents an allergy to the cow's milk formula
- B) Do not change formulas
- C) Change formulas because this likely represents lactase deficiency
- D) Switch to a formula based on short chain fatty acids since this likely represents an inability to absorb and metabolize fats

Answer 13.17.2 The correct answer is "B." Children will occasionally be fussy and have occasional diarrhea. This does not indicate a formula allergy or intolerance. Reflux and spitting up are also common in infants. Again, this does not indicate a formula allergy. The parents should be reassured that as long as the child is growing and is not having significant difficulties, continuing the current formula is acceptable.

HELPFUL TIP:

Remember, as noted above, reflux or spitting up does not mean formula intolerance. **Do not make multiple formula changes!** This medicalizes a normal pattern in children. The majority of spitting up and reflux will resolve by 1 year of age. If the child looks well and is growing, there is no need to change the formula.

The parents decide that you are correct and continue to feed the child the cow's milk formula. Much as you predicted, the child does well on this formula. However, the child is now becoming "constipated" and the grandmother would like to give this child a laxative (preferably some concoction from the "old country" that no one else can pronounce or formulate). She (the infant, not the grandmother) is having only one bowel movement per day rather than the three to four per day that occurred during the first several months of life.

Question 13.17.3 You let the parents know that:

- A) One stool a day is likely normal for this infant
- B) An infant having less than two to three bowel movements per day is likely constipated since bowel transit time is only 8.5 hours or so
- C) Infants fed soy-based formula tend to have softer stools than those fed cow's milk formula
- D) Breastfed infants may normally have up to 10 stools per day
- E) A and D

Answer 13.17.3 The correct answer is "E." The number of bowel movements in a normal infant can vary widely from 10 per day in a breastfed infant to 1 per day or every other day in a formula-fed infant. What is more important is whether the

child has to strain to pass stool, how hard the stool is, etc. The number of stools per day is less important.

On further questioning, it becomes clear that the grandmother may be correct. This child is having a hard time passing stool and passes only small amounts of hard stool with great effort (red-purple face, lots of crying, etc.). The parents would like some advice.

Question 13.17.4 Which of the following is a reasonable suggestion to treat this infant's constipation?

- A) Change to a formula with a preponderance of whey protein
- B) Treat with corn syrup (whatever brand is cheapest)
- C) Add fruit juices if the child is older than 2 months
- D) Treat with lactulose

Answer 13.17.4 The correct answer is "D." Let's look at this in detail (since parents will tell you all of the details of their child's stools and often bring in a "selfie" of the stool...yes, it's happened!). "A," whey protein, was thought in the past to ease constipation. This has turned out not to be the case. "B" is problematic for a different reason. Many corn syrups in the past contained glycoproteins that were metabolized into non-absorbable sugars. *This is no longer true for many corn syrups; the formulation has changed.* Fruit juices contain sorbitol and are effective. However, they should not be used under the age of 4 months. Beyond that age, sorbitol-containing juices such as pear, prune, or apple may be used to treat constipation. As an aside, glycerin suppositories can be used sparingly for very hard stool in the rectum. Routine use of glycerin suppositories may lead to tolerance (a dependence on manual stimulation to stool) as well as irritation of the rectal and anal mucosa. Finally, polyethylene glycol solution is reasonable in those greater than 4 months of age as are sorbitol-containing purees such as prunes (assuming the child is taking solids).

The child does well after the parents implement your lactulose plan, but she continues to have some reflux symptoms. This is getting worrisome to the parents although the child is growing well.

Question 13.17.5 Which of the following is recommended as standard therapy in treating this child's reflux?

- A) Prone positioning of the child when sleeping
- B) Use of a proton pump inhibitor
- C) Elevating the head
- D) Thickening the formula with rice cereal
- E) None of the above

Answer 13.17.5 The correct answer is "E." This child has physiologic reflux. None of these interventions should be recommended as "standard therapy" for physiologic reflux. Treatment of uncomplicated reflux in infants without warning signs/symptoms is not routinely recommended and may medicalize a benign clinical variant. A watchful waiting approach is appropriate for these infants ("happy spitters"), though it may be messy!

Warning signs/symptoms include poor weight gain, excessive irritation with regurgitation, apnea, or wheezing. Children with concern for apnea or wheezing should have a thorough medical evaluation before attributing these symptoms to reflux. Of the interventions previously mentioned, thickening the formula (“D”) may be helpful to prevent episodes of reflux and may be considered if reflux is concerning to the family. However, the benefit is often minimal. Addition of cereal increases the caloric density of feedings and should not be recommended for overweight infants. Thickening feeds with cereal may also be problematic for premature infants, as the increased viscosity may require increased energy expenditure and cause fatigue. Placing the child in prone position (“A”) while sleeping increases the risk of SIDS. Neither an H₂ blocker, a proton pump inhibitor (“B”), nor elevating the head (“C”) has been shown to reduce reflux. In fact, elevating the head (as in a car seat) may increase reflux.

HELPFUL TIP:

In infants with gastroesophageal reflux disease (defined as having symptoms such as weight loss and not just physiologic reflux), a trial of 2 to 4 weeks of extensively hydrolyzed (“hypoallergenic”) formula or amino acid-based formula, increased caloric density of formula, or thickened formula is reasonable. H₂ blockers and PPIs have also been used but with very limited success. Prokinetic agents such as metoclopramide and erythromycin help improve gastric emptying, but studies have failed to show much efficacy for GERD. In 2009, the FDA issued a black box warning linking chronic metoclopramide use with tardive dyskinesia.

► Objectives: Did you learn to ...

- Give appropriate advice for nutrition and feeding during infancy?
- Diagnose and manage constipation in infancy?
- Treat an infant with significant gastroesophageal reflux?

► CASE 13.18

A 23-year-old G2P1 female at 31 weeks of gestation presents to the ED and delivers precipitously. Her pregnancy was uncomplicated. The neonate is a 1.25-kg male. The helicopter is on its way to transport this premature infant to your regional pediatric hospital. However, it is going to be at least 3 hours because of weather concerns. The infant has moderate respiratory distress.

Question 13.18.1 In the meantime, the BEST treatment for this newborn is:

- Antibiotics
- Corticosteroids
- High-flow 100% oxygen
- Routine care (warmth, stimulation, etc.) and nothing else
- Intubation and surfactant administration

Answer 13.18.1 The correct answer is “E.” Without any further information, you must assume that this patient is at significant risk for neonatal respiratory distress syndrome (RDS). The appropriate treatment is surfactant. The dose of surfactant depends on the preparation, and the timing of administration varies by source (some authors favor immediate administration “prophylaxis,” while others recommend “early rescue” treatment—usually within 2 hours of delivery). Surfactant therapy has good evidence for decreasing morbidity and mortality and should be used in all premature infants who are at risk for RDS (see next question) or acutely symptomatic. On the basis of synergistic interactions, experts recommend combination therapy with **antenatal** corticosteroids for the mother (if possible; see Chapter 15) and surfactant for the premature infant. “A” is incorrect as it is not the most important initial therapy although empiric antibiotic therapy is often indicated in premature infants due to difficulty in distinguishing between RDS and sepsis. “B” is incorrect because steroids for the **newborn infant** are associated with adverse neurodevelopmental outcomes. As for “C,” excessive oxygen can be toxic to premature infants, and initial resuscitation should begin with blended oxygen or room air. “D” might be the second-best option if surfactant were unavailable but note that it says “and nothing else.” It is highly unlikely this premature infant would need “nothing else” (college tuition may be nice). Surfactant is undoubtedly indicated here. Securing the airway for transport will likely also be needed anyway.

HELPFUL TIP:

Surfactant has been shown to decrease air leaks and mortality from RDS, but does not decrease the incidence of chronic lung disease or bronchopulmonary dysplasia.

Question 13.18.2 All of the following are risk factors for neonatal RDS EXCEPT:

- Cesarean section
- Gestational diabetes
- Male sex of infant
- Prolonged rupture of membranes

Answer 13.18.2 The correct answer is “D.” Prolonged rupture of membranes is associated with a **decreased** risk of neonatal RDS. All of the others are associated with an increased risk. Of course, increasing prematurity is associated with increasing risk of RDS as is multifetal pregnancy, especially in the second fetus delivered in a twin pregnancy.

HELPFUL TIP:

The lecithin/sphingomyelin (L/S) ratio is the traditional method for assessing fetal lung maturity. If the L/S ratio is >2, the risk of RDS is low. Other options include phosphatidylglycerol level and direct surfactant measures. It is important to realize that these tests have fairly low-positive predictive values.

**HELPFUL TIP:**

As premature infants grow into adults, keep an eye on their blood pressures and glucose levels. Infants who were born prematurely and at very low birth weight (<1.5 kg) have more problems with hypertension and glucose intolerance as adults.

Because of your congenial bedside manner and amazing command of medical knowledge, this family returns to see you many times over the ensuing years. After looking at yourself in the mirror and reflecting on how awesome you are, you turn your attention to the newest addition to the family, a 4-day-old male infant you delivered—this time in the labor and delivery unit and at term. Gestation and delivery were uncomplicated. He is breastfed and was doing well until this morning. Unfortunately, his mother noticed today that he is breathing harder, eating poorly, and looking more yellow. You note a respiratory rate of 72 and crackles on lung examination, so you order a chest x-ray.

Question 13.18.3 Which of the following diagnoses is most likely?

- A) Neonatal respiratory distress syndrome (RDS)
- B) Persistent pulmonary hypertension (PPHN)
- C) Pneumonia
- D) Pneumothorax
- E) Retained fetal liquid lung syndrome (RFLLS) (AKA transient tachypnea of the newborn).

Answer 13.18.3 The correct answer is “C.” Pneumonia is more likely than the other options because of the timing of the symptoms. Neonatal pneumonia may be early (within the first week of life) or late onset. The pathogenic organisms involved are different for early and late disease. Patients presenting with early onset pneumonia are more likely to have acquired the infection in utero or during delivery; GBS is the most common pathogen in these cases. Patients presenting with late pneumonia may have acquired the disease during delivery, during hospitalization, or while in the community; GBS, *E. coli*, *S. aureus*, *Listeria*, HSV, and *Chlamydia* may all cause pneumonia in these patients. Temperature instability in the newborn is a good clue to an infectious etiology like pneumonia or sepsis. “A” is incorrect since RDS should not occur in a full-term infant nor present this late. “B” is incorrect because persistent pulmonary hypertension should present shortly after birth with hypoxemia and cyanosis. “D”, pneumothorax, is a common result of birth trauma; up to 2% of infants may sustain a pneumothorax during delivery. However, very few infants with a pneumothorax are symptomatic, and you would expect the symptoms to occur shortly after delivery. In addition, breath sounds would be absent or diminished, and there would not be rales. RFLLS (“E”), previously known as transient tachypnea of the newborn, is incorrect because the “transient tachypnea” is a result of delayed reabsorption of alveolar fluid, occurs within 1 to 2 hours of birth and resolves on its own. RFLLS is more

commonly seen in infants delivered by C-section and late-preterm infants.

You found your rectal thermometer (it was in your hand all along—just like your cell phone), and it turns out that your patient is febrile. The chest x-ray shows a left lower lobe infiltrate.

Question 13.18.4 After evaluation with a complete sepsis workup, which of the following is the MOST appropriate antibiotic selection in this setting?

- A) Ampicillin
- B) Ceftriaxone
- C) Gentamicin
- D) Vancomycin
- E) A and C

Answer 13.18.4 The correct answer is “E.” Pneumonia in the newborn period is most likely due to GBS or Gram-negative rods. Community-acquired bacteria are also possible, but less likely. The initial treatment regimen should cover the most common organisms. Ampicillin (“A”) provides excellent coverage for GBS and *Listeria*, while gentamicin (“B”) provides excellent Gram-negative coverage. In combination with ampicillin, a third-generation cephalosporin is a reasonable alternative to gentamicin. Ceftriaxone (“B”), however, is relatively contraindicated in neonates, as it displaces bilirubin from albumin-binding sites resulting in more severe hyperbilirubinemia and the risk of bilirubin encephalopathy (this infant is jaundiced). Ceftriaxone may also cause fatal precipitates in the lung and kidney when co-administered with calcium (perhaps not an immediate concern for this patient). And, *the risk of death may be higher with a cephalosporin when compared to gentamicin*. If absolutely necessary, cefotaxime or another third-generation cephalosporin may be used. It would be prudent to provide empiric antibiotic coverage for all likely bacterial pathogens. Staphylococcal pneumonia in the neonatal period is uncommon, but for severely ill infants, coverage for it should be considered. In this case, vancomycin (“D”) is reasonable which will cover MRSA, MSSA and streptococcus. It should not be used alone due to its lack of Gram-negative coverage. Given this infant’s age, a complete sepsis evaluation (blood, urine, and CSF cultures) is indicated (and ideally before antibiotics, if the infant is stable).

**HELPFUL TIP:**

Remember the possibility of sustained paroxysmal supraventricular tachycardia with CHF in the infant who is tachypneic. These children often present with poor feeding, weakness, tachypnea, and rales. Treatment includes vagal maneuvers (such as placing a bag of ice over the face for 15 to 30 seconds...and watching the horror on the parents’ faces as they think you are suffocating the kid). Other options include cardioversion and adenosine.

► Objectives: Did you learn to ...

- Provide appropriate treatment to an infant at risk for neonatal RDS?
- Identify risk factors for neonatal RDS?
- Describe causes of respiratory distress in the neonatal period?
- Initiate treatment for neonatal pneumonia?

► CASE 13.19

A 20-day-old term male infant is brought to the clinic for evaluation of fever. He was born via uncomplicated vaginal delivery. Mom was GBS negative. In clinic, the infant has a temperature of 38.5°C but is otherwise vigorous with normal vital signs.

Question 13.19.1 What should be done next?

- Discharge home with follow-up the next day
- Treat with empiric antibiotics. Cultures are not necessary for this age group
- Obtain a chest x-ray
- Admit to the hospital
- Treat with ibuprofen

Answer 13.19.1 The correct answer is “D.” Fever in a neonate (younger than 28 days) or young infant (age 29–90 days) is defined as a temperature 38°C or 100.4°F (rectal) or higher. Up to 15% of febrile neonates and young infants will have a serious bacterial infection such as bacteremia, urinary tract infection, meningitis, pneumonia, osteomyelitis, septic arthritis, omphalitis, mastitis, or scalp abscess. UTI is the most common. The infant may appear well with fever being the only manifestation of a serious infection. Risk stratification is based on age, comorbidities, laboratory studies, and the presence of viral infection such as bronchiolitis. There is no clear consensus on the best approach to evaluating and managing febrile infants younger than 90 days. Currently, all febrile neonates, ill-appearing infants, or those not meeting low-risk criteria should be admitted for a full evaluation (including urinalysis with urine culture, lumbar puncture, CBC, blood cultures) and empiric antibiotic therapy. “B” is incorrect as cultures should preferably be obtained prior to initiation of antibiotic therapy. You may obtain a chest x-ray as part of your evaluation, but the best answer is admission. Ibuprofen is not approved for use in infants younger than 6 months. See Table 13-7 for evaluation of a fever in a child 7 to 90 days of age.

The patient is admitted. Blood work including a complete blood count and blood culture is obtained. Urinalysis and urine culture are obtained via sterile catheterization. A lumbar puncture (LP) is performed after obtaining consent (of course) and cerebrospinal fluid is sent for culture and analysis. (Use lidocaine for the LP, even in these young infants ... it hurts!)

TABLE 13-7 EVALUATION OF THE FEBRILE NEONATE

Age < 7 days: ALL should receive full workup including urinalysis and urine culture, blood cultures, lumbar puncture with cultures, CBC, CXR, ampicillin + gentamicin. Admit.

Age 7–28 days: ALL should receive full workup including urinalysis and urine culture, blood cultures, lumbar puncture with cultures, CBC, CXR in those with respiratory symptoms. Ampicillin + cefotaxime or ampicillin + gentamicin. Admit.

Age 29–90 days:

Well-appearing: Urinalysis with culture and CBC (WBC of 5,000–15,000 and <500 bands suggests lower risk of infection); lumbar puncture not needed if child is well looking with reliable follow-up; CXR if respiratory rate >50 bpm, rales, rhonchi, other respiratory symptoms → If evaluation is low risk, consider ceftriaxone 50 mg/kg × 1 dose and return visit the next day for recheck. If high risk, based on CBC, clinical findings, then admit (see antibiotic choice below).

Ill-appearing: CBC, lumbar puncture with CSF culture, urinalysis with urine culture, and blood cultures; CXR if any respiratory symptoms (see above), Ceftriaxone + Ampicillin. Add vancomycin if CSF is abnormal. Admit to hospital.

Question 13.19.2 While waiting for your laboratory testing results what empiric antibiotics will you start?

- Ampicillin and clindamycin
- Gentamicin
- Vancomycin and metronidazole
- Ceftriaxone
- Ampicillin and cefotaxime

Answer 13.19.2 The correct answer is “E.” The choice of empiric antibiotics is based on most likely infecting bacterial organisms in a patient of this age. Bacterial infections in neonates likely were acquired during delivery. The most common organisms are GBS, *E. coli*, and *Listeria monocytogenes*. Empiric treatment should be with ampicillin and cefotaxime or ampicillin and gentamicin; not gentamicin alone as in “B” (you learned this from the case above!). Ampicillin provides coverage for *Listeria* and enterococci. Broadened coverage should be considered depending on focus of infection, and if Gram-positive cocci are seen on CSF Gram stain, vancomycin should be used instead of ampicillin. Empiric acyclovir treatment should be started if HSV risk factors are present.

While examining the patient, you notice he is not moving his right arm. When you ask the mom, she believes that it is new but is unsure when he stopped using it. Examination reveals tenderness over the right proximal humerus with overlying redness, swelling, and pain with moving the shoulder joint; a symmetric Moro reflex; and intact grasp reflex.

Question 13.19.3 Of the following, which is the MOST likely cause?

- Erb palsy
- Klumpke palsy
- Humerus fracture
- Osteomyelitis
- Cerebral vascular incident

Answer 13.19.3 The correct answer is “D.” Fever, pseudoparalysis (reluctance to move affected limb) and swelling with erythema of the affected area is concerning for osteomyelitis with associated septic arthritis. Osteomyelitis, an infection of the bone, usually results from hematogenous seeding. Infants have blood vessels that cross the growth plate allowing for bone infections to spread to the adjacent joint resulting in septic arthritis. *S. aureus* is the most common cause of osteomyelitis in all pediatric age groups. *H. influenzae* is less common since immunizations were begun; however, until culture results are available, it should be covered empirically in children aged 6 months to 4 years who have not yet completed their immunization series. GBS and Gram-negative rods such as *E. coli* are seen in neonates and should be covered empirically. “A” and “B” are types of brachial plexus injuries from birth trauma that result in paralysis and an *asymmetric* Moro reflex due to peripheral nerve injury. “C,” a humerus fracture, though rare can occur as a result of birth trauma but is unlikely based on delayed presentation. “E” is incorrect as most neonatal strokes present with seizures and/or altered mental status. Of note, the normal Moro and grasp reflexes in this child point us away from true paralysis.

**HELPFUL TIP:**

Neonates with osteomyelitis are commonly afebrile and present with nonspecific symptoms such as irritability, decreased movement of a limb (pseudoparalysis), or pain with moving the affected extremity (think pain during a diaper change). Often the diagnosis is delayed and misdiagnosed at first as a traumatic injury.

**HELPFUL TIP:**

Neonatal osteomyelitis often involves multiple bones.

You discuss your concerns with the mother.

Question 13.19.4 She asks you how you will diagnose a bone infection. Your response is:

- A) Clinically
- B) With cultures
- C) With x-ray
- D) With MRI
- E) All of the above

Answer 13.19.4 The correct answer is “E.” Osteomyelitis is a clinical diagnosis requiring you to think about it in your differential. Cultures and imaging confirm the diagnosis. There is no *specific* laboratory test. Frequently, a leukocytosis with left shift and reactive thrombocytosis are present. Inflammatory markers, including C-reactive protein and erythrocyte sedimentation rate, are usually elevated; CRP can be followed to document response to therapy; ESR takes too long to change to be of much use in monitoring treatment. Cultures of the blood, joint fluid,

and/or bone are positive in 50% to 80%. Plain x-rays can rule out other causes such as a fracture but are often not useful in early osteomyelitis as it can take up to 10 days to see changes such as a lytic lesion. MRI is the best imaging study allowing for abscess detection and differentiation between bone and soft-tissue infection. MRI often requires sedation and is expensive. A radionuclide bone scan is helpful for poorly localized pain and/or concerns about multiple bone involvement. Ultrasound can be helpful in septic arthritis.

An x-ray shows a lytic lesion in the proximal humerus. An MRI is obtained, and it is consistent with osteomyelitis. You consult your pediatric orthopedic colleagues who take the infant to the operating room to wash out the joint and obtain cultures.

Question 13.19.5 Cultures of the joint and bone grow GBS. What is the length of antibiotic treatment?

- A) 5–7 days
- B) 10–14 days
- C) 4–6 weeks
- D) 6 months
- E) 1 year

Answer 13.19.5 The correct answer is “C.” Acute osteomyelitis is treated with antibiotics for a minimum of 3 weeks with most courses lasting 4 to 6 weeks. The majority of patients may be treated initially with intravenous antibiotics followed by transition to oral antibiotics after clinical improvement and lack of contraindication to oral therapy. In neonates, the entire course is frequently completed intravenously due to lack of clinical trials. Even with appropriate treatment, neonatal osteomyelitis may result in permanent deformities to the bone or joint with resulting decreased range of motion, asymmetric limb length, and abnormal gait; therefore, long-term follow-up is mandatory. *Note: Now that she has had one child with invasive GBS disease, mom will need GBS prophylaxis during all future labors if she were to get pregnant again.*

**HELPFUL TIP:**

Antibiotic prophylaxis during labor decreases the incidence of early onset GBS disease (within the first 7 days of life), but does not affect late onset GBS disease (7 days to 3 months of age). See Chapter 15 for indications for antibiotic prophylaxis for GBS during labor.

► **Objectives: Did you learn to ...**

- Initiate a diagnostic investigation and management strategy for a febrile infant younger than 90 days?
- Diagnose and manage neonatal osteomyelitis?

**QUICK QUIZ: FEBRILE SEIZURE**

You are evaluating a 10-month-old fully immunized child after a simple febrile seizure. The child has been previously healthy and has not taken antibiotics recently. Physical examination is

unremarkable with no meningeal signs and a normal neurologic examination. The kid is cruising in the exam room trying to open drawers.

What diagnostic testing should be performed?

- A) Lumbar puncture
- B) EEG
- C) Neuroimaging such as head CT or MRI
- D) Serum electrolytes
- E) None of the above

The correct answer is “E.” The clue here is that the child looks normal and is cruising in the exam room. A child with a simple febrile seizure should rapidly return to normal mentation. Per the 2011 AAP guidelines, evaluation of a simple febrile seizure should focus on identifying the cause of the fever. Meningitis should always be considered, and a lumbar puncture should be performed if meningeal signs or symptoms are present. Previous recommendation was to perform a lumbar puncture on all infants younger than 12 months who presented with a simple febrile seizure. This recommendation was made before the widespread immunization against *H. influenzae* type b (Hib) and *S. pneumoniae*. Lumbar puncture (LP) is an **option** in infants 6 to 12 months of age who are not fully immunized or if the immunization status is unknown. Consider an LP in patients who have been on antibiotics because signs of meningitis may be masked. Routine evaluation with EEG, neuroimaging, serum electrolytes, or complete blood cell count should not be done if the only reason is to identify the cause of the febrile seizure.

▶ CASE 13.20

A previously healthy 3-year-old male presents to your clinic for evaluation of 6 days of fever. Mother has been checking axillary temperatures (and yes, not adding or subtracting a degree) which have reached at least 102°F each of the last 6 days. He is irritable. He was seen 2 days prior and given drops for “pink eye.” He now has a new rash and his hands and feet are red and puffy. He has been drinking well and is well-hydrated. On exam, you find a large cervical lymph node on the right, peeling lips, and a red tongue and throat. He has not had cough or runny nose.

Question 13.20.1 Which of the following represents the **BEST** treatment strategy for this child?

- A) Discharge home with watchful waiting
- B) Discharge home with a prescription for amoxicillin-clavulanate
- C) Referral to infectious disease for evaluation of prolonged fevers
- D) Admission for further evaluation and treatment
- E) Transfer to the emergency department for fluid resuscitation

Answer 13.20.1 The correct answer is “D.” Based upon your evaluation, he meets criteria for classic Kawasaki disease (KD), which was formerly known as mucocutaneous lymph

TABLE 13-8 DIAGNOSTIC CRITERIA FOR CLASSIC KAWASAKI DISEASE

Diagnosis of Kawasaki disease can be made in the presence of at least 5 days of documented fever AND at least 4 of the following^a:

1. Oral mucosal changes (lip erythema, lip cracking, “strawberry” tongue, oral mucosal erythema, pharyngeal mucosal erythema)
2. Nonexudative bilateral bulbar conjunctivitis (limbic sparing)
3. Rash (can be maculopapular, annular, or erythroderma)
4. Hand and foot changes (manifests as edema and erythema in the acute phase and/or periungual peeling in the subacute phase)
5. Cervical lymphadenopathy of at least 1.5 cm (often unilateral)

^aCareful history should be obtained, as some of the clinical features may have been present previously but resolved on presentation. Reported findings that have resolved should be counted.

node syndrome. The diagnosis of classic KD is based on the presence of documented fever for at least 5 days and the presence of at least four of five principal features (Table 13-8). KD is an acute vasculitis of childhood. The most feared complication of Kawasaki disease is coronary artery aneurysm. Prompt identification is needed so that further evaluation and treatment can occur to prevent this complication. Inpatient hospitalization is needed. Baseline echocardiography is needed to assess baseline cardiac structure, cardiac function, and coronary artery morphology, though should not delay initial treatment if not rapidly available. It would be inappropriate to send the child home (“A”), and antimicrobial therapy is not indicated (“B”). Infectious disease (“C”), rheumatology, and cardiology specialists may have additional expertise regarding KD; consultation is not necessary at this time. Since the child has adequate fluid status, fluid resuscitation (“E”) is not indicated.

HELPFUL TIP:

Other illnesses may present with similar signs and symptoms as KD. Viral illnesses (adenovirus, measles, etc.), tick-borne illnesses, scarlet fever, toxic shock syndrome, drug reactions, and other rheumatologic conditions should be considered as differential diagnoses. Features not consistent with KD, such as oral ulcers, exudative conjunctivitis or pharyngitis, petechiae, or bullous rash, should prompt consideration of another diagnosis.

HELPFUL TIP:

Children who remain untreated for KD have an approximately 25% chance of coronary artery aneurysms. It is a major cause of acquired heart disease across the world.

Your patient is admitted to the hospital. A baseline echocardiogram is done, with no coronary artery dilation.

Question 13.20.2 Of the following, which is MOST appropriate initial treatment for KD?

- A) Pulse-dose methylprednisolone
- B) Intravenous immunoglobulin
- C) Aspirin
- D) A and B
- E) B and C

Answer 13.20.2 The correct answer is “E.” The 2017 American Heart Association guidelines for diagnosis and management of KD recommends treatment with IVIG (2 g/kg) “as soon as possible” after diagnosis. IVIG is disease-modifying, as it decreases the likelihood of coronary artery aneurysms. Use of moderate- (30–50 mg/kg/day) or high-dose (80–100 mg/kg/day) aspirin is recommended for its anti-inflammatory and antiplatelet effects, though it does not appear to decrease the occurrence of coronary artery aneurysms. Most clinicians will continue moderate- or high-dose aspirin until afebrile for 48 to 72 hours and then transition to low-dose aspirin (3–5 mg/kg/day). Low-dose aspirin is continued until echocardiograms at 1 to 2 weeks and 6 to 8 weeks post-treatment are negative for coronary artery abnormalities. Children with coronary artery abnormalities generally continue aspirin indefinitely. The use of steroids in KD is controversial and may be considered in high-risk children (which is beyond the scope of this review). However, steroids, if used, should be used at the time of initial treatment with IVIG and given daily with a long taper, not pulse dosed.

HELPFUL TIP:

Children treated with IVIG for KD may have fever related to the IVIG. If children have persistent fever beyond 36 hours after completion of IVIG, this represents IVIG-resistant KD. If this occurs, a second dose of IVIG is indicated. Consultation with a KD expert may be indicated. Steroids, infliximab, cyclosporine, and other biologics have been used for refractory cases. IVIG-resistance in KD does increase the risk of coronary artery aneurysms.

HELPFUL TIP:

Some children may not meet classic (or “typical”) KD criteria, but they may have persistent fever and some signs and symptoms of KD without another clear cause. Such children should receive evaluation for incomplete (or “atypical”) KD. If children have 5 days of fever and two to three of the KD criteria in Table 13-8, they should have further laboratory testing to determine if echocardiography and treatment for KD is needed. See the American Heart Association Guidelines for further information (*Circulation*. 2017 Apr 25;135(17):e927–e999).

You treated your patient with IVIG, and his fevers disappeared within 24 hours after completion of the infusion. He did not have recurrence of fevers. His echocardiograms at 2 weeks

and 8 weeks post-treatment were normal, and aspirin was stopped. You are now seeing him 4 months post-treatment for his 4-year-old well-child visit. He is behind on some vaccines, including DTaP, hepatitis A, varicella, and influenza.

Question 13.20.3 Of the following, the most appropriate advice to give regarding administration of vaccinations is:

- A) All needed vaccines can be given at this time
- B) Inactivated influenza vaccine is contraindicated at this time
- C) Live-virus vaccines should be delayed for at least 11 months after IVIG
- D) Live-virus vaccines are contraindicated indefinitely
- E) All vaccines are contraindicated indefinitely

Answer 13.20.3 The correct answer is “C.” Vaccination remains important in children treated for KD. However, after IVIG, some circulating antibodies may persist for up to 11 months that may prevent the development of an adequate immune response to live-virus vaccines, such as measles and varicella. Thus, these should be delayed until 11 months after IVIG administration. One caveat: if a child remains on aspirin, varicella vaccination is NOT recommended due to the risk of Reye syndrome. The benefits of varicella vaccination while on low-dose aspirin may outweigh the risks if the likelihood of varicella exposure is high, and this should be discussed with the family. “B” is incorrect, as children should continue to receive the inactivated influenza vaccine. This is very important in children on aspirin, as influenza has been associated with Reye syndrome. “A,” “D,” and “E” are incorrect, as described above.

► **Objectives: Did you learn to ...**

- Diagnose Kawasaki disease (KD)?
- Manage acute and IVIG-refractory KD?
- Describe the recommended timing of vaccines after IVIG administration?

QUICK QUIZ: EYELID SWELLING

A 5-year old girl comes to your office with a 2-day history of right upper eyelid swelling, pain, and redness. She sustained an insect bite on her face when they moved into a new apartment last week. She has been afebrile. On examination, you can evert the eyelid and do not appreciate any conjunctival swelling, conjunctival injection, or proptosis. Her ocular movements are intact and painless.

Of the following, which is the MOST likely diagnosis?

- A) Preseptal cellulitis
- B) Orbital cellulitis
- C) Acute viral conjunctivitis
- D) Chalazion

The correct answer is “A.” Preseptal (or periorbital) cellulitis refers to infection of the dermis anterior to the orbital septum, and needs to be differentiated from the more severe orbital

cellulitis (“B”) which refers to an infection of the contents of the orbit, posterior to the orbital septum (see “helpful tip,” below). Well-appearing patients older than 1 year of age with preseptal cellulitis may be managed in the outpatient setting. Management is geared toward common infecting organisms (*Staphylococcus aureus*, *Streptococcus pneumoniae*, other streptococci and anaerobes). Oral clindamycin or amoxicillin-clavulanate are excellent choices for monotherapy. Alternatives include TMP-SMX with amoxicillin or a third-generation cephalosporin. Most patients improve within 24 to 48 hours. Treatment failure requires hospitalization for parental antibiotics. The infection can be caused by direct infection of the skin and soft tissues (i.e., insect bite) or from contiguous spread due to sinusitis or dental abscesses. Acute viral conjunctivitis (“C”) not only may present with mild periorbital swelling, but also would present with conjunctival injection. Chalazion (“D”) is a localized nonpainful swelling due to a blocked gland of the eyelid and would not affect the entire eyelid. This is noninfectious and is generally treated symptomatically with warm compresses. Curettage may be indicated for persistent lesions.

HELPFUL TIP:

Suspect orbital cellulitis in the presence of ophthalmoplegia, chemosis, proptosis, pain with eye movements, and decreased visual acuity! Orbital cellulitis requires urgent CT imaging, IV antibiotics, and consultation with an ophthalmologist.

▶ CASE 13.21

You receive telephone call from the mother of one of your patients, a 2-year-old previously healthy male. His mother is concerned that he had been walking around normally yesterday, but today will not stand or walk. This evening, he has become more irritable and cries if they try to put him in a standing position. He seems to be uncomfortable when they move his right leg while changing his diaper. There is no known trauma. He is eating and drinking less today. He feels warm, but they lost their thermometer and have not checked a temperature at home.

Question 13.21.1 Of the following, what is the MOST appropriate advice to give to his mother?

- A) Give a dose of ibuprofen and call if symptoms worsen
- B) Apply ice to his right leg and keep it elevated
- C) “Double-diaper” him to prevent movement of the affected leg
- D) Proceed to the ER for evaluation
- E) Proceed with “watchful waiting” this evening and call in the morning if symptoms continue

Answer 13.21.1 The correct answer is “D.” Failure to bear weight in an ambulatory child is NOT normal and requires further evaluation. The history is concerning for pathology of the

right hip and/or leg. The progressive nature of his symptoms and possible fevers raise concern for an infectious pathology, and requires urgent evaluation; thus, “E” would be incorrect. Symptomatic care, such as NSAIDs, rest, ice, and elevation (“A” and “B”) may be appropriate for sprains and strains, but there is no known trauma history. Plus, can you imagine having a cranky toddler do those things? “Double-diapering” (“C”) had historically been recommended for infants with concern for developmental dysplasia of the hip (DDH). This is not recommended treatment for DDH, as it does not provide enough limitation of hip movement. Infants with a positive screen for DDH (positive Ortolani or Barlow) should have appropriate imaging and be referred to an orthopedic surgeon and placed in a Pavlik harness.

Your patient presents to the ER for further evaluation. There, he is ill-appearing, but not toxic. He is febrile to 103.1°F. He is tachycardic, but has a normal blood pressure for his age. He is well hydrated. On exam, he resists passive movement of his right hip and holds it slightly externally rotated and flexed. You can flex and extend the right knee without difficulty. There is no pain to palpation of the long bones of his legs. He will not stand, despite your best efforts. X-rays of the hip show possible joint widening. X-rays of the right femur and knee are without bone lesions or fracture. His dad asks you, “So, what do you think is going on, doc?”

Question 13.21.2 Of the following, which is the MOST likely diagnosis?

- A) Transient synovitis of the hip
- B) Septic arthritis of the hip
- C) Femoral osteomyelitis
- D) Spiral fracture of the femur
- E) Slipped capital femoral epiphysis (SCFE)

Answer 13.21.2 The correct answer is “B.” This child’s presentation is most consistent with septic arthritis of the hip. Children with failure to bear weight, decreased range of motion, and new fever require thoughtful evaluation for possible osteoarticular infection. Children with septic arthritis of the hip often keep the hip flexed and mildly externally rotated, which widens the capsular volume, providing some comfort. Laboratory findings may be helpful in diagnosis and often include ESR > 40 mm/hr, CRP > 2.5 mg/dL, and WBC count > 12,000 cells/mm. Hematogenous seeding of the joint is the most common mechanism of infection. Transient synovitis (“A”) of the hip is a benign self-limited condition characterized by hip pain with an antecedent viral illness. It is the most common cause of acute hip pain in children between ages 3 and 8. The symptoms typically last for 3 to 6 days. Patients are well-appearing and afebrile. NSAIDs are useful in transient synovitis. Osteomyelitis (“C”) must be considered, but exam findings point more toward a septic hip. Osteomyelitis may present with fever without clear source and can be indolent. Osteomyelitis may have contiguous spread to adjacent joints. Femur fracture (“D”) is less likely without trauma, and x-rays do not indicate fracture. SCFE

(“E”), the displacement of the capital femoral epiphysis from the femur, is incorrect. This is most common in obese adolescents and requires surgical intervention.

You obtain an orthopedic surgery consult, and they agree that a septic hip is likely. They plan to obtain synovial fluid under ultrasound guidance to guide their therapy.

Question 13.21.3 Of the following, what synovial fluid findings would be MOST consistent with septic arthritis?

- A) White blood cells (WBCs) $<200/\text{mm}^3$ and $<25\%$ polymorphonuclear cells (PMNs)
- B) WBCs 200 to $2,000/\text{mm}^3$ and $<25\%$ PMNs
- C) WBCs 2,000 to $50,000/\text{mm}^3$ and $>50\%$ PMNs
- D) WBCs $>50,000/\text{mm}^3$ and $>75\%$ PMNs

Answer 13.21.3 The correct answer is “D.” Immediate synovial fluid sampling should occur if septic arthritis is suspected. Septic arthritis presents with a high WBC count in the synovial fluid, usually $>50,000$ cells/ mm^3 with a predominance of PMNs. “A” represents normal synovial fluid. “B” represents a noninflammatory arthritis and may be seen in osteoarthritis in older folks. “C” represents a noninfectious inflammatory arthritis (i.e., juvenile inflammatory arthritis, reactive arthritis). In children, sampling of synovial fluid often requires sedation. If there is a high-suspicion for septic arthritis, sampling of synovial fluid is often done under anesthesia in the OR so operative intervention can occur if results are concerning.

HELPFUL (AND SOMEWHAT ANNOYING) TIP:

Lyme arthritis should be considered if travel to an endemic area has occurred. Travel to Wisconsin or Connecticut is a big clue! Lyme arthritis frequently presents with synovial fluid analysis showing 2,000 to $50,000$ WBCs/ mm^3 . Sometimes, however, Lyme may present with higher synovial fluid WBC counts ($>50,000/\text{mm}^3$). Routine synovial fluid cultures are negative in Lyme arthritis. Additionally, while a WBC count of $>50,000/\text{mm}^3$ is pretty specific for infection, it isn't terribly sensitive (61% sensitive); use clinical judgment (see Chapter 12). Finally, *Kingella kingae* (discovered and named by Elizabeth King... go figure), a Gram-negative organism, may be the most common cause of septic arthritis in children 2 to 3 years of age. PCR and meticulous cultures will reveal this organism. Yeah, we never heard of it either until researching for this book.

You obtain labs (which support septic arthritis) and blood cultures. The orthopedic surgeon takes the child to the OR and performs a joint aspiration. There are $>100,000/\text{mm}^3$ WBCs with $>75\%$ PMNs, clinching the diagnosis. Your patient's dad has a lot of great questions. He next asks you, “Alright, so what are we going to do to fix this?”

Question 13.21.4 Of the following, which is the MOST appropriate therapeutic plan?

- A) Joint aspiration alone
- B) Urgent surgical irrigation and drainage of the hip
- C) IV antibiotics
- D) B and C
- E) None of the above

Answer 13.21.4 The correct answer is “D.” Prompt diagnosis and treatment is needed, as damage to the cartilaginous structures of the hip and blood supply to the femoral head can begin within 6 hours of infection and may be irreversible after 24 to 48 hours. Think of a hip infection like an abscess—source control is needed. Antibiotics are required to clear the infection from the joint and should be started immediately after obtaining blood and synovial fluid cultures. “A” is useful for diagnosis, but surgical drainage and irrigation of the hip is recommended, given possible morbidity of incomplete treatment.

Question 13.21.5 Of the following, which is the MOST appropriate empiric antibiotic regimen?

- A) Cephalexin
- B) Oxacillin
- C) Ceftriaxone
- D) Vancomycin
- E) Linezolid

Answer 13.21.5 The correct answer is “D.” Of the provided options, vancomycin is the most appropriate initial therapy for this toddler. The most common causal organisms are *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*. In hemodynamically stable patients, vancomycin monotherapy is appropriate. This will cover resistant organisms, including MRSA and resistant *S. pneumoniae*. The high prevalence of community-acquired MRSA necessitates the inclusion of MRSA coverage, pending cultures. Clindamycin may be considered, often in conjunction with an anti-staphylococcal beta-lactam, such as nafcillin, but *S. aureus* resistance to clindamycin may limit its usefulness in some areas. “A” and “B” would provide excellent Gram-positive coverage, except for MRSA. “A” is additionally incorrect, as it is an oral medication, and parental therapy is indicated initially. “C” would be indicated in addition to vancomycin if there was concern for Gram-negative infection or Lyme. *Hemophilus influenzae* type B should be considered in nonvaccinated individuals. *Kingella kingae* is an indolent organism that is difficult to culture and may cause septic arthritis and osteomyelitis in young children. *K. kingae* often requires holding of cultures for up to a week to grow. Addition of a cephalosporin (e.g., cefazolin) may be needed to provide coverage for this organism if cultures are negative and the child doesn't improve as expected. “E” is an excellent Gram-positive drug and would be a great choice if there were a contraindication to vancomycin (e.g., renal failure). Linezolid is quite expensive, which limits its use. It can also be

quite myelosuppressive. Antibiotic therapy should be tailored based on culture susceptibility data. In general, at least 3 weeks of total antibiotic therapy is indicated, with longer courses if complications or delayed improvement. Immunocompetent patients may be switched to enteral antibiotics once they show steady clinical improvement, decreased inflammatory markers, toleration of oral medication. In general, this is as effective as a prolonged parenteral course and avoids the complications of a central line. Special populations (i.e., neonates, immunocompromised patients) may require parenteral antibiotics for their full treatment course.

HELPFUL TIP:

In stable patients, blood and synovial fluid cultures should be obtained before starting antibiotics. Cultures and sensitivities will help guide antibiotic selection. Blood cultures are positive in ~40% of patients with septic arthritis. In rare cases, blood cultures may be positive when synovial fluid cultures are negative.

Your patient's synovial fluid cultures grew methicillin-sensitive *S. aureus*. After 4 days, he improved, was switched to oral antibiotics, and was discharged. On follow-up, his labs normalized, and he completed an appropriate 3-week course of antibiotics (sufficient if there is no associated osteomyelitis). You see the family again at his 3-year well-child visit in October and he is doing great! His dad asks you, "What shots does he need today?" You confirm that he has received vaccinations at prior well-visits according to the CDC recommended schedule.

Question 13.21.6 Of the following, which vaccines are indicated today?

- A) MMR
- B) DTaP
- C) Influenza, if not obtained yet this season
- D) All of the above
- E) B and C

Answer 13.21.6 The correct answer is "C." We couldn't end without a final vaccination question. No vaccinations are routinely administered at the 3-year well-visit, except for the yearly influenza vaccine, if it had not already been administered. Review the CDC website again to refresh your memory!

► Objectives: Did you learn to ...

- Generate a differential for refusal to bear weight in a toddler?
- Differentiate between transient synovitis and septic arthritis?
- Manage a patient with septic arthritis of the hip?

Clinical Pearls

- Do not agitate a child if you suspect epiglottitis as this may worsen airway obstruction.
- Do not perform routine head imaging in a child with simple febrile seizure. Direct your investigation toward evaluation and treatment of the underlying fever.
- Do not prescribe antibiotics for viral infections, including viral conjunctivitis and colds.
- Do not routinely perform VCUG for the evaluation of first febrile UTI.
- Do not use ceftriaxone in neonates as it displaces bilirubin from albumin-binding sites and can cause severe hyperbilirubinemia.
- Obtain blood cultures at birth followed by a minimum of 48 hours of antibiotics in infants born to mothers with chorioamnionitis.
- Perform universal hearing and metabolic screening in newborns.
- Recommend placing babies "Back to Sleep" to reduce the risk of SIDS. The addition of infant home apnea monitors does not provide additional benefit.

Adolescent Medicine

Stacey Appenheimer and Kelly Skelly

► CASE 14.1

A 14-year-old male presents to your clinic with his mother for a routine well-child examination. The patient's mother has some questions about puberty. Her son enjoys playing sports and she is concerned that he may be too small to play football. The past medical history is unremarkable.

Question 14.1.1 Which of the following can you tell the mother will likely be the first sign of puberty in this boy?

- A) Increase in penile length
- B) Enlargement of the testes
- C) Deepening of the voice
- D) Rapid increase in linear growth
- E) Coarsening of pubic hair

Answer 14.1.1 The correct answer is "B." Increase in the volume of the testes is the first sign of pubertal development in boys. The age of onset of puberty in the past was 12 years (range 10–14), but recent studies have shown that the mean age of onset is now 1.5 to 2 years earlier than these historical norms. In a study including more than 4,000 healthy boys, the mean age for entering puberty was 10.14 years for Caucasian boys, 10.04 years for Hispanic boys, and 9.14 years for African-American boys. "E" is of special note. While pubic hair appears shortly after the onset of puberty, it is initially long and straight and not in a mature distribution. Coarsening of the pubic hair is a more advanced pubertal stage, occurring approximately 1.5 years after the onset of puberty, and an increase in penile length occurs simultaneously. The maximal growth spurt occurs approximately 2 years after the onset of puberty. Changing of the voice is a secondary hormonal effect that is quite variable in nature.

From the mother, you learn that the patient's father began going through puberty during high school, and he did not reach his adult height until he was in college at about age 20. The patient's father is 5' 10" tall (~178 cm). The mother is 5' 3" tall (~160 cm). Physical examination reveals that your

patient is Tanner stage I for genitalia and pubic hair. His height and weight continue to track along their previously established curves on the growth chart, both at approximately the second percentile. The remainder of the examination is unremarkable.

Question 14.1.2 What is your next step in evaluation of this patient's short stature?

- A) Obtain radiographs of the left hand and wrist to assess bone age
- B) Draw blood to test for growth hormone and testosterone levels
- C) Obtain an endocrinology consult
- D) Order computed tomography (CT) imaging of the brain to rule out hypothalamic tumors
- E) Order magnetic resonance imaging (MRI) of the brain to rule out hypothalamic tumors

Answer 14.1.2 The correct answer is "A." In the face of a normal physical examination and appropriate linear growth velocity, the likelihood of an intracranial process is very low. An assessment of bone age can be obtained easily with a radiograph—typically of the left hand and wrist. If there is discordance between bone age and physical exam findings, further testing may be indicated.

You decide to obtain a radiograph of the hand and the wrist to assess bone age, and the radiologist reports the patient's bone age as consistent with 12 years and 3 months (remember that our patient is 14 years old).

Question 14.1.3 What is the most likely diagnosis for your patient?

- A) Growth hormone deficiency
- B) Sella turcica tumor
- C) Constitutional delay of growth and puberty
- D) Idiopathic testicular atrophy
- E) Testosterone receptor abnormality

Answer 14.1.3 The correct answer is “C.” The bone age of 12 years and 3 months is reassuring. Since there is no fusion of the growth plates, his bones are immature and still have the ability to grow. Had the bone age been 14, it is likely that his adult height would be short; the bones would no longer have the inherent ability to grow. Bone age assessment is an accurate tool for determination of expected growth. Constitutional delay is the most common diagnosis for short stature, and it is often associated with a delayed onset of puberty. Constitutional delay is a diagnosis of exclusion; a complete history and physical often rules out other diagnoses. Family history often reveals a parent who was a “late bloomer” but eventually had normal pubertal development. This adolescent’s history of normal linear growth velocity (albeit along the second percentile) is reassuring for the absence of growth hormone deficiency or intracranial abnormalities. This adolescent’s combination of appropriate linear growth velocity, appropriate adjustment for bone age, and paternal history of late pubertal development is classic for a constitutional delay.

When your patient’s height is plotted on a growth curve and adjusted for bone age rather than chronological age, the height now plots just below the 50th percentile. Your patient now has a question of his own. His biggest concern is that some of his classmates are starting to get taller, and he is afraid he will be too short to continue competing in sports. Once again, his mother is 5’ 3” tall (~160 cm) and his father is 5’ 10” tall (~178 cm).

Question 14.1.4 Based on what you know today, what is your best estimate of this patient’s adult height?

- A) 5’ 3” \pm 2 (160 \pm 5 cm)
- B) 5’ 5” \pm 2 (165 \pm 5 cm)
- C) 5’ 7” \pm 2 (170 \pm 5 cm)
- D) 5’ 9” \pm 2 (175 \pm 5 cm)
- E) 5’ 11” \pm 2 (180 \pm 5 cm)

Answer 14.1.4 The correct answer is “D.” You can provide a rough estimate of the patient’s adult height using the calculation for mid-parental height (MPH). Remember that the parent of the opposite gender—the mother in this case—must have the height adjusted for this calculation. For boys, add 5 inches to the mother’s height (12.5 cm) and then average this corrected maternal height with the paternal height to determine the MPH. For girls, subtract 5 inches from the paternal height and then average this corrected paternal height with the maternal height to calculate the MPH. In our patient’s case, his mother’s corrected height is 68 inches which averaged with his father’s height of 70 inches, equates to an MPH of 69 inches. A margin of error of ± 2 inches (5 cm) is often given with MPH estimates.

► **Objectives: Did you learn to ...**

- Evaluate a patient with growth concerns?
- Identify the clinical presentation of constitutional delay?
- Calculate mid-parental height (MPH)?

► CASE 14.2

Your next patient is a 16-year-old female cross-country runner who you are seeing in follow-up for right shin pain. She was diagnosed in the local emergency department 1 week ago with “shin splints” and told to limit her activities. In your office, she tells you that the pain has been worsening over the last 3 months, and she has progressively decreased the distance and time of her runs (but, of course she’s a runner, so she hasn’t quit). She denies fever, swollen joints, or other systemic symptoms. She normally has regular menses, but notes that she has irregular menses during cross-country season. The patient’s past medical history is significant for a stress fracture in her left foot 18 months ago. Your examination reveals tenderness at the middle one-third of the right tibia. In addition, she has pain on a single-leg hop. You are able to review her x-rays from the emergency department, which do not reveal any fractures or other abnormalities.

Question 14.2.1 What is the most appropriate next step to diagnose your patient’s leg pain?

- A) Ultrasound of the lower extremity
- B) MRI of the lower extremity
- C) Dual-energy x-ray absorptiometry (DEXA) scan
- D) Thyroid-stimulating hormone (TSH) level
- E) Urine pregnancy test

Answer 14.2.1 The correct answer is “B.” MRI is sensitive and specific for stress fractures and has become the preferred study. The patient’s history and examination are concerning for the presence of a tibial stress fracture. Stress fractures often present insidiously and cause gradual progression in symptoms over time until a critical point is reached in terms of sports participation. Half of stress fractures are not visible on plain radiographs.

Ultrasound is gaining popularity, but it is best used to rule out a stress fracture (given its high negative predictive value). DEXA scan can provide whole-body and site-specific measurement of bone mineral density, which may be related to the pathophysiology of stress fractures but does not help diagnose a site of injury. Radionuclide bone scans are often less expensive than CT or MRI, and they demonstrate sites of injury based on increased uptake of the radionuclide material. However, bone scans are not specific for stress fractures and are often falsely positive. Of note, plain radiographs may take months to become positive after a stress fracture and, while radiographs may be done, they will not be of use if the result is negative. Given the patient’s other complaints, TSH and urine pregnancy test may be warranted but will not assist in the diagnosis of her leg pain.

An MRI is obtained and confirms the presence of a stress fracture in the middle one-third of the right tibia. Because of your patient’s history, especially that of multiple stress fractures, you are concerned she may be suffering from the female athlete triad.

Question 14.2.2 What are the components of the female athlete triad?

- A) Low-energy availability (with or without an eating disorder), menstrual dysfunction, altered bone mineral density
- B) Depression, weight loss, sports-related injury
- C) Poor sports performance, low self-esteem, injury
- D) Weight gain, bony injury, mood changes
- E) Fanatical attachment to sports, testosterone abuse, anger management issues

Answer 14.2.2 The correct answer is “A.” The female athlete triad was first identified in the early 1990s and originally characterized as anorexia, amenorrhea, and osteoporosis. As more has been learned about the triad, the realization has been made that the triad likely represents a broader spectrum disorder within each category. Many young women with the triad will exhibit low-energy availability with or without disordered eating behaviors, such as caloric restriction or use of diuretics and diet pills, but would not meet the criteria for anorexia or bulimia nervosa. Menstrual dysfunction may include oligomenorrhea or irregular, intermittent menses, as well as amenorrhea. These young women may also have abnormal bone mineral density, with predisposition to bony injury, without having reached the strict criteria of osteoporosis.

The patient comes back to the office to receive her test results, and you take the opportunity to obtain more history. The patient admits that she is very concerned about her diet during her cross-country season, and she is very careful to choose foods that have very little fat but are often high in protein. She will occasionally “go overboard” and eat a lot, for which she compensates by taking part in extra workouts. She has also used laxatives in the past “to not gain weight when I eat too much.”

Question 14.2.3 Which of the following findings is NOT classically found in bulimia nervosa?

- A) Loss of dental enamel
- B) Enlarged parotid glands
- C) Metabolic acidosis
- D) Skin changes over the dorsum of the hands
- E) Maintenance of a significantly low body weight

Answer 14.2.3 The correct answer is “E.” Loss of dental enamel, skin changes over the dorsum of the hands, and enlarged parotid glands may be seen as a result of repetitive self-induced vomiting. While self-induced vomiting would cause a metabolic alkalosis through loss of stomach acid, repetitive use of laxatives can cause gastrointestinal losses of bicarbonate, resulting in a metabolic acidosis. **Individuals with bulimia nervosa often maintain a normal weight**, while anorexia nervosa has strict diagnostic criteria requiring maintenance of significantly low body weight, often less than 85% of the ideal body weight.

Your patient also relates that she began having her periods around age 12. While they were initially irregular, they seemed

to become more regular prior to starting high school. However, as she became more involved in high school sports, her periods became more irregular. During her off-season, her menses are “more regular,” though she cannot predict when they will occur. She recalls that her last period was about 13 weeks ago.

Question 14.2.4 In evaluating your patient’s menstrual dysfunction, what would be your next course of action?

- A) Obtain serum LH, follicle-stimulating hormone (FSH), and estradiol levels
- B) Order an abdominal and pelvic ultrasound
- C) Perform a speculum-assisted pelvic examination with Pap smear
- D) Obtain a urine beta-hCG
- E) Prescribe an oral progestin-only pill (progestin challenge)

Answer 14.2.4 The correct answer is “D.” The most common cause of secondary amenorrhea in women of childbearing age remains pregnancy. If pregnancy has been excluded, and the history and physical are reassuring, a progestin challenge can be helpful to determine if adequate estrogen is present; the progestin challenge should induce menses if adequate estrogen exists (see Chapter 15 for details on the evaluation of amenorrhea). Imaging studies and hormonal levels may help in excluding other diagnoses or may be warranted based on physical examination. A pelvic examination may be warranted based on history but is often not necessary in the *initial* evaluation of menstrual dysfunction. Pap smears are no longer recommended for women under the age of 21, regardless of sexual activity status.

Your patient’s pregnancy test is negative and a progestin challenge induced menses, indicating adequate circulating estrogen. A comprehensive plan is developed that includes psychological counseling, dietary modification, physical therapy, consultation with a nutritionist, and frequent follow-up. Over the next several months, the patient recovers from her injury, and returns to running on a modified schedule. However, she now complains of heavy, painful menses and wants to go on the “shot” to stop them.

Question 14.2.5 In your counseling about birth control options, which of the statements below is FALSE?

- A) The birth control pill can be used to treat irregular menses of the female athlete triad and will also increase bone deposition
- B) The effect of Depo-Provera (medroxyprogesterone) is to suppress the hypothalamic–pituitary–ovarian axis, creating a low estrogen state akin to perimenopause
- C) The FDA issued a “Black Box” warning on Depo-Provera that states “prolonged use ... may result in loss of bone density that may not be completely reversible after discontinuation of the drug”
- D) The risk of future fracture using Depo-Provera is unknown, as bone density is an incomplete measure of bone strength, and remodeling and recovery are significant
- E) Use of a long-acting reversible contraception (LARC) should be offered as first-line contraceptive choice

Answer 14.2.5 The correct (and “false”) answer is “A.” The other statements are all true. Starting a combined estrogen/progesterone contraceptive pill will restart a menstrual cycle but may not increase bone density. As to “E,” an American Academy of Pediatrics (AAP) policy statement from September 2014 recommends that a LARC be considered as a first-line contraceptive option in adolescents, including intrauterine device (IUD) or subdermal implant. These can provide 3 to 10 years of contraception and are effective and safe forms of birth control. Concerns about an increase in pelvic inflammatory disease (PID) with the IUD appear to be unwarranted.

In your routine anticipatory guidance, you discover that she avoids most dairy products due to a combination of prior concerns about fat content and lactose intolerance.

Question 14.2.6 What do you recommend for her daily intake of elementary calcium?

- A) 900 mg
- B) 1,100 mg
- C) 1,300 mg
- D) 1,700 mg
- E) 2,100 mg

Answer 14.2.6 The correct answer is “C.” While the absolute best intake of calcium for individuals is unknown, studies have shown positive calcium balance for adolescents with an intake of 1,200 to 1,500 mg daily. In its 2010 report, the Institute of Medicine (IOM) set 1,300 mg/day as the “adequate” dietary intake for boys and girls 9 to 18 years of age. This guideline was set to meet the needs of 95% of healthy children, with the upper limit of calcium intake set at 3,000 mg/day.

For most persons, 1,300 mg/day of calcium intake can be accomplished with four servings of dairy products (8 oz of milk = 8 oz of yogurt or cottage cheese = 1 inch cube of cheese) plus a varied diet that includes other calcium-rich foods (e.g., broccoli, collard greens, and turnip greens). It is generally preferable to achieve intake of calcium via diet, including fortified foods, because foods provide multiple nutrients that are important for bone health, such as phosphorus and magnesium. Unfortunately, adolescent girls’ average calcium intake is only 700 to 800 mg/day, and adolescent boys’ average intake is about 1,000 mg/day—and yet, we have an obesity epidemic. Ironic, but not funny.

Question 14.2.7 On average, what percentage of total body mineral content has a young woman deposited by the time she reaches 12 years of age?

- A) 20% to 30%
- B) 40% to 50%
- C) 70% to 75%
- D) 80% to 85%
- E) 95% to 100%

Answer 14.2.7 The correct answer is “D.” Research suggests that by age 12, a young woman has reached approximately 83%

of her peak bone mineral content, with 50% deposition happening from the time of “peak height velocity,” which is premenarchal through 1-year postmenarche. The ability to absorb calcium from the diet is also enhanced during this period. Rates of deposition begin to decline approximately 2 years postmenarche and no significant gains are seen after the age of 17. These statistics emphasize that osteoporosis, while manifesting in older adults, is truly an issue of adolescent preventive medicine.

Your patient returns from a high-powered sports medicine clinic in Palm Springs (or Laguna Beach ... or anywhere more likely to make TV than Iowa). She brings you her DEXA scan results that are consistent with osteopenia. She looks up from her Instagram feed and asks, “So, what are we gonna do about that, Doc?”

Question 14.2.8 You scour the literature and recommend:

- A) Alendronate
- B) Calcium and vitamin D
- C) Vigorous weight-bearing exercise
- D) Dehydroepiandrosterone (DHEA)
- E) All of the above

Answer 14.2.8 The correct answer is “B.” Alendronate has no proven benefit in adolescent osteopenic females. Recommending exercise is the usual course for older patients with osteopenia, but you need to be careful in the adolescent with weight concerns who may exercise excessively at baseline. DHEA is investigational and has not been shown to increase bone mineral density. Stick with the standard of care: calcium in the daily doses as recommended above and **vitamin D 600 IU daily** (note that this recommendation is a change in the 2010 IOM guideline—and, yes, that is the most recent guideline as of 2019).

► **Objectives: Did you learn to ...**

- Evaluate a stress fracture in an adolescent runner?
- Identify the “female athlete triad?”
- Recognize the importance of calcium and vitamin D intake and osteoporosis prevention in adolescence?

QUICK QUIZ: ADOLESCENT ATHLETES

According to most U.S. studies, what is the number one cause of sudden cardiac death (SCD) in adolescent athletes?

- A) Marfan syndrome
- B) Coronary artery disease
- C) Congenital malformation of coronary arteries
- D) Hypertrophic cardiomyopathy
- E) Long QT syndrome

The correct answer is “D.” Hypertrophic cardiomyopathy is an autosomal-dominant trait with highly variable penetrance that results in asymmetric septal wall hypertrophy. This may cause functional aortic outflow tract obstruction, as well as predispose

the athlete to arrhythmias. Unfortunately, this condition is often asymptomatic prior to the terminal event, and screening tests such as electrocardiographs and echocardiograms have not been proven effective at early detection of this condition. Aberrant coronary arteries are thought to be the second leading cause of SCD in young athletes. Marfan syndrome and long QT syndrome are less common.

► CASE 14.3

As part of your group's community outreach, you are participating in a sports physical screening (somehow your partner got to throw out the first pitch at a baseball game, and you got this ... we're guessing you must be new). One of the students is noted to be hypertensive with a blood pressure of 143/95 mm Hg. There is no family history of sudden death or early heart attack. He has never experienced any symptoms with exercise. His parents indicated on the form that they did not recall any history of previous heart murmur or high blood pressure. The remainder of the examination is unremarkable except for a I/VI systolic murmur. You ask the athlete to perform a Valsalva maneuver by holding his breath and bearing down while cardiac auscultation is repeated.

Question 14.3.1 Which of the following correctly describes the relationship between murmur intensity and the likely type of murmur?

- A) Valsalva maneuver increases flow murmur, decreases outflow tract obstruction murmur
- B) Valsalva maneuver increases both flow murmur and outflow tract obstruction murmur
- C) Valsalva maneuver decreases both flow murmur and outflow tract obstruction murmur
- D) Valsalva maneuver decreases flow murmur, increases outflow tract obstruction murmur

Answer 14.3.1 The correct answer is "D." The Valsalva maneuver decreases venous return to the heart, resulting in decreased diastolic filling. You would expect this to cause decreased flow through the outflow tract and thus a softer flow murmur. However, the decreased flow exacerbates the **functional** outflow tract obstruction of hypertrophic cardiomyopathy (there is less volume to push the septum out of the way resulting in a tighter functional stenosis), resulting in a louder murmur. In summary, benign flow murmurs will decrease in intensity with Valsalva maneuver, while the murmur of hypertrophic cardiomyopathy will increase with a Valsalva maneuver.

HELPFUL TIP:

The systolic crescendo-decrescendo murmur of hypertrophic cardiomyopathy increases in intensity when the patient moves from a supine to an upright position. S4 may be heard as well. Cardiac auscultation should be performed both supine and upright for a sports participation physical.

Reassured by a murmur that disappears with Valsalva maneuver and an otherwise unremarkable examination, you are now faced with an adolescent athlete with an elevated blood pressure confirmed by manual re-testing.

Question 14.3.2 What is the best recommendation for this athlete regarding sports participation and follow-up of his elevated blood pressure?

- A) Qualified participation pending serial blood pressure checks over the next 3 weeks
- B) Complete disqualification for 2 months, followed by return if ECG and echocardiogram are normal
- C) Disqualification from competition only for 1 month, but allowed to practice once seen by a nephrologist
- D) Full participation with no required follow-up based on reassuring history and examination
- E) Full participation with blood pressure re-check prior to the next competitive sport season

Answer 14.3.2 The correct answer is "A." It is important to remember that the diagnosis of hypertension cannot be made at a single screening visit. The screening may be affected by patient anxiety ("white coat hypertension"), recent caffeine ingestion, drugs, or a number of other factors (including a common occurrence of scheduling examinations right after practice and standing half naked with your peers.). The National Heart, Lung and Blood Institute guideline recommends that hypertension be diagnosed if blood pressure is above the 95th percentile for children/adolescents on three separate recordings of blood pressure on different occasions after several minutes at rest, sitting comfortably.

Because exercise is beneficial for blood pressure control, continued aerobic activity should be encouraged while the serial blood pressure readings are obtained. Debate exists as to recommendations regarding static exercises, such as weightlifting. While lifting of heavy weights can exacerbate high blood pressure, there is some evidence to suggest that use of light-to-moderate weights with repetition is beneficial. Certainly, the presence of any additional symptoms with exercise, such as headache or lightheadedness, would require more significant limitations in activity.

► Objectives: Did you learn to ...

- Identify important issues to address at the pre-participation physical examination?
- Evaluate an adolescent athlete with elevated blood pressure?
- Evaluate a cardiac murmur revealed on pre-participation physical examination?

► CASE 14.4

A 15-year-old female presents to your office for a well-adolescent examination. She is a healthy teenager with no complaints—well, she has the usual teenager complaints (her parents are "stupid," the teachers don't know anything, etc.).

You have incorporated into your routine a screening tool, the **Guideline for Adolescent Preventive Services (GAPS)** questionnaire, one of many such tools available. The questions cover all areas of adolescent development and are designed so that areas of concern are easily identified. See <https://www.uvpediatrics.com/health-topics/stage/#GAPS> for example.

Question 14.4.1 What are the three leading causes of mortality for adolescents?

- A) Leukemia, suicide, accidental drowning
- B) Childhood cancers, perinatally acquired HIV, suicide
- C) Congenital malformations, childhood cancers, suicide
- D) Accidental injury, homicide, suicide
- E) Childhood cancers, SCD, suicide

Answer 14.4.1 The correct answer is “D.” Accidental injury, homicide, and suicide are the three leading causes of death for adolescents and should be addressed during preventive health visits. As a category of accidents, motor vehicle fatality is the leading cause of death to teenagers, representing over one-third of all deaths. A high number of teens report unsafe driving behavior: 39.2% of teens have reported texting or emailing while driving. While most states have made texting and driving illegal, it is still important to discuss with your adolescent patients. Accidental injuries often involve the use of alcohol or other substances in combination with motor vehicle operation or other risk-taking behaviors. Ask about personal use of alcohol and if they are ever passengers of another teenager (or adult) who drives while impaired or intoxicated. The greater the number of teens in the car of a teen driver, the greater the likelihood of an accident. This argues for the law in some states that restrict the number of passengers in a teen driver’s car.

You also noticed that your patient checked “yes” for a history of use of alcohol and marijuana.

Question 14.4.2 What is the approximate frequency of lifetime use of these substances among 9th to 12th grade students according to the Centers for Disease Control and Prevention (CDC’s) 2017 Youth Risk Behavioral Survey (YBRS)?

- A) Alcohol 10% to 20%; marijuana 5% to 10%
- B) Alcohol 30% to 40%; marijuana 10% to 20%
- C) Alcohol 50% to 60%; marijuana 20% to 30%
- D) Alcohol 60% to 70%; marijuana 30% to 40%
- E) Alcohol 70% to 80%; marijuana 40% to 50%

Answer 14.4.2 The correct answer is “D.” The survey found 60.4% of adolescents reporting use of alcohol at some point in their lives, and 35.6% reporting use of marijuana. In addition, 28.9% have tried cigarettes (a decrease from 41.1% in 2013!).

HELPFUL TIP: A “NOT SO HEALTHY” ALTERNATIVE

Don’t forget to ask about “vaping” when questioning an adolescent about substance use. While cigarette use is declining, vaping is quickly catching on with

adolescents due to its marketing of flavorful nicotine that is supposed to be “healthier.” These companies know their target audience and have made “cooler” delivery mechanisms (many actually look like flash drives, such as Juul®). In fact, many adolescents don’t even equate vaping with use of tobacco products or health risks such as “popcorn lung” or potentially fatal lipoid pneumonia. The 2017 YBRS survey indicated 42.2% of adolescents surveyed have used vaping products. Eek!

HELPFUL TIP:

Screening tools for adolescent substance use include the “CRAFT” questions, developed by the “Center for Adolescent Substance Abuse Research” (CeASAR), Children’s Hospital Boston. Similar to the “CAGE” tool for adult alcohol assessment, the letters stand for:

- **C**—Have you ever ridden in a CAR driven by someone (including yourself) who was “high” or had been using alcohol or drugs?
- **R**—Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in?
- **A**—Do you ever use alcohol/drugs while you are by yourself, ALONE?
- **F**—Do you ever FORGET things you did while using alcohol or drugs?
- **F**—Do your family or FRIENDS ever tell you that you should cut down on your drinking or drug use?
- **T**—Have you gotten in TROUBLE while you were using alcohol or drugs?

After eliciting a positive response to questions about drug use, you ask the patient about depression, and she states that she has been feeling “down” for several months now.

Question 14.4.3 What would your next step be?

- A) Call the police and report the illegal use of substances by a minor
- B) Reassure the patient about her confidentiality rights, counsel her to quit using drugs, and see her back annually
- C) Negotiate next steps to guarantee the patient’s safety and consider counseling referral and/or initiation of medication therapy
- D) Obtain a nonconsented urine drug screen to document recent use of substances

Answer 14.4.3 The correct answer is “C.” Most state laws, as well as HIPAA, guarantee teenagers confidentiality; it can only be broken when there is an issue of imminent danger to self or others or physical/sexual abuse. It is recommended that the patient be involved and consent to who and how the information is shared. Rarely is there a need to involve police, unless there is an issue of abuse requiring a report or concern over safety if the patient is returned to the home environment.

Psychotherapy, pharmacotherapy, or a combination of the two are all reasonable treatment options in adolescent depression. If a medication is started, SSRIs are considered first-line therapy by most published guidelines due to their proven efficacy. However, they *should certainly be used with caution as studies suggest increased suicidality in teenagers treated with SSRIs. While there are increased attempts at suicide, there is NOT an increase in successful suicide.* Fluoxetine has the most favorable benefit/risk profile in adolescents due to its long half-life. The American Academy of Child and Adolescent Psychiatry website has resources outlining patient and parent information about the risks and benefits of pharmacologic treatments. In any case, close follow-up of a depressed adolescent (weekly visits or phone calls) is recommended early in the treatment course.

HELPFUL TIP:

As of February 2016, the U.S. Preventative Services Task Force now recommends screening for mood disorders in teenagers aged 12 to 18 *as long as there are adequate resources available to aide in diagnosis, treatment, and follow-up.* They provide this a grade B practice recommendation. There is insufficient evidence at this point for screening children aged 11 years of age or younger.

HELPFUL TIP:

The American Academy of Pediatrics has a position statement against the use of nonconsented urine drug screens as a “screening” tool due to the lack of accuracy and the violation of patient trust.

(ONE MORE) HELPFUL TIP:

A study published in *Lancet* found that adolescent self-harm (cutting, burning, etc.) occurs in about 10% of adolescents. However, you can reassure parents that this declines to 3% as a young adult (Moran P, et al. *Lancet*. 2012).

► Objectives: Did you learn to ...

- Identify and employ useful screening tools for routine adolescent examinations?
- Recognize the importance of screening and treating depression in adolescents?
- Describe common causes of death in adolescents?
- Understand the common lifetime experience use of alcohol, tobacco, and marijuana?
- Describe screening and treatment options for mood disorders and substance abuse?

► CASE 14.5

Your afternoon has a number of patients with sports-related complaints. A 14-year-old wrestler has arrived in the office complaining of a rash on his left shoulder. The rash appears to

consist of several small lesions with a vesicular appearance but no purulence and minimal erythema. There is neither tenderness to palpation nor tactile warmth in the affected area.

Question 14.5.1 What would be your best test to confirm your diagnosis of these lesions?

- A) Microscopic evaluation with potassium hydroxide (KOH) preparation of the contents of one of the lesions
- B) Gram stain of the contents of one of the lesions
- C) Culture of the contents of one of the lesions
- D) Tzanck smear of the contents of one of the lesions

Answer 14.5.1 The correct answer is “D.” A Tzanck prep will give you immediate information about whether this represents herpes simplex. This is important information when deciding whether or not this patient can return to wrestling. HSV PCR assays are a more sensitive method to confirm HSV infection in clinical specimens obtained from genital ulcers and mucocutaneous sites and should also be obtained. These newer tests tend to be much quicker than older assays and typically return within 24 to 48 hours depending on your lab. The point here is that the lesions described have the appearance of HSV, and a confirmatory test for HSV should be obtained.

The lesions have appeared within the past day, and your laboratory testing confirms that the diagnosis is herpes simplex. Your patient does not recall any previous lesions like these. He denies any systemic symptoms.

Question 14.5.2 What would be the best course of treatment for this patient?

- A) Cover the involved area to allow return to wrestling
- B) Treat with topical acyclovir and return to wrestling when lesions have crusted over
- C) Treat with oral acyclovir and return to wrestling when lesions have crusted over
- D) Treat with oral steroids to suppress the response and promote quicker return to wrestling
- E) Treat with topical antifungal medication and allow return to wrestling

Answer 14.5.2 The correct answer is “C.” Cutaneous herpes, also referred to in wrestling as *herpes gladiatorum*, is a highly contagious illness. “B” is incorrect because topical acyclovir is NOT effective in treating herpes simplex. Most state high school athletic associations have specific rules regarding the treatment of cutaneous disorders in wrestling, including herpes, tinea corporis, and impetigo. With regard to herpes simplex, all lesions must be fully crusted over **and** the athlete must have had at least 3 days of oral antiviral therapy prior to returning to competition. One study has shown that use of prophylactic valacyclovir 1 gram daily may be efficacious in lowering the incidence of HSV outbreaks in wrestlers (*Clin J Sport Med*. 2016;26(4): 272–278). “D” is incorrect because oral steroids would suppress the athlete’s immune response, which would allow for further spread of the lesions.

Your next patient is a 12-year-old male who is here for a sports physical. You review your patient's chart and scan his immunizations. The patient's mother remembers her son receiving his "kindergarten shots"; he has had no immunizations since. His records reveal the following vaccines: five doses of diphtheria-tetanus-acellular pertussis (DTaP), four doses of injectable polio vaccine (IPV), four doses of *Haemophilus Influenzae* Type B (Hib), three doses of hepatitis B; four doses of pneumococcal vaccine (PCV 13), two doses of measles-mumps-rubella (MMR), and two doses of varicella vaccine.

Question 14.5.3 Which, if any, immunizations would you offer today?

- A) None. The patient is up-to-date for all immunizations
- B) Conjugate pneumococcal vaccine
- C) Hepatitis A/B vaccine, conjugate meningococcal vaccine, IPV
- D) Hepatitis A vaccine; Tetanus, diphtheria, and pertussis (Tdap); conjugate meningococcal vaccine and start of the HPV series
- E) Human papillomavirus (HPV) vaccine, Tdap, varicella vaccine

Answer 14.5.3 The correct answer is "D." Universal vaccination for hepatitis B is included in the primary immunization series for infants, so most adolescents have been vaccinated. However, it is still important to make sure this is up-to-date. Hepatitis A vaccine is now being required in many states before entry to school and is universally recommended for all children ages 12 months to 2 years. A catch-up vaccination schedule is now recommended for ages 2 to 18 years. For those not up-to-date with their hepatitis B vaccination, a combined hepatitis A/B vaccine exists.

Most children receive their last DTaP prior to entering pre-school or kindergarten (age 4–5 years). Beginning in 2005, the CDC recommended giving the tetanus booster with pertussis (Tdap) at entry to middle school/junior high (ages 11–12) in place of the tetanus booster (Td).

For protection against some serotypes of *Neisseria meningitidis*, the CDC recommends universal vaccination with the conjugate meningococcal vaccine (e.g., Menactra) for teens, including a booster dose between ages 16 and 18 years.

The CDC recommends 9-valent HPV for routine vaccination of adolescents 11–12 years of age through age 26 (although you can start as early as 9 years of age). The upper age limit is now 45. For those 27–45 years of age, use shared decision making (MMWR 2019 Aug 16). "E" is incorrect because he has already had two doses of the varicella vaccine.

Question 14.5.4 Which statement does NOT accurately describe how the conjugate meningitis vaccine (Menactra) differs from the older polysaccharide meningitis vaccine (Menomune)?

- A) Menactra elicits a T-cell immune response that gives long-term immunity and allows for herd immunity

- B) Menactra protects against all the types of *N. meningitidis*: A, B, C, Y, W-135
- C) Menomune does not elicit a booster effect, may only be given once, and is recommended only at the onset of high-risk activity, such as living in dorms or being a military recruit
- D) Menactra should be offered at entry to middle school/junior high school (11–12 years) with a booster dose recommended between ages 16 and 23

Answer 14.5.4 The correct answer (and FALSE statement) is "B." Unfortunately neither Menomune nor Menactra protect against serogroup Type B. The other choices are correct. *N. meningitidis* Type B is endemic in North America and up until 2014, no vaccine was available. In 2014 and 2015, the FDA approved two meningococcal **Type B** vaccinations (three-dose MenB-FHbp (Trumenba®) and two-dose MenB-4c (Bexsero®)). The ACIP in October 2015 provided a grade B recommendation that MenB vaccination *may* be given *in addition* to Menactra and other indicated age-based vaccinations (preferably at a different anatomic site) between ages 16 and 23 with preferable dosing at 16 to 18 years to provide peak desired immunologic effect in the group that is at most risk. Additionally, high-risk populations including those with anatomic or functional asplenia, sickle cell disease, persistent complement component deficiency (including eculizumab use), or those in a serogroup B meningococcal disease outbreak should be vaccinated. Note that the two vaccines are not interchangeable.

HELPFUL TIP:

Review the vaccine recommendations since they are updated frequently by the CDC; vaccine recommendations can be found at <http://www.cdc.gov/vaccines/schedules/>.

► **Objectives: Did you learn to ...**

- Identify herpes gladiatorum and describe its treatment?
- Recommend vaccines appropriate for adolescents?

► **CASE 14.6**

A 15-year-old pale Caucasian female returns for her annual well-child check and sports physical. She is well known to your clinic, and over the years she has steadily gained weight. Her parents and a younger sibling are overweight, and now she has become obese by measure of the pediatric BMI percentages. In recent years, you have become more diligent with watching the BMI on her growth curve. She is aware of her weight problem yet has not voiced any plan for attempting weight loss.

Question 14.6.1 What defines "obesity" in adolescence?

- A) A BMI in the 85th to 94th percentile for age-sex-and-height-specific measures

- B) A BMI \geq 95th percentile for age-sex-and-height-specific measures
- C) The child has the appearance of being heavy
- D) The child complains of being fat or overweight
- E) BMI $>35 \text{ kg/m}^2$

Answer 14.6.1 The correct answer is “B.” A BMI at or above the 95th percentile is considered “obese.” A BMI in the range of 85th to 94th percentiles is considered “overweight.” The use of BMI allows for an objective measure, and although not perfect, can give a picture on the growth curve to patients and parents where they stand relative to age-sex-and-height-related norms. Strict BMI numbers (as in “E”) are not applicable to children and adolescents. A subjective concern about weight (“D”) is important but does not necessarily always warrant further evaluation.

Question 14.6.2 Her BMI is now at the 97th percentile, having jumped from the 86th percentile last year. What additional workup should be considered?

- A) Fasting plasma glucose level or hemoglobin A1c
- B) Fasting lipids
- C) Renal function testing with BUN and creatinine
- D) Liver function testing with ALT
- E) All of the above

Answer 14.6.2 The correct answer is “E.” Expert opinion suggests that once a child reaches a BMI at the 85th to 94th percentiles, a lipid panel and a fasting glucose or A1c should be obtained to evaluate for hyperlipidemia and early onset type 2 diabetes. When the BMI reaches the 95th percentile, renal function and blood pressure should be monitored, and liver function should be checked (for fatty liver). Fatty liver disease is possible at an early age and is reversible if weight loss can be achieved. Close attention to family history is essential. If family members are obese or have obesity-related comorbidities, early intervention and evaluation are even more crucial. For females who have started menses, it is important to assess for any changes in menstrual patterns.

Question 14.6.3 Which of the following is NOT a recommended early childhood intervention to prevent and/or treat obesity?

- A) Encouraging breastfeeding
- B) Decreasing screen time of electronic devices
- C) Planning fewer family meals
- D) Restricting calories from sweets and fast foods
- E) Improving efforts for exercise and outdoor activity

Answer 14.6.3 The correct answer is “C.” Helping with food preparation and sitting down as a family for meals can lead to consumption of more nutritious and lower caloric dense foods. Breastfeeding can lead to protection against obesity even into the teenage years. Formal recommendations suggest limiting TV, tablet, phone, computer use, and video games to less than 2 hours per day with minimal screen time for children under

age 2. Fast food, sweets, and desserts need to be limited to small servings or few servings per week. Finally, at least 60 minutes of exercise should be encouraged every day—doing a variety of activities will keep children more engaged and interested.

HELPFUL TIP:

If children do become overweight or obese, directed weight loss should be implemented. For kids with a BMI at the 85th to 94th percentiles, the goal is weight maintenance until they reach a BMI at the 84th percentile or less. For those with BMI at or above the 95th percentile, expert opinion recommends children age 2 to 11 years lose up to 1 pound per month and adolescents lose up to 2 pounds per week.

HELPFUL TIP: 5-2-1-0

The “5-2-1-0” mnemonic is a helpful way to counsel your patients and their parents on healthy lifestyle practices and has been a successful campaign supported by the American Academy of Pediatrics. The numbers stand for: **5** fruits and vegetables per day, **2** hours or less of screen time, **1** hour or more of physical activity, **0** consumption of sugary drinks.

During the examination of the patient, you notice acne, some coarse facial hair, and dark skin pigmentation around the base of her neck.

Question 14.6.4 What is another finding you may expect to see with further questions and tests?

- A) Normal menses
- B) Low free testosterone level
- C) Low DHEA sulfate (DHEA-S)
- D) Hypoglycemia
- E) Abnormal hypothalamic–pituitary axis hormones

Answer 14.6.4 The correct answer is “E.” While the earliest clinical manifestation is irregular menses, she is showing other signs of possible polycystic ovarian syndrome (PCOS). This can be associated with elevated prolactin, low TSH, and a marked elevation of FSH relative to luteinizing hormone (LH). PCOS can be associated with early menarche, dysmenorrhea, and amenorrhea. A pregnancy test should be done in any case of amenorrhea. PCOS is also associated with **elevations** of testosterone, DHEA-S, and androstenedione. If there are other significant physical examination findings such as elevated blood pressure, purple striae, and a “buffalo hump,” consider testing for Cushing syndrome. See chapter 15 for more on PCOS.

Her obesity is discussed openly during the office visit. As expected, she is ashamed and embarrassed about her weight

gain. She admits to not knowing what to do and she asks if anything can be done to quickly lose weight.

Question 14.6.5 Which of these medications would you recommend now as a first-line therapy for weight loss?

- A) Topiramate (Topamax)
- B) Bupropion (Wellbutrin)
- C) Orlistat (Xenical)
- D) Metformin (Glucophage)
- E) None of the above

Answer 14.6.5 The correct answer is “E.” No medication is approved for children or adolescents as a first-line therapy. Antidepressants are not helpful if used primarily for weight loss. If there is comorbid depression, which is more common in obese children, a “weight loss” or “weight neutral” antidepressant may be appropriate. Antiepileptic medications have not proven helpful. Metformin has been used for weight loss in children but is not approved by FDA and has only small effect on weight with unclear clinical significance. Orlistat is approved for children age 12 and older; however, the benefits are limited to 2 to 3 kg of weight loss. Side effects are often intolerable and include loose, oily stools and stool urgency (just mention the phrase “fecal incontinence” to a teenager and see how far you get). Experts agree that orlistat is only appropriate for adolescents with comorbidities caused by obesity. Obesity (“bariatric”) surgery (especially Roux-en-Y and gastric sleeve) is being performed more often on adolescents and is effective at reversing metabolic changes (insulin resistance, hypertriglyceridemia, etc.). It also improves sleep apnea and depression and improves quality of life.

HELPFUL TIP:

The risk of becoming overweight can decrease by 4% for each month of breastfeeding up to age 9 months.

HELPFUL TIP:

Weight loss in adolescence will likely lead to decreased cardiovascular disease as an adult (Juonala M, et al. *N Engl J Med*. 2011).

HELPFUL TIP:

The USPSTF recommends counseling to minimize ultraviolet radiation exposure (e.g., sun tanning) in fair skinned adolescents in order to reduce the risk of skin cancer (Grade B recommendation).

► **Objectives: Did you learn to ...**

- Define “overweight” and “obesity” in an adolescent?
- Identify risk factors associated with obesity in an adolescent?
- Manage an adolescent with a weight problem?

► **CASE 14.7**

You have watched your patient transform over the years from a rather normal-appearing boy into a very large, muscular, and intense young man. He is now 17 years old, and he has gained almost 45 lb in the last year alone as he prepares for his senior year of football and attempts to attract the attention of college recruiters (and potential mates). Without a doubt he has worked very hard on the field and in the weight room, but you also must raise the question of whether or not he has used some kind of supplement to help him change so drastically.

Question 14.7.1 Which of these substances is NOT prohibited by high school athletic associations or the NCAA?

- A) Erythropoietin
- B) Creatine
- C) Androstenedione
- D) Ephedrine
- E) DHEA

Answer 14.7.1 The correct answer is “B.” Creatine is allowed for use as a dietary supplement for athletes. However, the American College of Sports Medicine (ACSM) does NOT recommend the use of creatine in any athlete less than 18 years old. An estimated 8% of children 14 to 18 years old use creatine routinely. The NCAA does not allow colleges to provide athletes with creatine, but athletes can take it if they choose. All the other listed supplements are prohibited for use as performance-enhancing supplements. Other prohibited substances include anabolic steroids, pseudoephedrine, and blood transfusions.

Your patient does admit to using regular protein shakes and taking creatine. He denies the use of any illegal or prohibited substances and says he would never do anything dangerous. During his examination, his blood pressure is 146/92 mm Hg and his lab results show normal electrolytes, normal TSH, normal urinalysis, BUN 22 mg/dL, and creatinine 1.6 mg/dL (marked elevation for age 17).

Question 14.7.2 What is a possible side effect from the use of creatine?

- A) Gastrointestinal discomfort
- B) Edema
- C) Muscle cramps
- D) Acute kidney injury
- E) All of the above

Answer 14.7.2 The correct answer is “E.” All are potential adverse effects from creatine use. Most importantly, if used carelessly, creatine can lead to acute kidney injury. Creatine is excreted via the kidneys, and if overconsumed in the setting of dehydrating exercise, it can cause renal injury. Seventy-five percent of adolescent athletes who take creatine are either unaware of the proper dose or knowingly take too much. If

used, plenty of water is required to help avoid troubling side effects.

Question 14.7.3 All of the following substances can provide potential athletic performance benefits EXCEPT:

- A) Human growth hormone (HGH)
- B) Caffeine
- C) Creatine
- D) Electrolyte replacements
- E) Sodium bicarbonate

Answer 14.7.3 The correct answer is “A.” HGH has no proven benefits for enhancing sports performance. Other substances with no proven benefits include amino acids, beta-hydroxy-beta-methylbutyrate, androstenedione, DHEA, chromium, and iron (when not iron deficient). The other substances listed above can provide short-term or long-term benefits. Caffeine has only a transient effect to help sharpen focus and intensity for brief periods of activity. Creatine can improve strength for adult male athletes in those sports that require very short bursts of intense effort. Electrolyte replacement drinks (or tablets) and sodium bicarbonate can help for more prolonged endurance activities where dehydration and resulting electrolyte imbalances are common.

Your patient denies using “steroids,” but does know of older guys in the gym where he trains who have routinely used anabolic steroids.

Question 14.7.4 Besides the obvious added muscle girth, what are some other potential benefits of anabolic steroids for athletes?

- A) Improved lipid profile
- B) Taller stature
- C) Anxiety relief
- D) Lower blood pressure
- E) None of the above

Answer 14.7.4 The correct answer is “E.” There are no other clear benefits of anabolic steroids if used for athletics only. Potential negative effects include lower HDL, elevated blood pressure, left ventricular hypertrophy, gynecomastia, aggressive or even suicidal behavior, azoospermia, virilization of females, premature physeal closure in adolescents that could lead to shorter stature, and acute myocardial infarction. Approximately 33% of anabolic steroid users are not even athletes and use the substance to help improve physical appearance. Estimates in high school athletes show steroid use to be about 4% in males and about 2% in females. The temptation to use the illegal substance is driven by pressures to be better than peers, to fulfill one’s “full potential,” to live up to sports idols, and to help acquire college scholarships and/or sports contracts at a young age.

► **Objective: Did you learn to ...**

- Describe the effects of some common performance-enhancing drugs?

► CASE 14.8

A 14-year-old female comes into the office with a chief complaint of headache. She says the headache began after her soccer game yesterday. She recalls striking her head against an opponent when trying to head the soccer ball. During the remainder of the game, she began to feel a headache, and the harder she ran, the more “woozy” she felt. She denied any loss of consciousness, vomiting, visual symptoms, or neck pain. Today, she also has poor concentration and feels excessive fatigue.

Question 14.8.1 Which of the following is NOT a feature of a sports-related concussion (SRC)?

- A) Caused by an impulsive force transmitted to the brain
- B) Symptoms usually resolve spontaneously
- C) There is a functional disturbance to the body
- D) Neuroimaging always shows abnormalities
- E) Clinical symptoms are highly variable and inconsistent

Answer 14.8.1 The correct answer is “D.” There may be no evident structural brain injury with SRC. Evidence suggests that multiple concussions, or even lesser repetitive head injuries (such as with soccer “heading”) can eventually lead to structural tissue damage. The symptoms of concussions have a rapid onset and while most athletes recover within the first month, some have a slower recovery from SRC. Some evidence suggests adolescents are at greater risk of persistent symptoms with pre-injury history of mental health issues or migraine headaches.

HELPFUL TIP:

Concussion is defined as a disturbance in brain function caused by trauma to the head. It does not require loss of consciousness or amnesia. Lightheadedness, disorientation, and nausea, etc. after head injury are all possible signs of concussion. Symptoms of post-concussion syndrome may include headaches, difficulty concentrating, “dizziness,” lightheadedness, nausea, fatigue, irritability, anxiety, and depression. Symptoms generally resolve but may be long lived, especially in those over age 50, who may never return to baseline. In addition, the potential for developing chronic traumatic encephalopathy (CTE) is present and further study is ongoing.

HELPFUL TIP:

If an athlete sustains a head injury or a hard hit, the athlete should be removed from the game and a sideline assessment should be performed to assess for SRC. A simple standardized tool to use in the acute assessment of SRC and subsequent evaluations is the Sport Concussion Assessment Tool (SCAT-5) questionnaire (*Br J Sports Med.* 2018;51:838–847). The SCAT5 takes about 10 minutes to administer. **If a concussion is suspected, the athlete should NOT be allowed to return to the game.**

Question 14.8.2 Which of the following treatments is key for your patient with a concussion?

- A) Early return to aerobic exercise—today if possible
- B) Ibuprofen 800 mg every 8 hours as needed
- C) Avoiding excessive sleep
- D) Aspirin 325 mg daily as needed
- E) Full cognitive rest (put down that smartphone, tablet, and social media!), even missing school if needed

Answer 14.8.2 The correct answer is “E.” Caring for patients with an SRC requires graduated stepwise rehabilitation starting with full physical **and** cognitive rest. Once symptoms are clearly improving at rest, the student can get back to class and **slowly** be re-acclimated to physical activity. Sleep can provide a means of allowing the brain to rest and heal. No medications have proven helpful in alleviating the effects of a concussion. NSAIDs, aspirin, or acetaminophen may help with headache or pain.

**HELPFUL TIP:**

A recent randomized trial of early aerobic exercise in adolescents with concussion suggests that exercise is associated with more rapid recovery. In the study, randomized adolescents to exercise on a treadmill or stationary bicycle *at a speed that did not worsen or bring on their symptoms*. The group randomized to exercise returned to the classroom 4 days earlier (13 vs. 17 days) and had better long-term recovery (96% vs. 93%) (*JAMA Pediatr.* 2019 Feb 4 [e-pub]).

Question 14.8.3 In which case of head injury would neuroimaging be appropriate?

- A) Ongoing mild headache for several days
- B) Poor memory of the recent game and the events of the injury
- C) Any new seizure activity
- D) Loss of consciousness for less than 30 seconds
- E) Mild irritability, depressed mood, and insomnia

Answer 14.8.3 The correct answer is “C.” Seizure activity after head trauma or concussion requires imaging. Other symptoms that should prompt a head CT include severe headache, focal neurological symptoms, repeated emesis, difficulty arousing, slurred speech, prolonged poor orientation, concurrent neck pain, significant irritability, loss of consciousness for over 30 seconds, and any new neurologic or escalating symptoms. The initial study is normally a head CT, but if presenting after 48 hours from injury, a brain MRI is more suitable. Remember that the vast majority of concussion cases will **not** require imaging.

Question 14.8.4 Which of the following elements of past medical history may be relevant for this adolescent patient following her concussion?

- A) Depression
- B) Generalized anxiety disorder

- C) Attention-deficit hyperactivity disorder (ADHD)
- D) Migraine headaches
- E) All of the above

Answer 14.8.4 The correct answer is “E.” All of these conditions could be negatively affected by a concussion. Concussions can cause a temporary mood disorder and certainly aggravate depression and anxiety. Commonly, concussions will cause decreased concentration and inattentiveness. Teens who already have ADHD will likely have worsened symptoms and may need modification of their treatment. The headache of post-concussive syndrome may overlap or intensify an underlying headache diagnosis. Concussion may act as a trigger causing an increase in pre-existing migraines.

Your patient is an accomplished soccer player and feels a lot of pressure to return to action. She wants to play in the next game, and her coach and teammates are asking if she'll be back to practice this afternoon—which explains why your waiting room is so full of teenage girls wearing shin guards.

Question 14.8.5 What is your best advice about her return to practice and play?

- A) “Go back to practice today, but take it slow and avoid full speed play”
- B) “Try to participate in simple drills and just cheer on your teammates”
- C) “Go home and engage in cognitive rest. You may return to activity with graded return to play regimen once symptoms resolve”
- D) “Return to full, unrestricted team play as your soccer team needs you!”
- E) “Do whatever you want”

Answer 14.8.5 The correct answer is “C.” Her return to participation needs to be symptom guided. Each step of the recovery may be 24 hours. If she advances her activity with recurrence of symptoms, then she needs to go back to the prior step. The first step is no activity—complete physical and cognitive rest. The next step is return to full academic activities. Step three is light aerobic activity, followed by sport-specific drills. Next, the player can return to noncontact practice. If still symptom free, then she can return to full speed, contact practice. Finally, she can return to game action. If exertion causes any return of symptoms, then she is not ready and should return to the previous symptom-free stage. Even with normal neuropsychiatric tests, symptomatic athletes should not play. Additionally, academic accommodations may be necessary.

The above steps should be followed with the assistance of a healthcare provider or a qualified athletic trainer. The athlete cannot be put in the position of making the decision about how fast to return to regular play. SRC history should be obtained and considered for all athletes. Two or more concussions have

been shown to lower grade point averages and three or more concussions may cause prolonged symptoms over 3 months in duration.

HELPFUL TIP:

If a concussion occurs, please do not allow return to play the same game or even the same day. The risk for second-impact syndrome is much greater if a player returns to play too early after a concussion. This is most likely to occur when a player does not report symptoms (more common in male athletes) after sustaining a concussion, and then has another head trauma. The rare second-impact syndrome can lead to cerebral vascular congestion, cerebral edema, and even death. The greatest risk athletes are those under age 20. See the Berlin (McCrory) guidelines for more detailed recommendations on returning to activity. The reference is in the bibliography.

Question 14.8.6 Which of the following risk factors is associated with a prolonged post concussive syndrome?

- A) Younger athletes
- B) Females
- C) Poor social situation
- D) Diet lacking in B vitamins
- E) A and B

Answer 14.8.6 The correct answer is “E.” Younger athletes and girls tend to have a longer recovery time. Kids with a history of concussion, mood issues, ADHD, and migraine headaches also take longer on average to recover. Luckily, most children get better spontaneously. If we are talking about adults, the older the adult the less likely they will fully resolve post-concussion syndrome and may have prolonged symptoms (e.g., dizziness, headaches, fatigue).

HELPFUL TIP:

“Cognitive rest” after a concussion may need to include avoidance of reading, computer games, TV, Internet, smartphone use, homework, school attendance, and driving. Here’s the simple idea: pull back if the activity is exacerbating symptoms. Prevention of concussions is best accomplished by education of athletes, parents, and coaches, and by early recognition of more minor symptoms. Mouth guards do not have any proven benefit in preventing concussion, and helmets do not lessen the incidence of concussions; they just prevent more severe traumatic brain injuries.

► Objectives: Did you learn to ...

- Define concussion and recognize its importance in adolescent athletes?
- Treat a patient with concussion?

Clinical Pearls

- Consider long-acting reversible contraceptives (LARCs) as first-line therapy for contraception in adolescent females.
- Do not allow an adolescent return to play after incurring a concussion. Keep the athlete out and prescribe cognitive rest. Once symptoms have improved, slowly allow the adolescent to return to play in a graduated and prescribed fashion.
- Do not screen for substance abuse with nonconsented urine drug screens.
- Routinely screen adolescents for substance abuse and mood disorders if adequate support resources are available. Use standardized screening tools.
- Routinely vaccinate adolescents with Tdap, conjugate meningitis vaccine, and HPV series.

Obstetrics and Women's Health

Meghan Connett and Brigit E. Ray

► CASE 15.1

A 24-year-old nulligravida female presents for her annual examination. Her gynecologic history is remarkable for irregular menses, menstruating every 4 to 8 weeks. She would like a more reliable form of contraception (currently using condoms) and would like to have predictable menses, but is very concerned regarding weight gain with various contraceptive methods.

Question 15.1.1 How would you counsel her regarding weight changes and contraception?

- A) Studies show there is no significant difference in weight gain of women initiating oral contraceptive pills (OCPs) versus placebo
- B) Weight gain of 10 lb is expected during the first year of use with any type of OCPs
- C) Weight gain of 10 lb is expected during the first year of use with monophasic pills but not with triphasic formulations
- D) Weight loss of 10 lb is expected during the first year of use with Depo-Provera (medroxyprogesterone acetate)

Answer 15.1.1 The correct answer is "A." Studies have shown no significant weight gain with OCP use when compared with placebo. Trials have been conducted evaluating estrogen components of 20 to 50 µg, both monophasic and triphasic. There is no evidence to support the premise that triphasic formulations offer improvement in weight changes. Depo-Provera has variable effects on weight gain. Several studies have shown a weight gain of 3 to 6 kg in the first year of Depo-Provera use; however, other studies have shown no difference in weight gain between Depo-Provera and placebo.

HELPFUL TIP:

Recall that in 2004 the FDA placed a "black box warning" on Depo-Provera for bone loss that "may not be reversible." However, subsequent studies showed bone gain after stopping Depo-Provera. ACOG notes in 2014 that Depo-provera can be used for more than 2 years

if benefits outweigh the risks and bone mineral density will rebound when it is stopped. However, they also note that no high quality data exists about fracture risk later in life (Obstet Gynecol. 2014;123:1398-402)

Question 15.1.2 After reassuring her regarding the concerns of weight gain, you tell her about the additional potential benefit(s) of OCPs, which include:

- A) Improvement in acne
- B) Decreased dysmenorrhea
- C) Decreased menstrual flow
- D) Decreased risk of ovarian cancer
- E) All of the above

Answer 15.1.2 The correct answer is "E." Besides these, additional potential benefits of OCP use include regulation and predictability of menses, decreased anemia, decreased hirsutism, and decreased risk of endometrial and colon cancers. *Note:* the cancer risk reduction is based on epidemiologic studies, not randomized controlled trials. A recently published Danish national registry study did find an increased risk of breast cancer with OCP use, even with lowest dose estrogen use. However, the magnitude of this risk remained small (*N Engl J Med.* 2017;377(23):2228–2239).

HELPFUL TIP:

After starting OCPs, patients should follow up within a few months for blood pressure checks, assuring compliance, etc. With pap smear guidelines having changed to every 3-to 5-year screening intervals for most women, the annual "pap" to get birth control no longer makes sense.

After further discussion, she reports that she has headaches every 1 to 2 months. She has never been evaluated for migraines, but reports that her headaches are bilateral, posterior, throbbing, and relieved with sleep and over-the-counter medication. She denies associated aura, nausea, or focal neurologic changes.

Question 15.1.3 How would you counsel her regarding OCPs and headaches?

- A) Headaches are an uncommon reason for discontinuation of OCPs
- B) She should not use OCPs because they are contraindicated in anyone with headaches
- C) She should use progestin-only pills
- D) She can use OCPs, as it is hard to predict whether her headaches will be affected

Answer 15.1.3 The correct answer is “D.” Although headache is a frequently cited reason for women to discontinue OCPs, there is no strong correlation between headache frequency and intensity for most women. There is no evidence that the type of progestin or amount of estrogen will alter the headaches, except in women with menstrual migraines. Among women with migraines, headaches improve, worsen, or are unchanged after initiation of OCPs (helpful, right?). **There is an increased risk of stroke in women with a history of pseudotumor cerebri or migraines with aura or focal neurologic changes.** Therefore, OCPs are CONTRAINDICATED in these specific subgroups of women.

**HELPFUL TIP:**

Additional contraindications to combination OCP use include: any previous thromboembolic event or stroke, a history of estrogen-dependent tumor (e.g., some breast cancers), active liver disease, pregnancy (although accidental use of OCPs early in pregnancy has not been definitively linked to adverse outcomes), undiagnosed abnormal uterine bleeding, women older than 35 years who smoke (due to increased risk of cardiovascular disease), and **first 3 weeks postpartum** (2015 World Health Organization recommendation based on increased venous thromboembolism risk in the immediate postpartum period). See Figure 15-1 for quick reference guidance on contraceptive eligibility based on medical condition.

The patient wants to know how long she should use a backup method of contraception after starting the combination estrogen/progesterone OCP.

Question 15.1.4 You tell her the following regarding using a backup method:

- A) If she starts taking the pill during the first 5 days of her menstrual period, no backup method is needed
- B) If she starts taking the pill greater than 5 days after her onset of her period, she needs a backup method for 30 days
- C) She should use a backup method for 2 months after starting the pill regardless of when she started it
- D) The OCP provides effective contraception immediately and no backup method is needed

Answer 15.1.4 The correct answer is “A.” The old canard of requiring a month of backup contraception after starting OCPs or other hormonal birth control has fallen by the wayside. For

combination estrogen/progesterone OCPs, for example, **no** secondary method of contraception is needed as long as the OCP is started within 7 days of the onset of the last menses. If the OCP is started greater than 5 days after the onset of the last menses, only 7 days of a secondary contraception method (e.g., condoms, diaphragm) is needed; combination OCPs work within 7 days of the start date. Please see Table 15-1 regarding CDC recommendations for backup contraception.

**HELPFUL TIP:**

Rifampin, rifaximin, and rifabutin are the only antibiotics that reduce the effectiveness of OCPs. Therefore, there is no need for a backup method when giving penicillin for strep throat, for example.

**HELPFUL TIP:**

The thinking about methods of contraception has changed in the last several years. The intrauterine device (IUD) is becoming increasingly popular for nulliparous teenagers. IUDs clearly decrease pregnancy in this group when compared to OCPs and do not seem to increase the risk of STDs (*N Engl J Med.* 2014;371:1316–1323). Nor do they result in increased risky sexual activity.

The American Academy of Pediatrics (2014) recommends that a long-acting reversible contraceptive (LARC) be considered as a first-line contraceptive in adolescents; options include implants and IUDs. LARCs can provide 3 to 10 years of contraception and are effective and safe forms of birth control. The use of condoms goes down with LARCs, however (*JAMA Pediatr.* 2016;170(5):428–434).

Eight months later, the patient calls to speak with your nurse regarding nausea and vomiting. Apparently, she decided to stop taking her OCP. Her last menstrual period was 10 weeks earlier, and she had a positive home pregnancy test 5 weeks ago. Over the last week, she has been vomiting once every day, at various times, but is nauseated throughout most of the day. She wants to know if there is anything else that is “safe” that she can do to decrease the nausea.

Question 15.1.5 What is your most appropriate response?

- A) “This level of nausea and vomiting is abnormal and needs an immediate workup to rule out other pathology”
- B) “This level of nausea and vomiting is very common, and there are several modifications and over-the-counter medications that are safe”
- C) “This level of nausea and vomiting is very common; however, there are no medications that can be initiated in the first trimester”
- D) “This level of nausea and vomiting is very common. Metoclopramide, promethazine, and ondansetron are our first-line therapies”
- E) “Deal with it. You got yourself into this mess”

Summary Chart of U.S. Medical Eligibility Criteria for Contraceptive Use

Condition	Sub-Condition	CHC		POP		Injection		Implant		LNG-IUD		Cu-IUD

*Please see the complete guidance for a clarification to this classification. *Condition that exposes a woman to increased risk as a result of unintended pregnancy. Updated June 2012.

This summary sheet only contains a subset of the recommendations from the U.S. Medical Eligibility Criteria for Contraceptive Use, 2010. For complete guidance, see: <http://www.cdc.gov/reproductivehealth/unintendedpregnancy/USMEC.htm>

FIGURE 15-1 WHO medical eligibility criteria for contraceptive use. (Available from fhi360 at: <https://www.fhi360.org/sites/default/files/media/documents/resource-chart-medical-eligibility-contraceptives-english.pdf>.)

TABLE 15-1 BACKUP CONTRACEPTION WHEN INITIATING METHODS

Contraceptive Method	Backup Method: Initiation ^a
Copper-containing IUD (Paragard)	None needed
Levonorgestrel-containing IUD	7 days; only needed if >7 days after starting menses
Implant	7 days; only needed if >5 days after starting menses
Injectable	7 days; only needed if >7 days after starting menses
Combined hormonal contraceptives	7 days; only needed if >5 days after starting menses
Progestin-only pill	2 days; only needed if >5 days after starting menses (per CDC reference below)

Note: Barrier methods or abstinence from intercourse may be used during the recommended backup interval.

^aAny method may be initiated at any time if there is reasonable certainty the woman is not pregnant, based on the criteria of the Centers for Disease Control and Prevention.

Adapted from Klein DA, Arnold JJ, Reese ES. Provision of contraception: key recommendations from the CDC. *Am Fam Physician*. 2015;91(9):625–633 and Division of Reproductive Health, National Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control and Prevention (CDC). U.S. Selected Practice Recommendations for Contraceptive Use, 2013: adapted from the World Health Organization selected practice recommendations for contraceptive use, 2nd edition. *MMWR Recomm Rep*. 2013;62(RR-05):1–60.

Answer 15.1.5 The correct answer is “B.” Mild-to-moderate nausea and vomiting are very common in the first trimester of pregnancy, often improving by 16 weeks of gestation. Several modifications can improve symptoms, including small, frequent meals, avoiding fatty foods, and avoiding environmental triggers (perfumes, smoking, position changes, or certain movements). Over-the-counter remedies include ginger root or ginger ale, vitamin B6 (10–25 mg three to four times daily) and doxylamine (10–12.5 mg three to four times daily). Vitamin B6 and doxylamine may be used separately or in combination. For those who do not respond, antiemetics including metoclopramide or promethazine should be considered (thus, “D” represents a next step, not a first step). Ondansetron would be third line due to slightly greater potential risk to the fetus. Up to 2% of the time, nausea and vomiting represent hyperemesis gravidarum, which involves weight loss of more than 5% of pre-pregnancy weight or dehydration and ketonuria.

**HELPFUL TIP:**

Diclegis (doxylamine succinate and pyridoxine hydrochloride) is now an FDA-approved medication for nausea and vomiting during pregnancy. Patients should take two tablets at bedtime as a starting dose and may increase to one in the morning, one in the mid-afternoon, and two

at nighttime, if needed. However, it is way expensive and has no advantage over the combination of OTC doxylamine and pyridoxine.

Question 15.1.6 If the patient had instead presented with six to eight episodes of emesis daily, an 8-lb weight loss since her last menses, and a urine specific gravity of >1.030 and ketonuria, your workup should have included:

- A) Quantitative β -human chorionic gonadotropin (β -hCG)
- B) Serum electrolytes, BUN, and creatinine
- C) Thyroid-stimulating hormone (TSH)
- D) Pelvic ultrasound
- E) All of the above

Answer 15.1.6 The correct answer is “E.” As with any other severely nauseated and vomiting patient, it is reasonable to check for electrolyte imbalances. Severity of nausea and vomiting correlates with higher levels of hCG, as would be seen with a molar or twin pregnancy. Gestational trophoblastic disease, although rare, should be evaluated for with an hCG level. The ultrasound would confirm a twin pregnancy and could provide evidence of a molar pregnancy. TSH can exclude hyperthyroidism.

Fortunately, your patient’s symptoms improve with dietary changes, vitamin B6, and doxylamine. She presents for her initial prenatal visit at 12 weeks of gestation.

Question 15.1.7 You offer her the routine prenatal tests at this visit, which include all of the following EXCEPT:

- A) Syphilis testing
- B) HIV testing
- C) 1-hour glucose tolerance test
- D) Blood type and antibody screen
- E) Fetal nuchal translucency with maternal hCG and plasma-associated pregnancy protein A (PAPP-A)

Answer 15.1.7 The correct answer is “C.” Diabetes screening with a 1-hour glucose tolerance test (50-g carbohydrate load with blood glucose obtained at 1 hour) is typically performed between 24 and 28 weeks of gestation. Patients with risk factors for gestational diabetes, which our patient doesn’t have, are candidates for earlier screening, even at the first prenatal visit. Risk factors include history of previous pregnancy with gestational diabetes, polycystic ovarian syndrome (PCOS), history of macrosomia, high pre-pregnancy BMI, first-degree relative with diabetes mellitus type 2, and certain ethnic groups such as East Asians, Hispanics, and Pacific Islanders. Syphilis and HIV testing (“A” and “B”) are done to decrease the risk of perinatal transmission. The blood type and antibody screen (“D”) are used to identify mothers with blood antibodies that could cause hemolytic disease of the fetus. Mothers who are Rh negative will subsequently receive RhoGAM at 28 weeks as well. Two maternal serum markers, hCG and pregnancy-associated plasma protein (PAPP-A, an early screen for Down syndrome), and one fetal marker (nuchal

thickness) should be used between 11 and 14 weeks to evaluate for Down syndrome ("E"). This method offers a Down syndrome detection rate of approximately 85% with a 5% false-positive rate.

HELPFUL TIP:

Nuchal translucency looks at fluid collections in the posterior fetal neck. Increased translucency suggests increased fluid collection and is associated with abnormalities such as Down syndrome, Turner syndrome, and hemodynamic problems (cardiac abnormalities).

HELPFUL (AND IMPORTANT) TIP:

Since it does not screen for neural tube defects, first-trimester screening does not negate the need for a second-trimester maternal serum triple or quad screen. The triple screen, which screens for chromosomal abnormalities (e.g., Trisomy 21) and neural tube defects, includes levels for AFP (α -fetoprotein), HCG, and uE3 (unconjugated estriol). The quadruple screen adds an inhibin A. The triple or quadruple screen is done between 15 weeks 0 days and 19 weeks 6 days of gestation. The triple screen has a 70% sensitivity for neural tube defects and Down syndrome with a 5% false-positive rate. The quadruple screen has an 81% sensitivity and a 5% false-positive rate. See ACOG's patient chart for types of genetic testing and when to test (Fig. 15-2).

The patient has passed all of her screening tests with flying colors, and she returns at 36 weeks of gestation.

Question 15.1.8 What additional screening test(s) is/are obtained near 36 weeks of gestation?

- A) Amniocentesis
- B) 3-hour glucose tolerance test
- C) Fetal fibronectin (FFN)
- D) Group B streptococcus (GBS) culture or PCR
- E) All of the above

Answer 15.1.8 The correct answer is "D." There have been several updates on how to reduce the transmission of GBS to newborns. Newer (2019) recommendations from ACOG and the AAP recommend to start screening for GBS now at 36 weeks and no longer at 35 weeks. The test results are valid for up to 5 weeks which would last through 41 weeks of gestation. Give prophylactic antibiotics of IV penicillin G every 4 hours from active labor until delivery in women who screen positive for GBS, have a prior history of a neonate with GBS infection (regardless of testing results....just treat them) or have GBS status unknown with risk factors (pre-term labor, premature rupture of membranes/ prolonged rupture of membranes > 18 hours, fever of >38C or GBS positive status in prior pregnancy).

Rapid GBS testing, should only be done on those who present in labor with an unknown GBS status and no risk factors; there are a lot of false negatives. As noted above, those with risk factors get treated anyway. For patients with a penicillin allergy, a beta-lactam such as cefazolin is preferred for those with low risk of anaphylaxis. Clindamycin and vancomycin are options in patients with a severe penicillin allergy. Vancomycin is now preferred as there has been growing resistance to clindamycin. Use clindamycin only if GBS cultures show susceptibility and no indication of inducible resistance on testing. We recommend to work closely with your pharmacist colleagues to order the proper vancomycin dosing. (Obstet Gynecol. 2019 Jul; 134(1):e19-e40 and Pediatrics. 2019 Aug; 144(2):e20191881)

► Objectives: Did you learn to ...

- Describe contraception options?
- Provide appropriate routine prenatal care?
- Recognize nausea and vomiting of pregnancy and describe its appropriate management?

► CASE 15.2

You are taking obstetric calls for your group over Labor Day (Get it? Bad joke?) weekend. Labor and delivery calls you about a 27-year-old G1P0 at 38 weeks of gestation who awoke this morning complaining of wetness. However, when she went to the bathroom, she discovered significant vaginal bleeding that had soaked her bed. She denies any cramping or abdominal pain. She is on her way to the hospital—and so are you.

Question 15.2.1 You tell the nurses to call you with her vital signs and to initiate all of the following interventions immediately upon the patient's arrival EXCEPT:

- A) Obtain IV access
- B) Draw blood for type and screen
- C) Perform a digital vaginal examination
- D) Initiate fetal monitoring
- E) Draw blood for complete blood count

Answer 15.2.1 The correct answer is "C." A small-to-moderate amount of bleeding is not unexpected during labor; however, the profuse bleeding described by the patient is an obstetrical emergency. The first priorities are to obtain IV access ("A") and ensure that the mother is hemodynamically stable. Baseline laboratory evaluation ("E") will give some indication of the amount of blood loss and establish that blood is available for transfusion if necessary ("B"). Monitoring of the fetal heart rate (FHR) will evaluate fetal status ("D"). Also, an ultrasound should be done to evaluate for placenta previa. *A digital vaginal examination should NOT be performed until the diagnosis of placenta previa has been excluded.* A consultation with someone skilled in cesarean section should be obtained if the initial evaluation suggests that immediate fetal delivery is necessary.

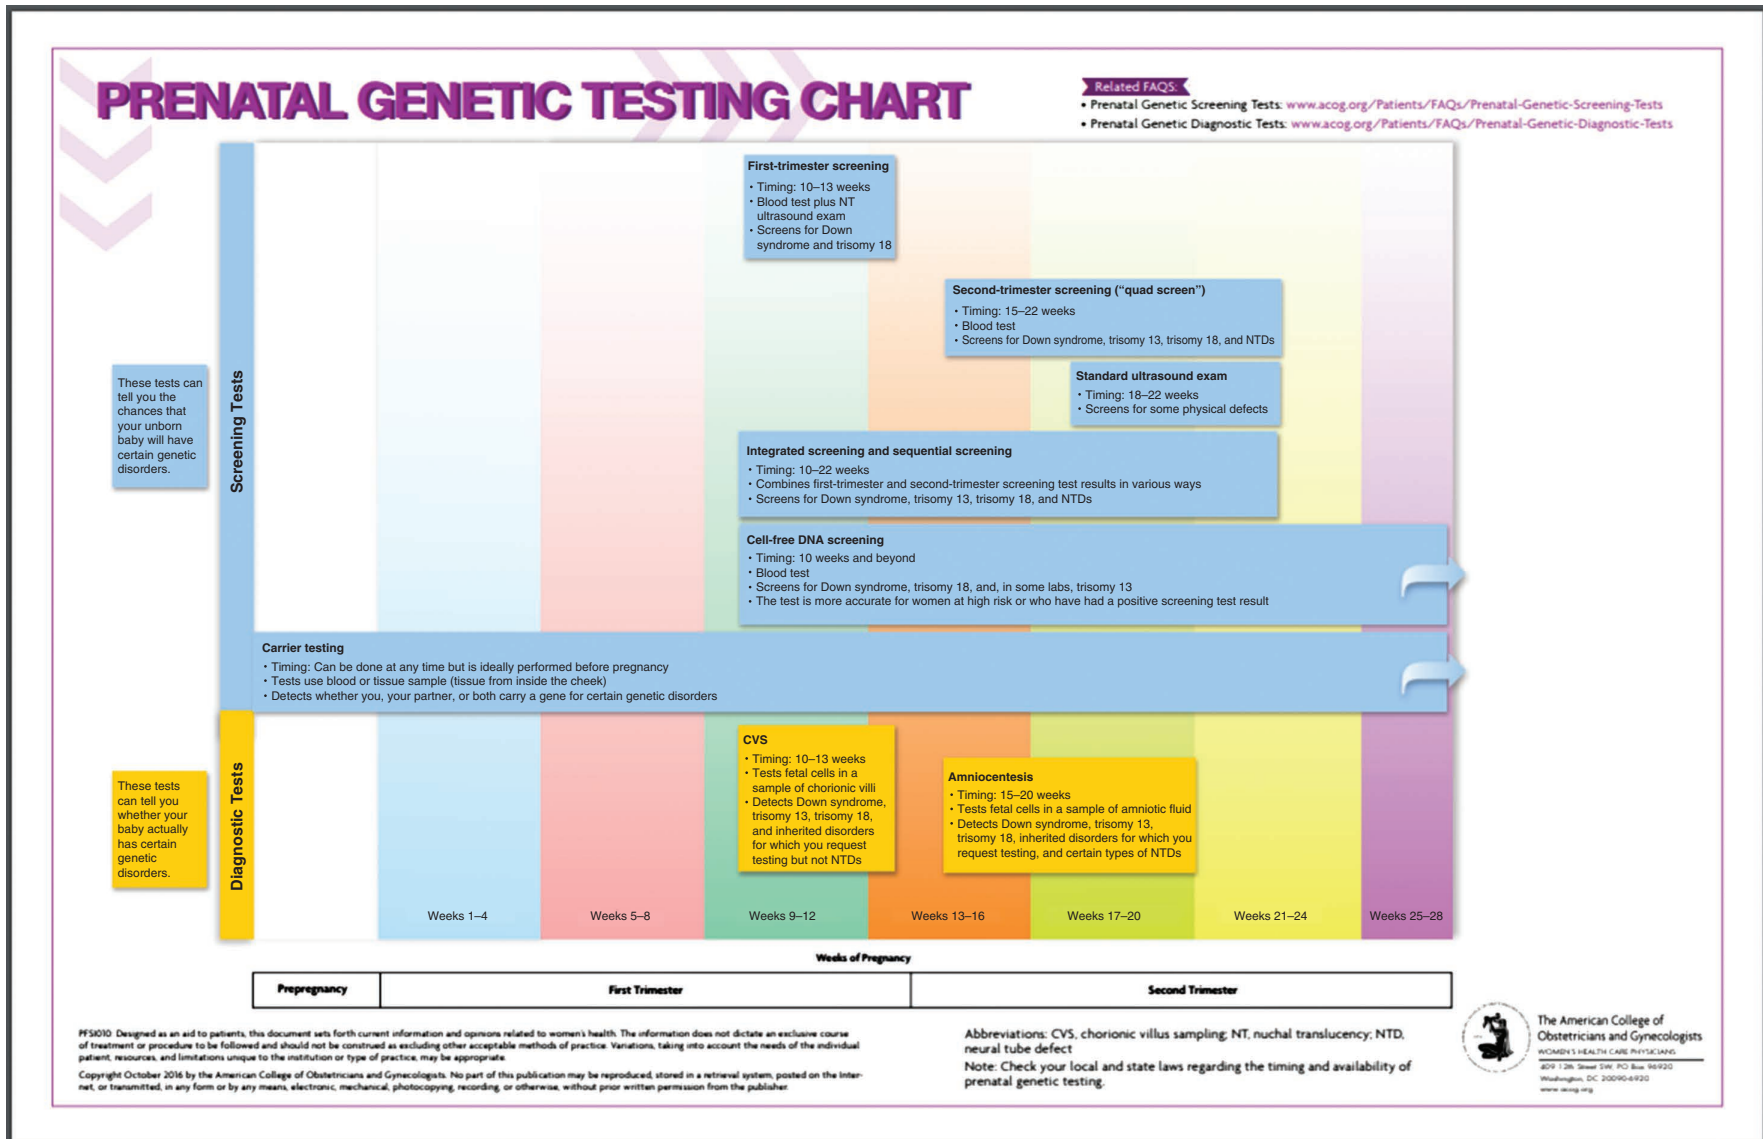

FIGURE 15-2 Prenatal genetic screening. Reprinted with permission from American College of Obstetricians and Gynecologists. Prenatal genetic testing chart (infographic). Washington, DC; American College of Obstetricians and Gynecologists; 2016. Available here: <https://www.acog.org/Patients/FAQs/Prenatal-Genetic-Testing-Chart-Infographic>. Retrieved September 11, 2019.

**HELPFUL TIP:**

Classically, placenta previa presents as *painless* third-trimester bleeding, whereas placental abruption classically presents as *painful* third-trimester bleeding. Note that these are the “classic” presentations, not pathognomonic.

When the patient arrives at the hospital, she alters her recollection of events (never happens in our practice) to say that the fluid soaking the bed sheets was blood-tinged and pink in color and first occurred 2 hours ago. She continues to have vaginal leakage but denies any bright red bleeding or contractions. Ultrasound reveals a fundal placenta (not a placenta previa) without any evidence of abruption. Fetal heart tones are in the 140s and reactive. Sterile speculum examination reveals fluid, which is nitrazine and ferning positive (both evidence of ruptured membranes). Her GBS culture performed 2 weeks ago is negative. She is still not feeling contractions, and there are no contractions on the monitor.

Question 15.2.2 What is the most appropriate next step in the management of this patient?

- A) Begin an induction of labor
- B) Send her home after 4 hours of reassuring fetal monitoring
- C) Treat her with IV penicillin for GBS prophylaxis
- D) Repeat her GBS test to confirm GBS status

Answer 15.2.2 The correct answer is “A.” A patient should not be sent home after rupture of membranes. She is at risk for intrauterine infection, and induction is indicated to reduce the risk of infection at term. Induction of labor, even with an unfavorable cervix, is not associated with an increase in cesarean or operative vaginal delivery, but it is associated with fewer maternal infections (chorioamnionitis), shortened time from rupture of membranes to birth, and fewer neonatal intensive care unit admissions. “C” and “D” are incorrect. Her GBS status was negative 2 weeks ago. Although GBS colonization can be transient, since the test was collected after 35 weeks it should be reliable. Even if her membranes were ruptured for more than 18 hours, she would not require treatment with antibiotics unless she developed a fever (remember she is GBS negative ... review the criteria in answer 15.1.8). *If a fever develops, think chorioamnionitis when choosing antibiotic therapy.*

Sterile vaginal examination reveals a cervix that is 3 cm dilated, 2 cm long (effacement), soft, anterior, and vertex at a –1 station. The patient agrees to an induction of labor.

Question 15.2.3 The best induction method for this patient is to:

- A) Insert intracervical laminaria
- B) Begin IV oxytocin at 2 milliunits per minute
- C) Insert intravaginal dinoprostone (Prepidil, Cervidil)
- D) Have her partner sit on her abdomen
- E) Have her run a few laps around L&D (or walk around the hospital)

Answer 15.2.3 The correct answer is “B.” The use of intra-vaginal and intracervical methods for cervical ripening could be cautiously considered in patients with premature rupture of membranes with an *unfavorable* cervix; but “C” is not the best choice—she is already 3 cm dilated with a Bishop score of 6! Drugs for cervical ripening may include prostaglandins which act in the cervix to facilitate smooth muscle relaxation resulting in softening and dilatation of the cervix. They also may induce myometrial contraction. Currently, the only prostaglandin labeled by the Food and Drug Administration (FDA) for such purpose is the prostaglandin E2 agents such as dinoprostone (Prepidil, Cervidil). Prostaglandin E1 agents such as misoprostol (Cytotec) inserted intravaginally are also commonly used for cervical ripening but *do not carry a label by the FDA for this indication*. Intracervical use of laminaria (an expanding pledget placed in the cervix, such as “A”) is generally reserved for pregnancy termination. “D” would not be comfortable and may cause undue harm to mom and the fetus—and it’s kind of weird. “E” is not the best choice. While walking may stimulate contractions (as can “stripping” the membranes if they are intact), she already has ruptured membranes and a more aggressive approach is warranted.

Oxytocin should be carefully titrated via IV route for labor induction or augmentation. The general starting doses are 0.5 to 2 milliunits per minute, increased by 1 to 2 milliunits every 20 to 40 minutes, to a maximum dose rarely exceeding 30 to 40 milliunits per minute.

The patient is currently in labor (success!), and now her cervical examination is 6 cm dilation, 1 cm effaced, and –1 station. The amniotic fluid is still clear, having ruptured approximately 22 hours ago. She has had an epidural placed for analgesia. The FHR baseline has increased to 165 beats per minute with minimal variability. Contractions occur every 3 minutes. Maternal temperature is now 38.6°C, and her pulse is 110 bpm. The patient denies any complaints.

Question 15.2.4 Given the history of prolonged rupture of membranes and fever, which of the following is the most likely diagnosis?

- A) Normal labor
- B) Epidural fever
- C) Nosocomial infection
- D) Chorioamnionitis

Answer 15.2.4 The correct answer is “D.” Chorioamnionitis is the most likely diagnosis and the diagnosis of most concern given the prolonged rupture of membranes (we gave you this answer above—you got that, right?). Treatment should be initiated immediately. “A” is incorrect as fever is not a normal part of labor. “B” is possible, but not as likely and a dangerous assumption. There is an association between the use of epidural analgesia and a rise in maternal temperature. Etiologies proposed for this temperature increase include lack of pain-induced hyperventilation and decreased perspiration due to sympathetic blockade. “C” is extremely unlikely given her brief time in the hospital.

Question 15.2.5 What is the next step in the care of this patient?

- A) Increase the oxytocin to hasten delivery
- B) Remove the epidural
- C) Initiate broad-spectrum antibiotics
- D) Call your backup for cesarean section (or do it yourself)
- E) Give acetaminophen 1,000 mg orally

Answer 15.2.5 The correct answer is “C.” Initiation of antibiotics is associated with a decrease in both maternal and neonatal morbidity. Multiple organisms are isolated in more than 66% of cases; therefore, antibiotics should be broad. Approved regimens include ampicillin and gentamicin, ticarcillin/clavulanate, or piperacillin/tazobactam. If the patient is penicillin allergic, cefazolin and gentamicin may be used for mild penicillin allergy. For those with severe penicillin allergy, clindamycin OR vancomycin with gentamicin is recommended. There is no need to increase the oxytocin (“A”); she has already made good labor progress. There is also no need to proceed with a cesarean delivery (“D”) unless there is another indication, such as non-reassuring FHR pattern. Although epidural anesthesia is associated with increased maternal temperature, it should only be removed if it is felt to be contributing to maternal pathology (e.g., meningitis, epidural abscess, or epidural bleed). Acetaminophen (“E”) is fine, but it should not be used in lieu of antibiotics.

The patient’s labor is progressing. Her cervix is 9 cm dilated, completely effaced, and station is +3. Her temperature is 39°C. The FHR pattern is shown in Figure 15-3.

Question 15.2.6 What is the FHR interpretation?

- A) Baseline 165 beats per minute, reactive
- B) Baseline 165 beats per minute, with periods of bradycardia
- C) Baseline 165 beats per minute, with late decelerations
- D) Baseline 165 beats per minute, with variable decelerations

Answer 15.2.6 The correct answer is “C.” The FHR pictured is described as Category II (see Table 15-2) with a baseline of about 165 beats per minute. There is moderate variability present. Following each contraction, there are late decelerations to the 110s. “A” is incorrect since “reactive” refers to a nonstress test, not fetal monitoring during labor (see Helpful Tip below for more). “B” is incorrect as fetal bradycardia is defined as an FHR of less than 110 beats per minute for at least 10 minutes. “D” is incorrect. Variable decelerations vary with respect to timing, duration, and depth.

HELPFUL TIP:

Nonstress tests are performed outside of the intrapartum period. A reactive nonstress test is defined as two accelerations of at least 15 beats above baseline and lasting at least 15 seconds within a 20-minute interval in gestations **greater than 32 completed weeks**. In gestations less than 32 weeks, reactive is defined as two accelerations at least 10 beats above baseline and lasting at least 10 seconds.

Question 15.2.7 What is the likely etiology of the fetal heart rate (FHR) tracing in Figure 15-3?

- A) Head compression
- B) Placental insufficiency
- C) Cord compression
- D) Any of the above is equally likely to cause the tracing

Answer 15.2.7 The correct answer is “B.” Late decelerations are believed to be secondary to transient fetal hypoxia in response to decreased placental perfusion. Prompt evaluation and intervention is warranted. Early decelerations are generally reassuring and attributed to fetal head compression. Variable decelerations are the most common decelerations seen in labor and indicate cord compression. Variable decelerations can sometimes be relieved by maternal repositioning or amnioinfusion (infusing saline or Ringers Lactate to “re-expand” the uterus and relieve the pressure on the cord).

Question 15.2.8 What is the LEAST appropriate course of action now?

- A) Administer maternal oxygen
- B) Stop oxytocin
- C) Forceps or vacuum-assisted vaginal delivery
- D) Consider cesarean delivery
- E) Reposition mother (roll to one side or knee–chest)

Answer 15.2.8 The correct answer is “C.” Increasing maternal oxygenation (“A”) may improve fetal oxygenation. Oxytocin can decrease placental blood flow via uterine stimulation, and hence should be decreased or stopped if non-reassuring FHR changes are present (“B”). If there is evidence of maternal hypotension, maternal hydration may be indicated. Another option is position changes (left lateral) to improve placental perfusion (“E”). Maternal position can affect uterine blood flow and placental perfusion. The gravid uterus may compress the vena cava while supine. Because the patient is 9 cm dilated, forceps or vacuum-assisted vaginal delivery (“C,” also known as operative vaginal delivery) is NOT indicated; dilation needs to be complete (10 cm) in order to use forceps or vacuum. Cesarean delivery (“D”) should be anticipated if the above interventions do not improve the fetal heart tracing.

The FHR changes resolve with your appropriate interventions. The patient progresses to complete dilation and delivers vaginally 1 hour later. Maternal antibiotics are discontinued following delivery, and the maternal temperature 2 hours after delivery is 37°C. On postpartum day 1, your patient complains of sore breasts from breastfeeding but no particular swelling of the breast (beyond what is expected postpartum), and her abdomen is sore “all over.” She is having a moderate amount of lochia, and her temperature is 38.4°C.

Question 15.2.9 The most likely cause of the fever at this time is:

- A) Endometritis
- B) Mastitis
- C) Deep vein thrombosis
- D) Septic pelvic thrombophlebitis

FIGURE 15-3 Fetal Monitoring Tracings.

TABLE 15-2 FETAL HEART TRACING CATEGORY DEFINITIONS

Category I Tracing (normal): FHR include ALL of the following:

- Baseline FHR within normal range at 110–160 bpm
- Moderate baseline FHR variability
- Absent late or variable decelerations
- Accelerations may be present or absent

CATEGORY II Tracing: Includes all FHR tracings that are not categorized as Category I or Category III. May represent an appreciable part of those encountered in clinical practice (atypical ... may represent fetal hypoxia). Any of the following:

- Bradycardia with FHR <110 bpm **WITH** variability
- Fetal tachycardia with FHR >160 bpm
- Minimal baseline variability or absent baseline variability **WITHOUT** recurrent decelerations, or marked baseline variability
- Absence of induced accelerations after fetal stimulation
- Recurrent variable decelerations accompanied by minimal to moderate baseline variability
- Prolonged deceleration >2 minutes but <10 minutes
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics such as slow return to baseline, “overshoots,” or “shoulders”

CATEGORY III Tracing (abnormal):

EITHER

- Absent baseline FHR variability AND any of the following:
 - Recurrent late decelerations
 - Recurrent variable decelerations
 - Fetal bradycardia

OR

- A sinusoidal pattern

Adapted from American College of Obstetricians and Gynecologists. ACOG Practice Bulletin no. 106: Intrapartum fetal heart rate monitoring, nomenclature, interpretation and general management principles. *Obstet Gynecol.* 2009;114(1):192–202.

Answer 15.2.9 The correct answer is “A.” Whenever fever occurs in the immediate postpartum period, endometritis should be suspected. The presence of intra-amniotic infection (chorioamnionitis) increases the risk of postpartum endometritis to 13% (or 1 in 8 women, if you prefer fractions). Antibiotics are not routinely continued for chorioamnionitis after a vaginal delivery because the “source” of the infection (the placenta) has been removed. Mastitis (“B”) is characterized by a swollen, firm, tender breast with systemic symptoms including fevers, chills, and flu-like symptoms. However, it was stipulated that the breasts were normal for our postpartum patient, making mastitis unlikely (and bilateral mastitis is very unlikely, anyway). *Staphylococcus aureus* is the typical pathogen in mastitis. Pregnancy and the postpartum period increase a woman’s risk of thrombogenesis. In fact, this persists up to 12 weeks postpartum. However, DVT (“C”) is not a likely source of the fever. Septic pelvic thrombophlebitis (“D”) is a diagnosis of exclusion and is usually entertained when fever spikes continue despite treatment for endometritis.

You start appropriate antibiotics and the patient does well. The family, in gratitude, names the child after you (adding the suffix “-tops” to the child’s name, like “Triceratops”) and makes you the godparent necessitating gifts for the next 18 years on the child’s birthday.

HELPFUL TIP:

Infants born to women with chorioamnionitis have a fourfold increase in neonatal mortality and a threefold increase in the incidence of respiratory distress, neonatal sepsis, and intraventricular hemorrhage.

► Objectives: Did you learn to ...

- Triage and manage third-trimester bleeding?
- Recognize and treat a patient with premature rupture of membranes?
- Evaluate and manage intrapartum fever?
- Interpret FHR patterns and begin initial management of abnormal patterns?
- Appreciate the risk factors, evaluation, and management of postpartum infection?

► CASE 15.3

You are seeing a 31-year-old G2P1 at 41 weeks of gestation by definite last menstrual period and 16-week ultrasound. She continues to note fetal movement and her examination is normal: BP 120/68 mm Hg, urine dipstick negative for protein and glucose, fundal height 42 cm, fetus is vertex, FHR 156 bpm. Her cervix is soft, anterior, 2 to 3 cm dilated, 50% effaced, and +1 station. She was induced with her first pregnancy, and this time she wants to have a “natural labor.” You decide to calculate a Bishop score.

Question 15.3.1 The Bishop score helps to determine:

- The health of the fetus
- The need for cervical ripening agents for induction and helps to predict labor induction success
- The maturity of the fetal lungs
- The risk of fetal demise in the post-term fetus
- The results of a Catholic intramural baseball game

Answer 15.3.1 The correct answer is “B.” The Bishop score, which takes into account cervical dilation, effacement, consistency, and position, as well as fetal station, is a useful tool to determine if cervical ripening agents are needed for induction and to predict induction success. Calculators are readily available online.

The patient’s Bishop score is favorable at 9–10.

Question 15.3.2 Which of the following is the most appropriate recommendations at this point?

- She should be induced at once; there is a high chance of fetal mortality after 41 weeks of gestation
- Since her antepartum course has been uncomplicated to date, it is safe for her to await spontaneous labor until 43 weeks of gestation
- She should undergo a nonstress test and ultrasound for amniotic fluid index
- She should plan for a cesarean section

TABLE 15-3 GUIDELINES FOR DATING BASED ON ULTRASONOGRAPHY

Gestational Age Range based on LMP	Method of Measurement	Discrepancy between Ultrasound Dating and LMP Dating that Supports Re-dating
$\leq 13\ 6/7$ weeks • $\leq 8\ 6/7$ weeks • $9\ 0/7$ weeks to $13\ 6/7$ weeks	CRL	• More than 5 days • More than 7 days
$14\ 0/7$ weeks to $15\ 6/7$ weeks	BPD, HC, AC, FL	More than 7 days
$16\ 0/7$ weeks to $21\ 6/7$ weeks	BPD, HC, AC, FL	More than 10 days
$22\ 0/7$ weeks to $27\ 6/7$ weeks	BPD, HC, AC, FL	More than 14 days
$28\ 0/7$ weeks and beyond ^a	BPD, HC, AC, FL	More than 21 days

AC, abdominal circumference; BPD, biparietal diameter; CRL, crown rump length; FL, femur length; HC, head circumference; LMP, last menstrual period.

^aBecause the risk of re-dating a small fetus that may be growth-restricted, third-trimester re-dating should be guided by careful consideration of the entire clinical picture and close surveillance.

Adapted from American College of Obstetricians and Gynecologists. Method for estimating due date. Committee Opinion No. 611. *Obstet Gynecol.* 2014;124:863–866.

Answer 15.3.2 The correct answer is “C.” By definition, a term gestation is one completed in 38 to 42 weeks. There is no significant increase in fetal mortality in an uncomplicated pregnancy at term. Virtually all reports suggest an increase in perinatal morbidity and mortality when pregnancy goes beyond 42 weeks of gestation. Antenatal surveillance of post-term pregnancies should be initiated at 41 weeks of gestation.

**HELPFUL TIP:**

Accurate determination of date of conception is important in reducing the false diagnosis of post-term pregnancy. The estimated date of delivery is most reliably and accurately determined early in pregnancy. Ultrasound may assist in determining dates but has a standard of error that is dependent on the gestational age (see Table 15-3).

Question 15.3.3 At 41 weeks she is really (really, really) tired of being pregnant and wants “a natural way” to induce contractions. Which of the following nonpharmacologic methods of inducing or augmenting labor is LEAST likely to be effective?

- A) Stripping the amniotic membranes
- B) Prolonged walking
- C) Amniotomy
- D) Nipple stimulation

Answer 15.3.3 The correct answer is “B.” Stripping membranes (“A”) appears to be effective in initiating spontaneous labor within 72 hours. Amniotomy (“C”) may be used for labor induction, especially if the Bishop score is favorable. However, a Cochrane review from 2013 did not find strong evidence supporting the use of amniotomy alone and it is not additive to oxytocin for induction. Nipple stimulation (“D”) causes release

of oxytocin and may be utilized for labor induction, but its marginal benefit is only seen in patients with a favorable Bishop score. Walking (“B”) does not result in labor induction or augmentation, but it’s not harmful either.

**HELPFUL TIP:**

Sexual intercourse is sometimes recommended to induce labor. Studies are of low quality and use various endpoints ... also, it is difficult to standardize the intervention (a lesser editorial team might insert a joke here—but not us). One of the better quality studies (*Obstet Gynecol.* 2006;108(1):134–140) did find that coitus was associated with reduced need for labor induction at 41 weeks.

Question 15.3.4 If induction becomes necessary, which of the following pharmacologic interventions would be the best approach to your patient who has a cervix that is soft, anterior, 2 to 3 cm dilated, 50% effaced, and +1 station?

- A) IV oxytocin
- B) Intracervical PGE2 (dinoprostone, Prepidil)
- C) Intravaginal PGE2 (dinoprostone, Cervidil)
- D) Intravaginal PGE1 (misoprostol, Cytotec)
- E) None of the above. All pharmacologic interventions are contraindicated

Answer 15.3.4 The correct answer is “A.” This patient does not need further cervical ripening but is a candidate for induction of labor. If cervical ripening were needed, there are several available agents. Option “D,” PGE1 (misoprostol, brand name Cytotec) can be administered intravaginally or orally (but note that the Food and Drug Administration [FDA] has not approved it for use in pregnancy). As to “B” and “C,” PGE2 (dinoprostone, brand name Cervidil) is administered

intravaginally. PGE2 gel (dinoprostone, brand name Prepidil) can be administered either intravaginally or intracervically. Because the cervix is favorable in this case, proceeding with oxytocin is the best option.

Your patient's husband is called up for active duty in Iraq (or Afghanistan ... or Libya or ... sadly, we are on the 5th edition of this book and have not needed to change this scenario) and is due to report in the next few days. She is now 41 2/7 weeks of gestation and desires induction so he can be with her for the delivery. You admit her to labor and delivery the following morning. The initial FHR monitoring before induction (also known as a nonstress test) is shown in Figure 15-4.

Question 15.3.5 What is the correct interpretation?

- A) Baseline 150 beats per minute; not reactive
- B) Baseline 150 beats per minute; reactive
- C) Baseline 180 beats per minute; decelerations to 150s; not reactive
- D) Baseline 180 beats per minute; moderate variability; reactive

Answer 15.3.5 The correct answer is “B.” The baseline is about 150 beats per minute. There are two accelerations greater than 15 beats and lasting longer than 15 seconds, which meets the criteria for a reactive nonstress test. There is one contraction and evidence of uterine irritability noted as well.

HELPFUL TIP:

When interpreting FHR tracings, variability is an important element that demonstrates fetal cardiac response to parasympathetic input. The small waveform fluctuations within the baseline heart rate tracing represent the FHR variability. After 28 weeks of gestation, variability should be present. It is categorized as absent (no amplitude, flat tracing), minimal (0–5 beat amplitude), moderate (6–25 beat amplitude), or marked (>25 beat amplitude). The absence of variability is associated with fetal decompensation or distress.

You perform amniotomy with return of particulate meconium-stained fluid. Her cervix is now 5 cm dilated, 80% effaced, with vertex at +1 station. You elect to continue monitoring progress.

Question 15.3.6 Which of the following choices of labor analgesia is MOST appropriate at this point?

- A) Epidural analgesia
- B) Local perineal anesthetic infiltration
- C) Bilateral pudendal nerve block
- D) All of the above are equally appropriate

Answer 15.3.6 The correct answer is “A.” Epidural analgesia offers the most effective form of pain relief and generally may be utilized once the patient is determined to be in active labor.

Various local anesthetic agents (“A”) are available for local infiltration of the perineum and vagina to provide analgesia for **episiotomy or laceration repair following delivery but not for labor**. Bilateral pudendal nerve blocks (“C”) are useful during the **second** stage of labor, as a supplement to epidural analgesia for anesthesia of the sacral nerves, or as an option for operative vaginal delivery anesthesia (e.g., forceps, vacuum). Opioid agonists and agonist–antagonists are also available and commonly employed. However, some reports suggest that the analgesic effect of opioids in labor is limited when using the lower doses that are generally regarded as safer for the fetus.

The nurse notices some changes on the fetal heart monitor. The current FHR is shown in Figure 15-5.

Question 15.3.7 What is the correct interpretation of this FHR tracing?

- A) Baseline 160 beats per minute; reactive
- B) Baseline 160 beats per minute; variable deceleration to the 90s
- C) Baseline 160 beats per minute; late decelerations to the 90s
- D) Baseline 160 beats per minute; early decelerations to the 90s

Answer 15.3.7 The correct answer is “B.” A variable deceleration to the 90s occurs with the first contraction on this strip. Variable decelerations vary with respect to timing, duration, and depth—thus, the name “variable.” They are not uniform. Variable decelerations represent changes in the FHR in response to cord compression. Please refer to Table 15-2 with definitions and FHR tracing categories.

HELPFUL TIP:

A systematic review in 2013 showed no benefit in outcomes for continuous FHR monitoring compared to intermittent FHR monitoring. Unfortunately, there are more cesarean sections and operative vaginal deliveries when continuous FHR monitoring is used. However, much of FHR monitoring use is dictated by local practice patterns, expert consensus, and medicolegal concerns.

Question 15.3.8 Given the findings in Figure 15-5, which of the following should be performed next?

- A) Check the patient's cervix
- B) Place a fetal scalp electrode
- C) Begin IV oxytocin infusion
- D) Place an intrauterine pressure catheter and begin an amnio-infusion
- E) Take a coffee break; you've got a long night ahead

Answer 15.3.8 The correct answer is “A.” Variable decelerations are common in labor, and brief variable decelerations are benign. When variable decelerations become recurrent, progressively deeper, and longer lasting with delayed return to baseline, they are non-reassuring and may reflect fetal hypoxia. A pelvic examination should be performed to determine if the

FIGURE 15-4 Fetal Monitoring Tracings.

FIGURE 15-5 Fetal Monitoring Tracings.

umbilical cord is prolapsed or if there has been rapid descent of the fetal head or rapid progression of labor. Oxytocin, “C,” should not be considered in this patient since she is having adequate contractions. Replacement of the amniotic fluid (“D,” amnioinfusion) with normal saline infused through a transcervical catheter has been reported to decrease both the frequency and severity of repetitive variable decelerations and can decrease rate of cesarean section. However, it would first be helpful to assess the cervical status. *Of note, amnioinfusion is no longer recommended as a prophylactic intervention for moderate or severe meconium.*

Labor progresses without incident. Your patient is now completely dilated and effaced, with fetal head at +3 station. She is comfortable with her epidural and able to push with good effort. The FHR tracing is reassuring. Contractions are every 3 minutes.

Question 15.3.9 Appropriate management at this point is:

- A) Continue pushing
- B) Vacuum-assisted delivery
- C) Forceps-assisted delivery
- D) Midline episiotomy
- E) Augment with oxytocin

Answer 15.3.9 The correct answer is “A.” At this point, labor is progressing and maternal–fetal status is reassuring. You should continue expectant management. No intervention is indicated.

HELPFUL TIP:

Episiotomies should *not* be performed routinely. Indications for episiotomy are typically related to non-reassuring fetal status and shoulder dystocia. There is no evidence that episiotomies reduce perineal trauma, postpartum dyspareunia, etc. In fact, an episiotomy increases the risk of third- and fourth-degree tears and increase blood loss.

She pushes for 3 hours. She is now exhausted. The fetal head now separates the labia with contractions, and then recedes slightly. You consider offering assistance with delivery.

Question 15.3.10 In counseling your patient and her husband about the maternal risks of operative vaginal delivery, which of the following should you discuss?

- A) Vaginal trauma
- B) Shoulder dystocia
- C) Fetal injury
- D) Perineal and rectal trauma
- E) All of the above

Answer 15.3.10 The correct answer is “E.” Maternal risks of operative vaginal delivery include injury to the lower genital tract and rectal sphincter involvement in the case of a third- or fourth-degree laceration. In addition, fetal complications need to be discussed. Shoulder dystocia is more common with operative delivery than with a spontaneous vaginal delivery (see the following for more information).

Question 15.3.11 Each of the following is a fetal risk of operative vaginal delivery EXCEPT:

- A) Cephalohematoma
- B) Skull fracture
- C) Brachial plexus injury
- D) Respiratory distress syndrome
- E) Facial nerve palsy

Answer 15.3.11 The correct answer is “D.” Risk of respiratory distress syndrome is not increased by assisted delivery. Neonatal cephalohematoma, retinal hemorrhage, and jaundice (secondary to breakdown and reabsorption of the cephalohematoma) are more common with vacuum-assisted delivery than with forceps-assisted delivery. Skull fracture and facial nerve injury is more common with forceps-assisted delivery than with vacuum-assisted delivery. Shoulder dystocia with resultant brachial plexus injury is more common with vacuum-assisted delivery, prolonged time required for delivery, and increasing birth weight. Note that injury can occur before operative delivery as a result of abnormal labor forces (we don’t think anyone has told the malpractice attorneys ...).

Delivery of an 8-lb baby is accomplished without operative vaginal assistance. The mere presence of the vacuum on the table was enough to entice the uterus to perform one last massive contraction—assisted by the infant clawing its way out when it saw the vacuum coming. Following spontaneous delivery of the intact placenta 15 minutes later, you note a large gush of blood.

Question 15.3.12 Which of the following is the most likely source of the bleeding?

- A) Uterine atony
- B) Vaginal laceration
- C) Cervical laceration
- D) Retained placenta

Answer 15.3.12 The correct answer is “A.” Postpartum hemorrhage is most commonly associated with uterine atony. Risk factors include prolonged labor, over-distended uterus (such as from two or eight gestations [remember Octomom?]), very rapid labor, high parity, chorioamnionitis, retained placental tissue, poorly perfused myometrium, halogenated hydrocarbon anesthesia, and previous uterine atony. Maternal trauma to the genital tract (“B” and “C”) may result in postpartum hemorrhage and should be routinely investigated, particularly following operative delivery. A retained placenta cotyledon is another common source for postpartum hemorrhage. The placenta should be inspected, and if there is any question of retained products of conception, the uterus should be manually explored.

Question 15.3.13 Which of the following should be undertaken next?

- A) Obtain IV access and initiate hydration
- B) Begin bimanual uterine compression
- C) Inspect vagina and cervix for lacerations

- D) Obtain blood for type and screen for possible blood transfusion
- E) All of the above

Answer 15.3.13 The correct answer is “E.” Postpartum hemorrhage is an **obstetrical emergency** and must be addressed immediately. The gravid uterus receives 500 mL of blood per minute, which can lead to massive hemorrhage if not addressed quickly. Additional personnel should be notified to help with obtaining IV access and blood draws, while you quickly try to identify the source of bleeding.

After thorough exploration of the vagina and uterus, you suspect uterine atony is the cause of bleeding. While continuing uterine massage, you think about your options.

Question 15.3.14 Which of the following is/are options in treating this patient’s bleeding?

- A) Dilute oxytocin (Pitocin) IV
- B) Methylergonovine (Methergine) IM
- C) Carboprost tromethamine (Hemabate) IM
- D) Misoprostol (Cytotec) PR
- E) All of the above

Answer 15.3.14 The correct answer is “E.” All of the drugs listed cause smooth muscle contraction of the uterus. Oxytocin can be given as a dilute IV solution or IM. It should never be administered as an undiluted IV bolus, due to the risk of **hypotension** and cardiac arrhythmia. Methergine (methylergonovine) is an ergot alkaloid and may be administered orally or intramuscularly (**not intravenously**). *Caution should be used in women with hypertension, as Methergine can cause hypertension.* Hemabate (carboprost tromethamine) is an F-2 prostaglandin analog that is administered IM or directly into the uterine myometrium. *Caution should be used in women with asthma, as Hemabate can cause bronchoconstriction.* Cytotec (misoprostol) is a prostaglandin E1 analog that works well and can safely be administered to women with asthma or hypertension. Rectal or oral administration can be used, but rectal administration is preferred in a patient with potential hemodynamic instability. This can be a lifesaver especially in third-world countries where other options may not exist. Please see Table 15-4 for further information on treatments on postpartum hemorrhage.

HELPFUL TIP:

A large, randomized international trial, the WOMAN trial, has shown the benefits of using tranexamic acid in setting of postpartum hemorrhage. There was significant reduction in mortality (1.5% vs. 1.9% [$P=0.045$] for tranexamic acid compared to placebo). The World Health Organization (WHO) recommends early use of intravenous tranexamic acid (TXA) *within 3 hours of birth* in addition to standard care for women with clinically diagnosed postpartum hemorrhage following vaginal birth or caesarean section (*Lancet*. 2017;389(10084):2105–2116). The sooner the better: TXA saves fewer lives as time goes on.

TABLE 15-4 MANAGEMENT OF POSTPARTUM HEMORRHAGE

Drug ^a	Dose and Route	Frequency	Contraindications	Adverse Effects
Oxytocin	IV: 10–40 units per 500–1,000 mL as continuous infusion or IM: 10 units	Continuous	Rare, hypersensitivity to medication	Usually none. Nausea, vomiting, hyponatremia with prolonged dosing Hypotension can result from IV push, which is not recommended
Methylergonovine	IM: 0.2 mg	Every 2–4 h	Hypertension, preeclampsia, cardiovascular disease, hypersensitivity to drug	Nausea, vomiting, severe hypertension particularly when given IV, which is not recommended
Carboprost (Hemabate)	IM: 0.25 mg Intramyometrial: 0.25 mg	Every 15–90 min, eight doses maximum	Asthma, relative contraindication for hypertension, active hepatic, pulmonary, or cardiac disease	Nausea, vomiting, diarrhea, fever (transient), headache, chills, shivering, hypertension, bronchospasm
Misoprostol	600–1,000 micrograms oral, sublingual, or rectal	One time	Rare, hypersensitivity to medication or to prostaglandins	Nausea, vomiting, diarrhea, shivering, fever (transient), headache

IV, intravenously; IM, intramuscularly; PG, prostaglandin.

^aAll agents can cause nausea and vomiting.

Modified from Lyndon A, Lagrew D, Shields L, Main E, Cape V, eds. Improving health care response to obstetric hemorrhage version 2.0. A California quality improvement toolkit. Stamford (CA): California Maternal Quality Care Collaborative; Sacramento (CA): California Department of Public Health; 2015.

She requires IV crystalloid and four units of packed red cells for symptomatic anemia following delivery. Both mother and infant eventually do well, and the patient and baby are discharged on postpartum day 2. You schedule a follow-up appointment in 2 days. You are concerned about Sheehan syndrome, given the severe postpartum hemorrhage.

Question 15.3.15 All of the following are characteristic of Sheehan syndrome EXCEPT:

- A) Failure in lactation
- B) Amenorrhea
- C) Desire to be a punk rocker
- D) Decreased LH/follicle-stimulating hormone (FSH)
- E) Adrenal cortical insufficiency

Answer 15.3.15 The correct answer is “C.” Severe intrapartum or postpartum hemorrhage may result in pituitary necrosis due to hypovolemia and hypoperfusion. This leads to a global hypopituitarism known as Sheehan syndrome. Sheehan syndrome is characterized clinically by endocrine deficiency syndromes as a result of loss of anterior pituitary function. Initial symptoms may be vague (lethargy, anorexia, weight loss, difficulty with lactation), and the syndrome can go unrecognized. Later manifestations include failure of lactation, amenorrhea, breast atrophy, loss of pubic and axillary hair, adrenal cortical insufficiency, and hypothyroidism. Desire to be a punk rocker is “Sheena syndrome.” If you don’t get it, you missed the Ramones.

► **Objectives: Did you learn to ...**

- Recognize the risks of prolonged pregnancy and identify appropriate timing of intervention?
- Describe the indications and risks associated with induction of labor?

- Interpret intrapartum FHR patterns and choose appropriate management options?
- Evaluate analgesia options, contraindications, and risks during labor and delivery?
- Recognize the indications for and management of operative vaginal and abdominal delivery?
- Evaluate and manage postpartum hemorrhage?

QUICK QUIZ: WHAT’S SCARIER THAN TWINS?

While on call for your small community hospital, a nurse on the labor and delivery ward calls you about a patient with preterm contractions. You come in to see the patient and find a 33-year-old G1P0 at 26 weeks of gestation by in vitro fertilization. She is usually followed at an academic hospital 400 miles away. She looks worried and says, “I’m going to have twins. But not now!” She recalls her prenatal lab results were unremarkable. She recalls her ultrasound showed “two heart beats.”

All of the following risks are increased with a multifetal gestation EXCEPT:

- A) Preterm labor
- B) D-isoimmunization (Rh isoimmunization)
- C) Preterm rupture of membranes
- D) Intrauterine growth restriction
- E) Twin–twin transfusion syndrome

The correct answer is “B.” The most significant complication of multiple gestations is preterm labor resulting in preterm delivery. Preterm rupture of membranes and intrauterine growth restriction also occur more frequently in multiple gestations than singleton pregnancies. The risk of all these complications is

directly proportional to the number of fetuses. Twin–twin trans-fusion syndrome rarely occurs and is associated with mono-chorionic gestations. Multifetal gestations do not increase the risk of D-isoimmunization.

► CASE 15.4

After a busy day in clinic, you get the traditional 5 PM call from labor and delivery. The nurse tells you that your partner's patient is presenting with concerns for preterm labor. She is a 24-year-old G1 at 26 weeks by LMP and first-trimester ultrasound. She is having contractions but no vaginal discharge. The contractions started about an hour ago and are 5 to 6 minutes apart. The nurse asks if you want to check fetal fibronectin (FFN).

Question 15.4.1 A NEGATIVE fetal fibronectin is associated with:

- A) Fetal lung immaturity
- B) Ruptured fetal membranes
- C) A decreased risk of preterm birth
- D) An increased risk of preterm birth

Answer 15.4.1 The correct answer is "C." FFN is a base-membrane protein produced by the fetal membranes. A negative test is useful in assessing the risk of preterm delivery during the following 2-week period. With a properly performed test in a symptomatic patient, up to 99.5% of patients with a negative FFN will not deliver in the subsequent 7 days. *A positive test is not useful as the test has low positive predictive value.* In performing FFN testing, the following criteria must be met: intact amniotic membranes, minimal cervical dilation (<3 cm), and sampling between 24 0/7 and 34 6/7 weeks. Recent sexual intercourse and the presence of vaginal discharge or bleeding may cause a false-positive test. Collect the swab in the posterior vaginal fornix before cervical checks and transvaginal ultrasound as these can also cause the test to be falsely positive. FFN does not assess fetal lung maturity ("A"). Ruptured membranes ("B") would cause a positive FFN.

You are wondering if this patient is a good candidate for corticosteroid therapy.

Question 15.4.2 Regarding the risks and benefits of corticosteroid therapy for fetal lung maturation, which of the following is FALSE?

- A) Corticosteroid therapy is recommended for all pregnant women between 24 and 34 weeks of gestation who are at risk of preterm delivery within 7 days
- B) Corticosteroid therapy has been associated with an increased risk of neonatal infection
- C) Antenatal corticosteroid therapy reduces the incidence of respiratory distress syndrome, intraventricular hemorrhage, and necrotizing enterocolitis
- D) Corticosteroids accelerate the production of pulmonary surfactant in the fetal lungs

Answer 15.4.2 The correct answer is "B." There is no evidence that antenatal corticosteroid therapy increases the risk of neonatal infection. However, maternal infection is a **relative** contraindication to corticosteroid therapy. Corticosteroids are recommended for all pregnant women between 24 and 34 weeks of gestation who are at risk of preterm delivery within 7 days. Corticosteroids may be given after 34 weeks if there is documented fetal lung immaturity and delivery will likely occur before lung maturation.

Question 15.4.3 Which of the following FDA-approved tocolytics is regarded as first-line therapy to abort preterm labor?

- A) Nifedipine
- B) Magnesium sulfate
- C) Prostaglandin inhibitors
- D) Ritodrine
- E) None of the above

Answer 15.4.3 The correct answer is "E." Is this a trick question? Not really. The only FDA-approved agent for use as a tocolytic *was* ritodrine, a β -adrenergic receptor agonist, which was pulled from the market in the United States in 1993. There are no currently available FDA-approved tocolytics. Thus, other agents have been investigated. Terbutaline, magnesium sulfate, prostaglandin inhibitors, and calcium channel blockers have all been studied and may be utilized in select cases for tocolysis—but realize that these drugs are not approved by the FDA for this indication and that they carry substantial risks. Indomethacin has also been used successfully for tocolysis. Again, it is not approved for this indication.

HELPFUL TIP:

Tocolysis only staves off labor by 48 hours at best, so the real goal should be to prolong the pregnancy until steroids have time to be effective. Contraindications to tocolysis include: evidence of fetal distress, fetal anomalies, abruptio placentae, placenta previa with heavy bleeding, and severe maternal disease.

You examine the patient after ordering an FFN. Her cervix is 1 cm dilated at the external os and closed at the internal os, long, and posterior. Ultrasound shows that the infant is vertex. The monitor shows FHR baselines of 140 and 145 bpm. Contractions are irregular, occurring every 4 to 9 minutes. Urine dipstick shows a specific gravity of 1.030.

Question 15.4.4 The LEAST appropriate intervention in this 26 week gestation is:

- A) Continuation of monitoring
- B) Oral hydration
- C) Obstetrical consult for cerclage placement
- D) Test for group B streptococci, gonorrhea, and chlamydia
- E) Administration of corticosteroids

Answer 15.4.4 The correct answer is “C.” Cerclage (a stitch to hold the cervix closed) is indicated for incompetent cervix, not preterm labor. A cerclage is typically placed for incompetent cervix (two or more consecutive second-trimester losses with minimal or no symptoms) in the first part of the second trimester after fetal viability has been established. It would not be used at 26 weeks. The patient should be evaluated carefully, and the frequency of uterine contractions should be assessed during the initial management (“A”). Because dehydration may result in uterine irritability, rehydration (“B”) may stabilize the uterus. There is no proven benefit of hydration in the patient who is euvolemic. Get cultures (“D”) to prevent perinatal transmission, even though treatment of positive cultures has not been established to aid in the prevention of preterm birth. Corticosteroids (“E”) are discussed earlier.

HELPFUL (AND USELESS IF NOT AT LEAST INTERESTING) TIP:

Delivery rates in Israel go up around Jewish holiday fast days likely because of the relative dehydration.

► **Objectives: Did you learn to ...**

- Recognize preterm labor and manage it appropriately?
- Understand the indications, contraindications, risks, and benefits of tocolytics and corticosteroids?

► **CASE 15.5**

A 33-year-old G1 at 35 2/7 weeks presents to labor and delivery. Her pregnancy has been complicated by preterm labor. Her GBS status is unknown. On admission, she is uncomfortable with regular contractions every 3 to 4 minutes. The FHR baseline is 135 bpm with moderate variability. Her cervix is 6 cm dilated, completely effaced, with a bulging amniotic sac and fetus in vertex presentation.

Question 15.5.1 Which of the following is your best course of management?

- A) Administer corticosteroids
- B) Administer tocolytics
- C) Initiate GBS prophylaxis
- D) Discharge her to home until she is in active labor
- E) A, B, and C

Answer 15.5.1 The correct answer is “C.” GBS prophylaxis is indicated for preterm delivery if GBS status is unknown. Appropriate antibiotics include penicillin or ampicillin or an alternative intravenous agent if the patient has a penicillin allergy as previously discussed in question 15.2.5. This patient is outside the window (24–34 weeks) for corticosteroid administration (“A”). Given the gestational age (>34 weeks), advanced cervical dilation, and high likelihood of imminent delivery, tocolysis should be avoided (“B”).

HELPFUL TIP:

Indications for GBS prophylaxis: (1) GBS screen positive during current pregnancy; (2) GBS bacteriuria anytime during current pregnancy; (3) prior history of giving birth to a neonate with GBS disease; (4) unknown GBS status **plus** fever **or** preterm labor **or** prolonged rupture of membranes. No GBS prophylaxis is indicated in women who are **culture negative** with fever (but think about chorioamnionitis!), preterm labor, or prolonged rupture of membranes.

HELPFUL TIP:

The risk for recurrent premature delivery in subsequent pregnancies is about 15%. 17 α -Hydroxyprogesterone caproate given IM (brand name Makena) *may* reduce the incidence of preterm birth when started at 16 to 20 weeks and can be offered to a woman with a singleton gestation and a history of a prior spontaneous preterm singleton birth. Recent data suggests that *vaginal* progesterone may be less effective than once thought (*Lancet*. 2016;387(10033):2106–2116). Remember that “may” is the logical equivalent of “may not”. If prior preterm birth was secondary to an incompetent or shortened cervix, then a cerclage should also be considered (*Obstet Gynecol*. 2012;120(4):964–973).

► **Objective: Did you learn to ...**

- Describe indications for GBS prophylaxis?

QUICK QUIZ: PRETERM BIRTH

Risk factors for preterm birth include each of the following EXCEPT:

- A) Multiple gestation pregnancy
- B) Maternal bacteriuria
- C) Maternal history of preterm contractions with term birth
- D) Maternal smoking
- E) Maternal hypertension

The correct answer is “C.” While preterm contractions are concerning, a maternal history of preterm contractions with term birth does not increase the risk of preterm delivery in a subsequent pregnancy. Multiple gestations, history of preterm birth, smoking, cocaine use, asymptomatic bacteriuria, and hypertension are all risk factors for preterm birth.

► **CASE 15.6**

A 37-year-old G3 P0111 (all those numbers indicate the following: 0 full term, 1 preterm, 1 abortion/miscarriage for any reason, 1 living child) presents for routine obstetric care at 10 weeks of gestation. Her second pregnancy was complicated

by preeclampsia with severe features at 35 weeks requiring induction of labor and magnesium sulfate therapy. Her past medical history is uncomplicated. Her blood pressure is 132/86 mm Hg, urine protein is negative, and physical examination is unremarkable. Uterine size is consistent with dates and fetal heart tones are auscultated. The patient wonders if she will need to deliver early and need magnesium again.

Question 15.6.1 You counsel her that her risk of recurrent preeclampsia with severe features is in the range of:

- A) <5%
- B) 10%–20%
- C) 50% to 60%
- D) >90%

Answer 15.6.1 The correct answer is “B.” The risk of recurrence of preeclampsia is affected by both gestational age at diagnosis and the severity of preeclampsia. Preeclampsia at an early gestational age or preeclampsia with severe features increases the risk of recurrence. The overall recurrence risks are estimated at less than 10% for mild preeclampsia and greater than 20% (or more) for preeclampsia with severe features. Risk factors for preeclampsia include young maternal age, advanced maternal age, diabetes, and chronic hypertension, among many others.

The patient would like to do anything reasonable to prevent preeclampsia again.

Question 15.6.2 In addition to obtaining baseline laboratory evaluation (CBC, AST, ALT, creatinine, 24-hour urine for protein) to aid in early diagnosis, you recommend the following therapy:

- A) Low-sodium diet
- B) Diuretic for hypertension and edema
- C) Aspirin 81 mg daily
- D) Subcutaneous heparin therapy at prophylactic doses
- E) None of the above

Answer 15.6.2 The correct answer is “C.” ACOG's Task Force on Hypertension in Pregnancy from November 2013 recommends the use of 81 mg aspirin daily in patients who have a history of early-onset preeclampsia with preterm delivery or in patients with a history of preeclampsia in more than one prior pregnancy. USPSTF recommends the use of low-dose aspirin as a preventive medication after 12 weeks of gestation in women who are at high risk for preeclampsia. Calcium supplementation? Not so much.

Because of her age (37 years), the patient also inquires about her risk for delivering a baby with Down syndrome.

Question 15.6.3 What is her estimated risk of a Down syndrome baby with this pregnancy?

- A) 1/9,000
- B) 1/1,200
- C) 1/150
- D) 1/12

Answer 15.6.3 The correct answer is “C.” The risk of Down syndrome begins to rise rapidly at age 35, with an estimated risk of 1/250 at age 35, 1/150 at age 37, and 1/70 at age 40.

After hearing her age-related risk for Down syndrome, the patient asks about what tests she should have to screen for Down syndrome.

Question 15.6.4 You counsel her regarding various tests and offer:

- A) First-trimester triple screening (PAPP-A, hCG, and nuchal lucency)/integrated screening
- B) Chorionic villus sampling (CVS)
- C) Amniocentesis
- D) Second-trimester quadruple screening (hCG, maternal serum alpha fetal protein [MSAFP], estriol, inhibin A)
- E) Cell-free fetal DNA testing from maternal peripheral blood
- F) All of the above

Answer 15.6.4 The correct answer is “F.” All patients should be offered first-trimester screening, and if declined, they should be offered second-trimester quadruple screening. Because of her advanced age (>35 years at the time of delivery), the patient should be offered CVS and amniocentesis as well. Patients should understand that the first- and second-trimester screening tests are just that—**screening methods**. However, both CVS and amniocentesis can diagnose Down syndrome, in addition to other chromosomal abnormalities. CVS is typically completed between 10 and 13 weeks of gestation, whereas amniocentesis is performed after 15 weeks. Both are invasive procedures, which carry risks, including pregnancy loss, rupture of membranes, and fetal injury. Cell-free fetal DNA testing is a newer and noninvasive screening test that can be done after 10 weeks of gestation in patients at high risk for aneuploidy. If abnormal, it should be followed up with a diagnostic test, such as an amniocentesis. Please see Figure 15-3 for further information on prenatal screening options.

The patient has a negative first-trimester screening, which decreases her Down syndrome risk to 1/800. She declines an amniocentesis. You draw her MSAFP (maternal serum AFP) only at 17 weeks, because, as you learned above, the first-trimester screening does not evaluate for neural tube defects. The AFP is normal. She subsequently undergoes diabetes screening between 24 and 48 weeks with a 1-hour post-50-g glucose test, which shows a glucose level of 170 mg/dL.

Question 15.6.5 The next step is:

- A) Order a 3-hour glucose tolerance test
- B) Set up diabetes teaching and a consult with a nutritionist/dietician
- C) Start glyburide
- D) Start insulin
- E) All of the above

Answer 15.6.5 The correct answer is “A.” It is recommended to perform a 1-hour 50-g glucose load **screening** test for gestational diabetes between 24 and 28 weeks of gestation. Earlier testing *may* be suitable if risk factors are present (see Table 15-5) for gestational diabetes. However, the test should be repeated between 24 and 28 weeks as a proportion of women will have a negative screening test early on and then subsequently develop gestational diabetes. The cut-off for a “positive” test is somewhat controversial but is agreed to be between 130 and 140 mg/dL; typically cut-offs are based on individual institutional standards. Since hers is abnormal (≥ 140 mg/dL), the next step is to perform a second, **diagnostic** test which is the fasting 3-hour glucose tolerance test, utilizing a 100-g glucose load with measurement of blood sugars at 0 (fasting) and 1, 2, and 3 hours post glucose load. A woman with two out of three abnormal values on her 3-hour glucose tolerance test is diagnosed as having gestational diabetes. As with the 1-hour glucose tolerance test, there are variations in standards of “cut-offs” for a “positive test”; you should refer to your institution’s standards.

HELPFUL TIP:

The International Association of Diabetes in Pregnancy Study Group has previously proposed a more aggressive universal screening approach using a *single* 2-hour OGTT after administration of a 75-g glucose load during the second trimester. A *single* glucose value meeting or exceeding the set thresholds (fasting < 92 mg/dL, 1 hour < 180 mg/dL, 2 hour < 153 mg/dL) would equate to a “positive” screen for gestational diabetes. These proposed changes have been met with some resistance as there would potentially be a significant increase in the number of women diagnosed with gestational diabetes who would not be at risk of adverse outcomes (*Obstet Gynecol.* 2018;131(2):e49–e64).

TABLE 15-5 RISK FACTORS FOR GESTATIONAL DIABETES TO WARRANT PRE-/EARLY GESTATIONAL SCREENING

Body mass index > 25 (or > 23 in Asian Americans) with one of the following risk factors:

- First-degree relative with history of diabetes
- Previous history of gestational diabetes
- Prior birth of infant $> 4,000$ g (9 lbs)
- High-risk ethnicity (i.e., African Americans, Latinx, Native American, Asian American, Pacific Islander)
- Hypertension
- HDL < 35 mg/dL or triglycerides > 250 mg/dL
- PCOS
- Physical inactivity
- Impaired glucose tolerance or fasting glucose on prior testing (i.e., FPG or A1c)

Adapted from American College of Obstetricians and Gynecologists Committee on Practice Bulletins. ACOG Practice Bulletin No 180: Gestational Diabetes. *Obstet Gynecol.* 2018;131(2):e49–e64; and American Diabetes Association. Classification and Diagnosis of Diabetes. *Diabetes Care.* 2017;40(suppl. 1):S11–24.

The patient completes her glucose tolerance test with values of:

- Fasting: 92 mg/dL
- 1 hour: 194 mg/dL
- 2 hours: 169 mg/dL
- 3 hours: 148 mg/dL

(Her institution’s cut-offs are as follows: fasting 95 mg/dL; 1 hour 180 mg/dL; 2 hours 155 mg/dL; and 3 hours 140 mg/dL)

Question 15.6.6 The next step in management is:

- Continue routine prenatal care
- Set up diabetes teaching and a consult with a nutritionist/dietician
- Start glyburide
- Start insulin

Answer 15.6.6 The correct answer is “B.” Your patient has three out of her four results above the accepted thresholds. If a patient has two or more glucose levels that are above the accepted cut-off ranges, she is diagnosed with gestational diabetes (GDM). The recommendation is to initiate dietary modifications including carbohydrate restriction with frequent blood sugar monitoring and exercise. If the target glucoses (< 95 mg/dL fasting and < 120 mg/dL 2-hours post-prandially) cannot be met with dietary changes alone, medical therapy should be started.

Although insulin has been the standard therapy and is still preferred as it does not cross the placenta, glyburide or metformin are also equally appropriate for first-line therapy and have been used with increasing popularity despite this being an “off-label” indication. Of note, metformin has been shown to cross the placenta with the long-term influence on neonates still unclear. Additionally, glyburide has been shown to have increased risk of hypoglycemia and has not been shown to be as effective as insulin or metformin. Therefore, remember: *Insulin is better than metformin, which is better than glyburide* (*BMJ.* 2015;350:h102 and *Obstet Gynecol.* 2018;131(2):e49–e64).

The patient is seen for her 32-week visit and her fundal height is only 28 cm (which surprises you, given her diagnosis of gestational diabetes ... the babies of diabetic mothers tend to be large!). She has been compliant with the dietary changes and her blood sugars are usually 80s fasting and 120s 2-hour postprandial. She has gained 20 lb so far in the pregnancy. You send her for an ultrasound, which reveals an infant measuring only 28 3/7 weeks of gestation, weighing 1,168 g (< 10 th percentile). Amniotic fluid volume and umbilical artery Dopplers are normal.

Question 15.6.7 Appropriate follow-up includes:

- Changing the estimated due date
- Scheduling an induction
- Repeating the ultrasound for growth in 1 week
- Repeating the ultrasound for growth in 4 weeks

Answer 15.6.7 The correct answer is “D.” Current ultrasound techniques are not sensitive enough to assess growth at weekly intervals (“C”), and therefore waiting 4 weeks would give a better

assessment of growth rate. This infant demonstrates intrauterine growth restriction. The patient had a first-trimester ultrasound with her first-trimester screening, which establishes her due date. *It is inappropriate* to change her due date based on a 32-week ultrasound ("A"). Initiating an induction would be inappropriate without further investigation, given the early gestational age ("B"). You could do an ultrasound at 1 to 2 weeks to assess amniotic fluid and umbilical Doppler but not fetal size. Antenatal surveillance is indicated at this time with bi-weekly nonstress testing.

The patient continues with bi-weekly nonstress tests and her ultrasound at 35 weeks reveals appropriate interval growth but remains growth-restricted at a weight of 1,846 g (<10th percentile). Today her blood pressure is 146/88 mm Hg and urine protein on dipstick is +1. Ugh ... she can't seem to catch a break.

Question 15.6.8 At this time, appropriate intervention includes:

- A) Administering corticosteroids
- B) Obtaining a 24-hour urine for protein
- C) Following up with a routine appointment in 1 week
- D) Starting labetalol
- E) Starting lisinopril

Answer 15.6.8 The correct answer is "B." Given the patient's elevated blood pressure and 1+ protein on dipstick, you need to be concerned about recurrent preeclampsia. Urinary excretion of protein may be transient, and a 24-hour urine protein level is a more accurate reflection of proteinuria and the preferred method to diagnose preeclampsia (although, as noted below, urine protein is no longer required for a diagnosis of preeclampsia/eclampsia). Alternatively, a protein/creatinine ratio of at least 0.3 mg/dL can also be used for preeclampsia diagnosis. "A" is incorrect. The patient is at 35 weeks of gestation (although measuring smaller), which is beyond the recommended gestation at which corticosteroids are administered (24–34 weeks). This patient must be followed up in a couple of days so that you don't miss the diagnosis of preeclampsia. Although anti-hypertensives such as labetalol can be utilized in pregnancy, they are not routinely initiated for mild elevations in blood pressure at later gestations. We hope you avoided "E," as ACE inhibitors are contraindicated in pregnancy.

Serial blood pressure measurements in the clinic reveal no blood pressures greater than 146/88 mm Hg. Her nonstress test is reactive. The patient is sent home to collect her 24-hour urine and returns in 2 days. Her blood pressure is now 148/90 mm Hg and she has trace protein on urine dipstick. The 24-hour urine returns at 180 mg (her baseline 24-hour urine protein at the beginning of the pregnancy was 116 mg). She denies any headache, visual changes, nausea, or abdominal pain.

Question 15.6.9 Your diagnosis is:

- A) Gestational hypertension
- B) Preeclampsia
- C) Preeclampsia with severe features
- D) Acute renal failure

Answer 15.6.9 The correct answer is "A." She now has two blood pressure readings greater than 140/90 mm Hg and more than 6-hours apart, which satisfy the criteria for hypertension. Given that this elevation in blood pressure started after 20 weeks of gestation, it is likely pregnancy-related. She does not have protein >300 mg in a 24-hour urine collection, so she does not meet that diagnostic criterion for preeclampsia and does not have symptoms that would qualify her for a diagnosis of preeclampsia with severe features. *Note that proteinuria is no longer required to make the diagnosis of preeclampsia. Another abnormality such as elevated LFTs, thrombocytopenia, renal insufficiency, CHE, or CNS symptoms can make the diagnosis of preeclampsia even in the absence of proteinuria.* The diagnostic criteria for preeclampsia are outlined in Table 15-6.

TABLE 15-6 DIAGNOSTIC CRITERIA FOR PREECLAMPSIA

2013 Diagnostic Criteria for Preeclampsia

Blood pressure:

- ≥ 140 mm Hg systolic or > 90 mm Hg diastolic on **TWO** occasions at least 4 hours apart **AFTER** 20 weeks of gestation in a woman with history of previously normal blood pressure
- ≥ 160 mm Hg systolic or ≥ 110 mm Hg diastolic; hypertension can be confirmed within a short interval (minutes) to facilitate timely antihypertensive therapy

AND

- Proteinuria:
 - ≥ 300 mg per 24-hour urine collection (or this amount extrapolated from a timed collection)

OR

- Urine protein:creatinine ratio greater than or equal to 0.3 with each measured in mg/dL

OR

- Dipstick reading of 1+ (used only if other quantitative methods aren't available)

OR

In the absence of proteinuria, new-onset hypertension with the onset of any of the following (laboratory values further defined under "Diagnosis of Preeclampsia with Severe Features" below):

- Thrombocytopenia
- Renal insufficiency
- Impaired liver function
- Pulmonary edema
- Cerebral or visual symptoms

Diagnose "Preeclampsia with Severe Features" when there is the presence of any of the following:

- Blood pressure > 160 mm Hg systolic or ≥ 110 mm Hg diastolic on two occasions at least 4 hours apart while the patient is on bed rest (unless antihypertensive therapy is initiated before this time)
- Platelet count of less than 100,000/ μ L (thrombocytopenia)
- Serum creatinine concentrations greater than 1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease (renal insufficiency)
- Elevated blood concentrations of liver transaminases to 2 \times normal concentration, severe persistent right upper quadrant or epigastric pain unresponsive to medication and not accounted for by alternative diagnoses or both (impaired liver function)
- Pulmonary edema
- New-onset cerebral or visual symptoms

Adapted from American College of Obstetricians and Gynecologists. Executive summary: hypertension in pregnancy. *Obstet Gynecol.* 2013; 122(5):1122–1131.

She returns to the office for her appointment 5 days later at 36 weeks of gestation after having felt well over the week-end. However, today she developed a headache. Her blood pressure is 166/112 mm Hg and her urine dipstick reveals 3+ protein.

Question 15.6.10 Your next step is to:

- A) Start oral labetalol and see the patient back in 2 days for a blood pressure check
- B) Repeat the 24-hour urine for protein
- C) Admit to labor and delivery for blood work and monitoring, with plans to move toward delivery
- D) Immediate Cesarean section

Answer 15.6.10 The correct answer is “C.” The clinical picture is now developing into preeclampsia with severe features (headache, systolic BP >160 mm Hg, diastolic BP >110 mm Hg, and 3+ proteinuria ... see Table 15-6). The patient needs to be admitted for further monitoring of blood pressure and symptoms. In addition, blood work should be obtained including a CBC, and liver and renal studies. Starting oral labetalol would treat the patient’s hypertension, but this step alone is not prudent for a patient who appears to have preeclampsia with severe features. The 24-hour urine protein collection may be helpful in meeting the technical criteria to diagnose preeclampsia and can be done during admission; however, the results would not change the immediate management of the patient. If a faster evaluation is needed, the protein/creatinine ratio could be done in this case. However, as noted above, preeclampsia with severe features can also be diagnosed without the presence of proteinuria in the presence of certain clinical and/or laboratory findings (see Table 15-6).

HELPFUL TIP:

In a preeclamptic patient, blood pressure can be controlled with labetalol, hydralazine, or **oral** nifedipine. Avoid nitroprusside. The downside of BP control is that it reduces placental flow. **Also, treating the BP has no effect on the course of preeclampsia.** Therefore, treat BP only if >160/100 mm Hg **or** the patient is having end-organ symptoms. Further information on acute and emergent management of severe hypertension can be found in *Obstet Gynecol.* 2019;133(2):e174–e180.

You admit her to the hospital. Repeat blood pressure is 164/98 mm Hg and urine dipstick shows 3+ protein. Her cervix is soft, 2 cm dilated, 50% effaced, with fetus vertex at –2 station.

Question 15.6.11 What is the most appropriate intervention at this point?

- A) Begin induction of labor
- B) Start magnesium sulfate
- C) Prepare for a cesarean delivery in case it is needed
- D) All of the above

Answer 15.6.11 The correct answer is “D.” All of these options are important to consider at this time. Induction with oxytocin and treatment of preeclampsia with magnesium to prevent seizures are appropriate at this point. Obstetrical backup should be involved earlier rather than later unless you possess the skill to do the cesarean section yourself.

HELPFUL TIP:

Delivery of the baby (baby and placenta, really) is the ultimate treatment for preeclampsia and should be initiated as soon as feasible when the mother’s condition demands it.

You begin magnesium sulfate for the preeclampsia and oxytocin for induction. The induction proceeds without incident, and she delivers a viable male infant.

Question 15.6.12 How long will you continue the magnesium sulfate?

- A) Until delivery of the placenta
- B) For 12 hours after delivery
- C) For 24 hours after delivery
- D) Until the urine protein dipstick is negative
- E) Until discharge

Answer 15.6.12 The correct answer is “C.” Treatment should be continued for 24 hours following delivery.

HELPFUL TIP:

Monitor deep tendon reflexes, level of consciousness, and urine output for all patients on magnesium. Turn off the magnesium infusion if signs of toxicity emerge (e.g., decreased mental status, hyporeflexia) or if the patient is at risk for impending toxicity (e.g., from renal failure).

ANOTHER HELPFUL TIP:

Remember all those “mag checks” you did every 2 hours as a medical student? Well, *for patients with preeclampsia without severe features, ACOG no longer recommends magnesium sulfate as a routine intervention* (again, look at Table 15-6). Not a total waste of time, right? “Mag checks” did improve your rapport with your patients ... maybe... especially when you had to wake them up to check their reflexes. Remember that the purpose of magnesium sulfate infusion is to reduce the risk of seizures (i.e., the progression to eclampsia). The NNT for mild preeclampsia is 100.

YET ONE MORE HELPFUL TIP:

According to ACOG guidelines, bed rest should not be prescribed for patients with gestational hypertension or preeclampsia without severe features.

► **Objectives: Did you learn to ...**

- Screen for, diagnose, and manage gestational diabetes?
- Evaluate, diagnose, and manage hypertension in pregnancy?
- Define and manage preeclampsia?
- Identify intrauterine growth restriction?

► **CASE 15.7**

Now, you have to rush from L&D back to clinic (this never happens, right?) where you meet a 31-year-old woman for preconception counseling. She has a history of hypertension and a heart murmur. She has dyspnea when climbing stairs, but performs normal activities of daily living with minimal difficulty. She takes lisinopril 10 mg daily for hypertension. On physical examination, heart rate is 82 bpm and blood pressure is 138/90 mm Hg. Her height is 5' 6" and weight 160 lb. She appears well.

Question 15.7.1 Regarding the management of her chronic hypertension during pregnancy, which is the most appropriate next step?

- Discontinue lisinopril and begin methyldopa, labetalol, or nifedipine and recheck blood pressure in 2 weeks
- Increase lisinopril to 20 mg daily and recheck blood pressure in 2 weeks
- Make no changes at this time
- Discontinue lisinopril; recheck blood pressure in 2 weeks
- Either A or D is correct

Answer 15.7.1 The correct answer is "E." ACE inhibitors are contraindicated in pregnancy; therefore, a woman contemplating pregnancy should discontinue the medication or replace it with a safer alternative. In fact, for a woman capable of conceiving, ACE inhibitor use is discouraged unless no better alternative exists and the patient is using a reliable form of birth control. Women with mild chronic hypertension (systolic blood pressure 140–160 mm Hg) have a low risk for cardiovascular complications during pregnancy and can be managed with nonpharmacologic therapy as long as they are asymptomatic. In 2 weeks, when she has her return visit, if she is hypertensive (>140 – 160 / >100 mm Hg), select a medication regarded as safe during pregnancy; methyldopa, nifedipine, or labetalol would be preferred. You could also start one of these at the current visit while discontinuing the ACE inhibitor ("A"). Note that the ACOG recommendation is to treat chronic hypertension in pregnancy only if the BP is $>160/105$ mm Hg. If the patient has hypertension secondary to preeclampsia, ACOG would recommend treating the blood pressure only if the blood pressure is $>160/110$ mm Hg or if there are symptoms. These recommendations are controversial, and many would initiate blood pressure control in both groups at a lower BP. Treating hypertension reduces the incidence of "severe" hypertension, but does not change outcomes (*N Engl J Med.* 2015;372:407–417). See also *Obstet Gynecol.* 2019;133(1):e26–e50 if you are interested in this topic.

Question 15.7.2 Which of the following statements about cardiovascular physiology in pregnancy is INCORRECT?

- Blood volume and cardiac output increase by approximately 50% during pregnancy
- Heart rate increases by 10 to 20 beats per minute, peaking in the third trimester
- Systemic arterial pressure increases during the first trimester, reaches a peak in mid-pregnancy, and remains at that level until labor and delivery
- Left ventricular ejection fraction remains constant or increases slightly throughout pregnancy
- A temporary rise in venous return immediately following delivery may lead to a substantial rise in left ventricular filling pressure and cardiac decompensation in women with certain types of heart disease

Answer 15.7.2 The correct answer (and what does not happen in pregnancy) is "C." Systemic arterial pressure decreases during the first trimester, reaches a nadir during the second trimester, and returns to pre-pregnancy levels in the third trimester. The other statements are true. "E" deserves special mention. Immediately following delivery, relief of caval compression may cause a rise in venous return leading to clinical deterioration in some women with heart disease.

► **Objectives: Did you learn to ...**

- Manage hypertension during preconception counseling?
- Recognize normal cardiac physiological changes associated with pregnancy?

► **CASE 15.8**

You are seeing a 28-year-old female whose LMP was approximately 7 days ago. She is complaining of vaginal bleeding and states that she is going through one pad every 20 minutes. Needless to say she is concerned. She is not using anything for contraception. Her vital signs and examination are unremarkable except for blood at the cervical os.

Question 15.8.1 After ruling out pregnancy and assuring that her hemoglobin is stable, what is your next step?

- Fresh frozen plasma
- Cyclic medroxyprogesterone 10 mg a day
- DDAVP to maximize platelet function
- Observation: nonintervention is the best policy if the hemoglobin is normal

Answer 15.8.1 The correct answer is "B." This patient has abnormal uterine bleeding, which is a broad term that includes different functional and structural causes of uterine bleeding. Dysfunctional uterine bleeding (DUB) secondary to anovulation is a very common cause of abnormal uterine bleeding. One popular regimen for DUB is medroxyprogesterone 10 mg/day for 10 days. This should be followed by a withdrawal bleed. This regimen can be repeated for the first 10 days of the next 3 months.

Other options include starting a monophasic OCP (three pills twice a day for 1 day, two pills twice a day for 1 day, one pill twice a day for 1 day, and then finish out the pack). Conjugated estrogens are a third option. Tranexamic acid (an antifibrinolytic) 1.3 g orally three times daily for 5 days is an additional alternative for patients with contraindications to hormonal therapy. Consider prescribing an antiemetic if using OCPs since they may cause nausea. **Always remember to rule out pregnancy (including ectopic) first.**

Question 15.8.2 The most common side effect of medroxyprogesterone at the above dose includes:

- A) Bone marrow suppression
- B) Thromboembolic disease
- C) Depression
- D) Sore breasts

Answer 15.8.2 The correct answer is “C.” Many women will become depressed when taking this dose of medroxyprogesterone. They should be made aware of this ahead of time. The major side effect of the OCP regimen for abnormal uterine bleeding is nausea and vomiting. Consider giving the OCP regimen with an antiemetic. “B” is of note. Progesterones alone do not increase clot risk. They do inhibit thrombolysis, however.

HELPFUL TIP:

Another long-term option for patients with chronic abnormal uterine bleeding, after workup has been completed, is a levonorgestrel-containing IUD (e.g., Mirena, Skyla, Liletta).

Question 15.8.3 Causes of this patient’s bleeding could include all of the following EXCEPT:

- A) Hypothyroidism
- B) Von Willebrand disease
- C) Adenomyosis
- D) Parathyroid disease
- E) Uterine cancer

Answer 15.8.3 The correct answer is “D.” All of the remaining can cause abnormal bleeding. Obviously, uterine cancer would be unlikely in a 28-year-old. Other causes of abnormal bleeding to consider are cervical polyps, endometrial polyps, adenomyosis, fibroids, PID and endocrine problems such as PCOS and thyroid abnormalities.

► **Objectives: Did you learn to ...**

- Evaluate a patient with abnormal uterine bleeding?
- Treat a patient with abnormal uterine bleeding?

► **CASE 15.9**

A 37-year-old G3 P1112 (full term, preterm, abortions/miscarriage from any cause, living children) presents for an annual gynecologic examination and has questions regarding contraception. She is wondering if she is a candidate for an IUD.

Question 15.9.1 All of the following are contraindications to IUD placement EXCEPT:

- A) Pregnancy
- B) Acute pelvic infection
- C) Undiagnosed vaginal bleeding
- D) History of chlamydia infection

Answer 15.9.1 The correct answer is “D.” Although active cervicitis and acute pelvic inflammatory disease (PID) are contraindications to placement of an IUD, a prior chlamydia infection does not exclude a patient from obtaining an IUD. Undiagnosed vaginal bleeding can be a sign of either endometritis or structural abnormalities of the uterine cavity, which must be addressed prior to considering an IUD. If you chose “A,” some goons from the Board are coming to relieve you of your certification.

Your patient has none of these contraindications, and she would like to proceed with the IUD. Her friends have told her that IUDs work by causing abortions, and she is unsettled by this idea.

Question 15.9.2 The mechanism of action of IUDs (copper or progesterone) is:

- A) Abortifacient
- B) Causes a sterile inflammatory reaction to a foreign body
- C) Impairs sperm transport from the cervix to the fallopian tube
- D) B and C
- E) All of the above

Answer 15.9.2 The correct answer is “D.” Studies detecting levels of hCG reveal that this hormone is not present in IUD users during the luteal phase. Thus, the IUD is NOT an abortifacient. Studies suggest that the mechanism of action of IUDs includes interference with sperm transport from the cervix to the fallopian tube, inhibition of sperm survival, and endometrial inflammatory changes that inhibit implantation.

HELPFUL TIP:

The progesterone-releasing IUDs are approved for 3 to 5 years of contraception (depending on the brand) versus 10 years for the copper IUD.

After all of that counseling (that you can’t bill for), her husband undergoes a vasectomy. During a routine appointment 2 years later, she complains of worsening menorrhagia. She denies intermenstrual spotting. She has not noticed any lightheadedness or dizziness but does complain of generalized fatigue. On physical examination, you find a normal sized thyroid and an enlarged, irregular uterus measuring 10 to 12 weeks in size. There are no distinct adnexal masses, but this is somewhat difficult to discern due to the irregular uterus.

Question 15.9.3 Your initial workup in this 39-year-old female should include all of the following EXCEPT:

- A) CBC
- B) TSH
- C) CA-125
- D) Pelvic ultrasound
- E) Urine hCG (pregnancy test)

Answer 15.9.3 The correct answer is “C.” A CBC (“A”) will provide information regarding the hematocrit (and therefore the level of anemia) and platelet count—important information for someone with heavy menstrual bleeding. TSH (“B”) will screen for hypothyroidism, which is a common cause of menorrhagia in a 39-year-old female. A pelvic ultrasound (“D”) will aid in the evaluation of the mass palpated on examination and characterize the location and size of any uterine fibroids that may contribute to the bleeding; it will also evaluate for any adnexal masses. A pregnancy test (“E”) is always a good idea to rule out possible pregnancy, ectopic pregnancy, and miscarriage as an underlying etiology. CA-125 (“C”) is a nonspecific tumor marker that has a high false-positive rate in premenopausal women. Thus, CA-125 is **NOT** recommended as a screening test for ovarian (or endometrial) cancer. It can be used as an adjunct to pelvic ultrasound when a complex adnexal mass is identified.

The patient returns in 2 weeks following her ultrasound. Her hematocrit was 31% (indices are consistent with iron-deficiency anemia), platelets 195,000, and TSH 2.8 mU/L (normal). The ultrasound reveals a uterus measuring 12 × 8 × 6 cm, with multiple small intramural fibroids measuring less than 2 cm in diameter. There is one subserosal, pedunculated fibroid measuring 3.5 cm at the fundus.

Question 15.9.4 What is the most appropriate initial management?

- A) Expectant management and reassurance
- B) Nonsteroidal anti-inflammatory drugs (NSAIDs)
- C) Gonadotropin-releasing hormone (GnRH) agonists
- D) Blood transfusion
- E) Hysterectomy

Answer 15.9.4 The correct answer is “B.” Most fibroids are asymptomatic, although the most common symptom associated with leiomyomata (fibroids) is abnormal bleeding. This patient's fibroids are not impinging on the uterine cavity, but may be contributing to the patient's menorrhagia. Initial treatment of menorrhagia may include NSAIDs that inhibit prostaglandin synthesis. NSAIDs have been shown to reduce menstrual blood loss by 30% to 50% in women with menorrhagia. GnRH agonists (“C”) may be utilized to produce a medical menopause. However, they are expensive, and long-term usage is associated with significant side effects (e.g., osteoporosis). Hysterectomy (“E”) is the definitive treatment for leiomyomata in symptomatic women who have completed

childbearing. However, the mortality associated with hysterectomy is approximately 0.5/1,000, at age 37. It is generally reserved for women who have failed medical management or have symptoms or signs related to fibroid size. This patient's lab values do not suggest a degree of anemia necessitating a blood transfusion (“D”). Of particular note, levonorgestrel-releasing IUD can be used as an alternative. Studies have shown a reduction in uterine volume and bleeding and an increase in hematocrit after placement of IUD. If the fibroids are intracavitary, an IUD should **NOT** be used.

You start an NSAID. She responds moderately well. You add an OCP, which adequately controls her symptoms. If the patient had not responded to medical therapy, you might have considered referral to a gynecologist for potential surgical therapy.

Question 15.9.5 What other characteristic(s) would have prompted evaluation for surgery?

- A) Prolapsing fibroid through the cervix
- B) 5-cm submucosal myoma protruding 50% into the uterine cavity
- C) Rapidly enlarging uterus
- D) 20-week sized uterus and pelvic pressure
- E) All of the above

Answer 15.9.5 The correct answer is “E.” A fibroid prolapsing through the cervix (“A”) has a potential for necrosis and infection and may require surgical removal. A submucosal myoma, especially one that distorts the uterine cavity (“B”), can contribute to menorrhagia. A rapidly enlarging uterus (“C”) would be concerning for a uterine malignancy and would require further investigation. Larger uterine fibroids are more likely to contribute to symptoms of pelvic pressure and pain (“D”), which may only respond to surgical correction.

The patient returns in 1 year for her annual examination, and her pelvic examination is unchanged. However, she expresses concern that these fibroids could become cancerous.

Question 15.9.6 What is the risk of uterine malignancy (leiomyosarcoma) in a patient with fibroids?

- A) <1%
- B) 5% to 10%
- C) 40% to 50%
- D) 90% to 95%

Answer 15.9.6 The correct answer is “A.” The estimated incidence of leiomyosarcoma discovered at the time of surgery for fibroids is less than 1%. A leiomyosarcoma is a malignant tumor that does **not** arise from preexisting benign leiomyoma. Leiomyosarcomas typically arise in the fifth or sixth decade of life and are usually associated with abnormal bleeding or a rapidly enlarging uterus.

► **Objectives: Did you learn to ...**

- Recognize contraindications to IUD use?
- Treat menorrhagia?
- Describe management principles for uterine leiomyomas?

► **CASE 15.10**

A 20-year-old nulligravid female presents for evaluation of irregular menstrual cycles. Her past medical history is uncomplicated. Her gynecologic history is remarkable for menarche at age 12 years, irregular menses occurring every 21 to 40 days, and lasting 5 days, with last menstrual period 6 months ago. Her examination reveals no abnormal hair growth, no acne, normal Tanner stage V breast development, normal external genitalia and cervix, with a slightly enlarged uterus at 10 weeks size, and no adnexal masses.

Question 15.10.1 What is the first test you should order?

- A) Pelvic ultrasound
- B) Serum prolactin level
- C) Urine hCG
- D) Serum FSH
- E) Serum TSH

Answer 15.10.1 The correct answer is “C.” Primary amenorrhea is defined as either (1) the absence of menarche by 15 years with secondary sexual characteristics or (2) the absence of menarche by 13 years of age *with the complete absence* of secondary sexual characteristics. Secondary amenorrhea is defined as the absence of periods for three cycles in a woman who previously had menses. Pregnancy is the most common cause of secondary amenorrhea and thus must always be ruled out. After pregnancy has been excluded, the diagnostic focus is on differentiating between anatomic cause, ovarian failure, and endocrine abnormalities. The other tests may be done at some point, but a pregnancy test is first.

The urine pregnancy test is positive. Because of her irregular menses, you schedule her in 1 week for a vaginal ultrasound to confirm her gestational age. However, she calls your nurse in 3 days with vaginal spotting and lower pelvic cramping.

Question 15.10.2 The most important diagnosis to confirm or exclude is:

- A) Spontaneous abortion
- B) Incomplete abortion
- C) Inevitable abortion
- D) Ectopic pregnancy
- E) Twin gestation

Answer 15.10.2 The correct answer is “D.” Ectopic pregnancy is the leading cause of pregnancy-related death during the first trimester in the United States. Risk factors for ectopic pregnancy include prior PID, prior ectopic pregnancy, and prior tubal or other pelvic surgery. Spontaneous, incomplete, inevitable,

threatened, and missed abortions (or miscarriages) are terms to describe pregnancy loss occurring before 20 weeks of gestation. Each can result in significant maternal morbidity (including hemorrhage and infection) or death. However, these outcomes are less frequent than with an ectopic pregnancy.

Question 15.10.3 Which of the following tests is/are important in the management of this patient?

- A) Progesterone level
- B) Serum quantitative β -hCG
- C) Hematocrit, blood type, and screen
- D) Pelvic ultrasound
- E) All of the above

Answer 15.10.3 The correct answer is “E.” “A,” progesterone level, helps to assess the viability of the pregnancy. A progesterone level <5 ng/mL is non-reassuring (85% spontaneous abortion, 14% ectopic pregnancy), and a level >25 ng/mL is reassuring ($<2\%$ ectopic pregnancies). Two serum quantitative β -hCGs obtained 48 hours apart help assess viability. A rise in level of $>66\%$ will occur in 85% of normal pregnancies, but only 17% of ectopic pregnancies. Transvaginal ultrasounds should be able to detect an intrauterine pregnancy at hCG levels of 1,500 to 2,000 IU. With hCG levels below 1,500 IU, an ultrasound is often still helpful for identifying an adnexal mass and potential ectopic pregnancy. A blood type and screen and hematocrit are important to evaluate for Rh status and anemia and prepare for transfusion should the hemorrhage be significant.

Upon presentation, the patient has normal vitals and appears clinically stable. The blood work returns with a hematocrit of 38% and blood type A negative, antibody screen positive for anti-D. The hCG level is 5,500 IU and progesterone is 18 ng/mL. She has not received any treatment for this bleeding prior to coming to your office.

Question 15.10.4 While waiting for her ultrasound, you counsel her regarding her blood work, which indicates:

- A) She should receive RhoGAM immediately, given that she is Rh negative
- B) She has previously been exposed to the D antigen and has developed antibodies
- C) This fetus is D antigen positive and she has developed antibodies to *this* fetus
- D) She should receive RhoGAM only after confirming that she has an intrauterine pregnancy

Answer 15.10.4 The correct answer is “B.” Rh “negative” or “positive” refers to the D antigen, the antigen that is responsible for most cases of Rh sensitization. RhoGAM, or anti-D immune globulin, is used to prevent the development of Rh-D antibodies. If Rh-D antibodies are already present (i.e., the patient has already been sensitized), RhoGAM is not effective. This is why options “A” and “D” are incorrect. This patient has evidence of antibodies and has previously been exposed to the Rh-D

antigen. “C” is incorrect because not enough time has elapsed with her current bleeding to have induced antibody production to the D antigen. Without RhoGAM, 17% of mothers become sensitized. RhoGAM is recommended with ectopic pregnancies, spontaneous abortions, induced abortions, threatened abortions, amniocentesis, antepartum hemorrhage, and routinely at 28 weeks of gestation for Rh-D-negative women who are not already sensitized.

**HELPFUL TIP:**

If the Rh-D-negative woman is positive for D antibody, either she has previously been exposed to the D-antigen and mounted a response or she was given anti-D immune globulin during the previous 12 weeks (and it is still circulating).

The patient returns after her ultrasound, which reveals an intrauterine pregnancy measuring 6 weeks, 5 days gestation with cardiac activity at 110 beats per minute. The laboratory staff calls to report that the antibody screen was in fact an error, and the patient is A negative, antibody screen *negative* (“Oopsies!” says the lab tech). Therefore, you administer RhoGAM.

Question 15.10.5 You counsel the patient that her diagnosis at this time is:

- A) Threatened abortion
- B) Missed abortion
- C) Complete abortion
- D) Ectopic pregnancy
- E) All remain in the differential

Answer 15.10.5 The correct answer is “A.” Threatened abortion is defined as any vaginal bleeding in the first trimester but also incorporates those up to 20 weeks of gestation. 20 weeks of gestation, which accompanies a **currently viable** intrauterine pregnancy with a closed cervix. A missed abortion (“B”) is retention of dead products of conception in utero. A complete abortion (“C”) indicates the pregnancy and all products of conception have passed from the uterus. Ectopic pregnancy (“D”) is incorrect as you have already confirmed by ultrasound (above) that this is an intrauterine pregnancy.

Over the next 2 days, her cramping and bleeding increase and she passes tissue (complete abortion). The patient is somewhat anxious regarding her fertility and is concerned that she may have something “wrong” with her that led to the miscarriage.

Question 15.10.6 What is the most likely etiology of this miscarriage?

- A) Uterine anomalies
- B) Maternal infection
- C) Undiagnosed maternal diabetes
- D) Embryonic chromosomal abnormality
- E) Karmic retribution

Answer 15.10.6 The correct answer is “D.” Approximately 50% of first trimester spontaneous miscarriages are due to chromosomal abnormalities. Some of these miscarriages will occur prior to clinical recognition of the pregnancy and will go unrecognized by the patient. “A”–“C” can be responsible for a first-trimester miscarriage as well but are less common. As to “E,” ask your friendly neighborhood guru.

**HELPFUL TIP:**

The rate of spontaneous abortion increases with advancing maternal age. For women younger than 20 years with recognized pregnancies, the rate of spontaneous abortion is about 12%; the rate increases to 26% in women older than 40 years.

Question 15.10.7 The next step in the care of this patient is:

- A) Hysterosalpingogram
- B) Gonorrhea and chlamydia cultures
- C) Glucose screening
- D) Paternal chromosome testing
- E) Counseling and reassurance

Answer 15.10.7 The correct answer is “E.” Evaluation to determine the cause of this patient’s pregnancy loss is not recommended. In general, evaluation is not recommended for a single first-trimester spontaneous loss if the woman is otherwise healthy. Patients with two to three *consecutive* spontaneous pregnancy losses are candidates for an evaluation to determine the etiology.

► **Objectives: Did you learn to ...**

- Maintain a high degree of suspicion for pregnancy in a patient presenting with secondary amenorrhea?
- Identify causes of first-trimester bleeding?
- Define terminology used in spontaneous abortion (e.g., missed, completed, and threatened)?
- Manage early pregnancy loss?
- Describe Rh-D isoimmunization?

► **CASE 15.11**

You are now assuming care of a 28-year-old G3 P2002 at 38 3/7 weeks. Her pregnancy has been uncomplicated. On examination, you note her blood pressure is 102/66 mm Hg, urine dipstick is negative for protein and glucose, fetal heart tones are 154 beats per minute, and the fundal height is 44 cm. In reviewing her antepartum record, you note that her previous babies (Jimbo and Jumbo) weighed 8 lb 8 oz and 9 lb 6 oz at delivery. She has no history of shoulder dystocia. During this pregnancy, her lab results have been normal, and her 1-hour glucose after 75 g of glucose was 127 mg/dL at 28 weeks.

Question 15.11.1 Noting that she has a size–date discrepancy, what is your next step in the evaluation and management of this patient?

- A) 3-hour glucose tolerance test
- B) Nonstress test
- C) Fetal ultrasound for growth and amniotic fluid index
- D) Immediate induction of labor
- E) Contraction stress test (CST)

Answer 15.11.1 The correct answer is “C.” Size–date discrepancy can be caused by numerous maternal–fetal factors. Given the patient’s history, the likely etiologies are either fetal macrosomia or polyhydramnios. Additionally, her body habitus could render the fundal height measurement inaccurate (her weight is not noted). To best determine the etiology, an ultrasound with amniotic fluid index is warranted. A 3-hour glucose tolerance test (“A”) is not indicated since her screening glucose tolerance test was normal. A nonstress test (“B”) may be warranted depending on the outcome of the fetal ultrasound and amniotic fluid index. However, if growth and fluid were normal, a nonstress test would not be indicated. The CST (“E”) is utilized to assess fetal well-being in utero. A CST is done by administering oxytocin to induce contractions and observing the resulting FHR tracing. All else being equal, a CST is not warranted at this time.

HELPFUL TIP:

Controversy surrounds the issue of induction for fetal macrosomia. Induction for macrosomia has not been shown to improve maternal or fetal outcomes.

Question 15.11.2 Risk factors for fetal macrosomia include all of the following EXCEPT:

- A) Gestational age
- B) Maternal smoking
- C) Excessive maternal weight gain
- D) Multiparity (not a multiple gestation)
- E) Macrosomia in a prior infant

Answer 15.11.2 The correct answer is “B.” Maternal smoking is associated with restricted fetal growth. All of the others are associated with macrosomia. Additionally, male fetus and high maternal birth weight, and bad karma from a previous life are associated with macrosomia.

Ultrasound findings demonstrate a fetus in the vertex presentation with an estimated fetal weight of 4,200 g (9 lb 2 oz) and an amniotic fluid index of 12.6 cm (normal). You check her cervix and note that she is 1 cm dilated, 50% effaced, with vertex at 0 station.

Question 15.11.3 The optimal management at this time is:

- A) Induction of labor
- B) Cesarean section
- C) Expectant management

- D) Repeat the ultrasound weekly
- E) Initiate a weight loss program

Answer 15.11.3 The correct answer is “C.” Fetal macrosomia is generally defined as a birth weight greater than 4,500 g. Large for gestational age implies a birth weight greater than the 90th percentile for a given gestational age (or 4,000 g at delivery). Expectant management with spontaneous labor onset generally has been shown to have the best outcomes; all interventions entail an increase in fetal and maternal morbidity.

HELPFUL TIP:

According to ACOG (2009 and re-affirmed 2016), prophylactic cesarean section may be considered for estimated fetal weight >5,000 g in nondiabetic pregnancies and >4,500 g in diabetic pregnancies. While this practice does seem relatively common, it continues to remain controversial and has not been established in clinical trials nor appears to eliminate risk of birth-related trauma (*Obstet Gynecol.* 2016;128(5): e195–e209).

HELPFUL TIP:

Maternal risk from macrosomia is primarily related to labor abnormalities and includes postpartum hemorrhage, significant vaginal lacerations, cesarean delivery, and infection.

Contractions start spontaneously. Shortly after arrival to labor and delivery at 39 weeks, your patient has spontaneous rupture of membranes with clear fluid and requests an epidural for management of labor pain. Her cervix is 5 cm dilated, 90% effaced, and 0 station. FHR baseline is 145 bpm with moderate variability and no decelerations (a Category I tracing). Four hours later, she is comfortable after epidural is placed. Her cervix is unchanged.

Question 15.11.4 Appropriate intervention at this time is:

- A) Induction of labor
- B) Augmentation of labor
- C) Cesarean section
- D) Expectant management
- E) Ultrasound to confirm vertex presentation

Answer 15.11.4 The correct answer is “B.” Her labor has suffered from arrest of dilation and descent. At this time, the appropriate management is augmentation of labor. Induction of labor is the technical term for initiating uterine contractions before the onset of spontaneous labor, so “A” is incorrect. While expectant management (“D”) may be acceptable at this point after counseling the patient, there is a risk of prolonged rupture of membranes and chorioamnionitis. Cesarean section (“C”) at this point would be premature

and unnecessary as dilation to 6 cm with failure of progression despite 4 hours of adequate contractions is considered the threshold for “active phase arrest” (*Obstet Gynecol.* 2016;123(3):693–711).

With IV oxytocin, she proceeds to complete and after 2 hours of pushing is ready to deliver. You anticipate a shoulder dystocia.

Question 15.11.5 Appropriate maneuvers to reduce a shoulder dystocia include all of the following EXCEPT:

- A) McRoberts maneuver (flexing the patient's knees up against the abdomen)
- B) Suprapubic pressure
- C) Fundal pressure
- D) Delivery of the posterior arm
- E) Wood's corkscrew

Answer 15.11.5 The correct answer is “C.” Fundal pressure may further worsen impaction of the shoulder and may result in uterine rupture—both are generally considered bad outcomes. All the others may be used to help relieve shoulder dystocia. To manage dystocia, the Advanced Life Support for Obstetrics (ALSO) course uses the “HELPERR” mnemonic: H—call for **help** (wait ... aren't *you* the help? Call for more help!), E—**evaluate** for episiotomy, L—**legs** flexed at the hip and knee (McRoberts maneuver), P—**suprapubic** pressure, E—**enter** to rotate fetus (Rubin II, Wood's corkscrew maneuver, reverse corkscrew maneuver), R—**remove** posterior arm, and R—**roll** the patient. There is no evidence that any one maneuver is superior to another in releasing an impacted shoulder or decreasing the chance of injury. Typically, McRoberts maneuver is used first. Last resort techniques include intentional fracture of the fetal clavicle, cephalic replacement (aka, the Zavanelli maneuver—pushing the head back up into the pelvis and performing a cesarean section), and transcutaneous symphysiotomy. Why obstetricians continue to use confusing eponyms is beyond us. But if you want to belong to the club, you need to know the secret passwords ...

HELPFUL TIP:

Risk factors for shoulder dystocia include: previous shoulder dystocia, gestational diabetes, post-dates pregnancy, maternal short stature, abnormal pelvic anatomy, suspected fetal macrosomia, protracted active phase of first stage of labor, protracted second stage of labor, and assisted vaginal delivery.

In the same way that carrying an umbrella prevents a thunderstorm, merely being prepared for dystocia obviates the need for special maneuvers. The parents, happy with your care, name the baby after you but add “hotep” to the name, as in Graberhotep. Happy day! Time to talk to her about nursing.

Question 15.11.6 You tell her the benefits of breastfeeding, which include all the following EXCEPT:

- A) Species-specific and age-specific nutrients for infants
- B) Adequate iron for *premature* newborns
- C) High level of immune protection from colostrum
- D) Decreased risk of breast and ovarian cancer in mothers who breastfeed
- E) Fewer illnesses while the infant is breastfed

Answer 15.11.6 The correct answer is “B.” The benefits of breastfeeding for infants, women, families, and society are well documented. However, human milk may not provide adequate iron for **premature** newborns, term infants whose mothers have low iron stores, and infants older than 6 months. All the other choices are correct.

HELPFUL TIP:

Breast milk should only be kept at room temperature for 6 hours. However, it is safest to refrigerate it for 4 days maximum or freeze immediately. Do not heat refrigerated breast milk in the microwave, as it will destroy valuable micronutrients. Warming in hot water is a better way of reheating. And while we're at it, why do we assume babies want warm milk and then assume that toddlers want cold milk? Cold breast milk is OK for babies if parents want to try it—no need to warm the milk to body temperature.

Your patient and her infant do well and are discharged home on postpartum day 2.

Question 15.11.7 How do you counsel your patient regarding follow-up care after discharge?

- A) She's good to go without follow-up. Baby is delivered and everybody is doing well! You can go for vacation on the beach in Costa Rica
- B) Schedule follow-up in 3 weeks
- C) Schedule follow-up in 6 weeks
- D) Provide your “card” for any questions and see her in 1 year for her annual well-woman exam
- E) B and C

Answer 15.11.7 The correct answer is “E.” The immediate time period following birth is a critical period for both the woman and her infant, given the numerous new stressors and changes both are undergoing. Therefore, in 2018 ACOG recommended redefining postpartum care as a continuum instead of a single visit and thus affectionately labeling it the “fourth trimester” (and then the “fifth trimester” lasts until the kid graduates from college and starts paying for his or her own stuff, right?). It is recommended that women have contact with their maternal care provider within the first 3 weeks postpartum for an initial visit to address any acute issues following pregnancy and delivery and to further define and

tailor ongoing care as needed (“B”). This initial visit should be followed by a more comprehensive well-woman visit to address ongoing care needs, psychological health, postpartum problems, and reproductive planning no later than 12 weeks following birth (“C”). “A” and “D” deserve particular mention as these would be poor delivery of care and you may as well say “Hasta la vista” to your practice.

She returns for her postpartum examination in 3 weeks and notes she is adjusting well. Her mood is doing great and she feels she has finally figured out “that whole breastfeeding thing.” You schedule her for another visit in 6 weeks. At this visit, she notes incontinence of urine several times a day, especially with coughing, laughing, and sneezing. She has not experienced nocturia, dysuria, or hematuria.

Question 15.11.8 These symptoms are indicative of which type of incontinence:

- A) Stress incontinence
- B) Urge incontinence
- C) Overflow incontinence
- D) Functional incontinence
- E) Psychogenic incontinence

Answer 15.11.8 The correct answer is “A.” Stress incontinence is the involuntary loss of urine during physical activity such as coughing, laughing, jumping, running, and sneezing. Urge incontinence is the involuntary loss of urine associated with an abrupt and strong desire to void (detrusor overactivity). Overflow incontinence is the involuntary loss of urine due to under-activity of the detrusor muscle (e.g., neurogenic bladder) or obstruction (e.g., BPH in men) but this (urinary outlet obstruction, *not* BPH) is becoming more common in women. Functional incontinence is loss of urine associated with physical limitations (e.g., mobility restriction, arthritis, and dementia) in persons who have otherwise adequate bladder control. Psychogenic incontinence, incontinence secondary to severe depression or other psychological problem, is a rare disorder in this population and should be considered a diagnosis of exclusion. It is more frequent in patients with dementia.

Question 15.11.9 Which of the following is most important prior to initiating incontinence therapy?

- A) Evaluate for a vaginal fistula using a dye instillation test
- B) Obtain urinalysis followed by urine culture if abnormal
- C) Refer for cystoscopy
- D) Order urodynamic studies

Answer 15.11.9 The correct answer is “B.” The first step in the diagnosis of incontinence is a detailed history and physical examination. A urinalysis and urine culture should be obtained to exclude urinary tract infection. Bacteriuria should be obtained because the endotoxin produced by *Escherichia coli* may trigger abnormal detrusor activity or act as an α -adrenergic blocker

causing urinary outlet obstruction as noted above (cool, huh?). Additional diagnostic tools may include a voiding diary, stress test (have the patient cough or bear down and see if there is leakage from the urethra), checking a postvoid residual, cystometry, and cystourethroscopy. If there is concern for a vaginal fistula elicited by the history and physical examination, dye instillation testing may be warranted (IV dye to evaluate for a ureteral fistula, bladder instillation to evaluate for a bladder fistula).

HELPFUL TIP:

Bariatric surgery (gastric banding, etc.) reduces the rate of urinary incontinence in women who qualify: body mass index (BMI) >40 or BMI >35 + comorbidities (DM, sleep apnea, severe joint disease, weight-related cardiomyopathy).

When you have completed your evaluation, you determine that she has stress urinary incontinence.

Question 15.11.10 The best initial treatment option is:

- A) Pelvic muscle exercises
- B) Trial of oxybutynin hydrochloride
- C) Fitting of a pessary
- D) Surgical consult
- E) Incontinence pads

Answer 15.11.10 The correct answer is “A.” Pelvic muscle exercises (e.g., Kegel exercises) facilitate improved urinary control in 40% to 75% of patients. The correct method can be taught during a routine pelvic examination. Pelvic physical therapy can be used to provide feedback on the patient’s success with these exercises. “B” is incorrect. Oxybutynin hydrochloride is approved for detrusor instability (i.e., urge incontinence) and does not appear to be effective for stress incontinence. It also has significant anticholinergic side effects. “C” is incorrect. Several vaginal pessaries have been designed with the intent of providing differential support to the urethrovaginal junction for treatment of stress urinary incontinence. This is an option for many women, especially those who want to avoid surgery, but a pessary would not be the initial treatment. “D” is incorrect. Surgical correction is typically reserved until 6 to 12 months postpartum, as the symptoms may continue to improve during that time. Note that surgical mesh has a very high rate of complications when used for the treatment of incontinence (mid-urethral sling) and, according to the FDA, has NO benefit over the traditional surgical treatment of stress incontinence. We would not subject our relatives (even our in-laws) to this treatment.

► **Objectives: Did you learn to ...**

- Evaluate and manage fetal macrosomia?
- Manage a delivery complicated by shoulder dystocia?
- Discuss the benefits of breastfeeding?
- Classify urinary incontinence and treat stress-type incontinence?

▶ CASE 15.12

A 31-year-old nulligravid single female presents for a health maintenance examination. She has no gynecologic concerns, and her last menstrual period was 3 weeks ago. She uses oral contraception and has regular cycles. Her examination is unremarkable. The Pap smear returns with high-grade squamous intraepithelial neoplasia (HSIL).

Question 15.12.1 You notify her of the Pap smear findings and explain this indicates:

- A) She has cervical cancer
- B) She needs further diagnostic testing including colposcopy and possible biopsy
- C) She needs treatment with cryotherapy or laser ablation
- D) She should have the Pap smear repeated in 3 to 4 months
- E) She should be enrolled in a hospice program

Answer 15.12.1 The correct answer is “B.” Cervical cytology is the most effective cancer-screening program ever implemented. Both types of screening, liquid based and traditional Pap smears, have the same accuracy, and both types are endorsed for screening. Abnormal Pap smear findings require further investigation with colposcopy and directed biopsy, if indicated. Given the finding of high-grade intraepithelial neoplasia on the Pap smear, repeating the Pap smear in 3 months is inappropriate. An endocervical specimen (Pap smear or endocervical curettage) will need to be performed regardless of the appearance of the ectocervix to exclude endocervical pathology. Treatment with a non-excisional procedure (“C”) is not acceptable and premature without a biopsy to confirm the diagnosis first.

You perform a colposcopy, and the cervix appears grossly normal. An endocervical Pap smear is obtained. There are acetowhite changes with areas of mosaicism at the squamocolumnar junction from the 4 o'clock to 11 o'clock position. The colposcopy is adequate.

Question 15.12.2 When you discuss the cervical findings you explain that:

- A) She needs a biopsy of the abnormal area
- B) Given the previous Pap smear, you recommend a “see and treat” loop electrosurgical excision procedure (LEEP)
- C) The findings are consistent with dysplasia; no further therapy is warranted
- D) She needs a repeat Pap smear in 3 to 4 months
- E) Either A or B would be acceptable choices

Answer 15.12.2 The correct answer is “E.” When acetic acid is applied to the cervix, abnormal cells tend to turn white (“acetowhite”), and as the acetowhite fades, the degree of vascularity can be appreciated. Mosaicism, or mosaic changes, refer to areas with increased vascularity and are indicative of abnormal changes, often dysplasia. However, “visual” findings at colposcopy are no more than suggestive, so “C” is incorrect. Biopsy of the area is warranted to obtain a tissue diagnosis. The

see-and-treat approach (“B”) is an option for our patient since she is 31 years old; however, the see-and-treat approach should not be done in young women between the ages of 21 and 24 per the current ASCCP guidelines (yes, 21-24). In this age range, lesions often regress spontaneously. However, consider the “see-and-treat” approach in any patient who is unlikely to follow up.

The endocervical Pap smear is negative for dysplasia. You also performed a biopsy of the acetowhite change area, which revealed high-grade cervical intraepithelial neoplasia (CIN III).

Question 15.12.3 Which of the following do you recommend?

- A) Hysterectomy
- B) Trachelectomy
- C) Cytological follow-up
- D) LEEP or LASER ablation
- E) 5-fluorouracil intravaginally

Answer 15.12.3 The correct answer is “D.” While some patients with severe dysplasia (CIN III) may be candidates for a hysterectomy (“A”), it would be an overly aggressive approach in this 31-year-old female who has never been pregnant and may wish to conceive in the future. Additionally, women who had high-grade CIN before hysterectomy can develop recurrent vaginal dysplasia (VaIN) or cancer at the vaginal cuff. Likewise, trachelectomy (removal of the entire cervix) (“B”) would be overly aggressive with no added benefit over a LEEP procedure. Cytological follow-up or “expectant management” (“C”) is **NOT** recommended for high-grade dysplasia in this patient. The likelihood of regression is low in this patient's age demographic, while the likelihood of persistence or progression to cancer is unacceptably high. Young women between 21 and 24 do have the option proceeding with treatment (which is preferred with CIN III or inadequate colposcopy) OR observation with cytology and colposcopy at 6-month intervals for 12 months. A LEEP or ablation therapy would be the best recommendation in this patient. The use of 5-fluorouracil intravaginally (“E”) is typically not recommended for initial treatment of **cervical dysplasia**. It is used instead for **vaginal dysplasia**, when the extent of disease precludes complete excision or destruction.

Your patient wants to know the likelihood of regression to “normal” without treatment.

Question 15.12.4 What will you counsel?

- A) About 90% of CIN III lesions will become invasive cancer without aggressive treatment
- B) About one-third of CIN III lesions spontaneously regress
- C) About two-thirds of CIN III lesions spontaneously regress
- D) About 90% of CIN III lesions will remain CIN III on follow-up after 10 years

Answer 15.12.4 The correct answer is “B,” although the data on prognosis varies due to variation in histologic diagnoses of CIN. In some studies, about one-third of untreated CIN III lesions

will spontaneously regress, while about 50% will persist and the remaining will progress to invasive carcinoma. Other studies have shown progression to invasive carcinoma much higher.

She is concerned about future childbearing if she undergoes a LEEP.

Question 15.12.5 All of the following are possible complications of LEEP EXCEPT:

- A) Cervical incompetence
- B) Cervical stenosis
- C) Cervical ectopic pregnancy
- D) Decreased fertility
- E) Premature rupture of membranes

Answer 15.12.5 The correct answer is “C.” Cervical incompetence, stenosis, decreased fertility, and premature rupture of the membranes have been identified following all types of cone procedures, including LEEP, and are estimated to occur following less than 1% of procedures. Each of these complications seems to be related to the volume of tissue removed with the procedure rather than the procedure itself. Cervical ectopic pregnancy is quite rare and has NOT been associated with cone or LEEP procedures.

She undergoes LEEP treatment as recommended. The pathology reveals CIN III with margins uninvolved.

Question 15.12.6 What do you counsel her about follow-up?

- A) She should return for a Pap smear and pelvic examination in 1 year
- B) She should return for a Pap smear plus HPV co-testing in 12 and 24 months
- C) She should return for a Pap smear in 2 to 3 months
- D) She should return for a colposcopy and Pap smear in 2 to 3 months
- E) She should just “chill out”; no follow-up is indicated

Answer 15.12.6 The correct answer is “B.” The current recommendations for follow-up include a Pap smear plus HPV co-testing at 12 and 24 months. If both are negative, HPV co-testing should then be repeated 3 years later and if all remains negative, she then may return to routine age-based screening. If any of the Pap smears reveal atypical squamous cells (ASC) or higher grade dysplasia, or positive high-risk HPV, the patient should undergo repeat colposcopy.

At the follow-up evaluation at 12 months, her cervix appears normal, without lesions or discharge. The Pap smear returns as normal with negative high-risk HPV co-testing; however, testing is limited by absence of endocervical cells on the Pap smear.

Question 15.12.7 What is the best recommendation for management of this patient now?

- A) Repeat Pap smear and co-testing in another 12 months
- B) Cervical dilation and endocervical curettage
- C) Cervical dilation and endocervical Pap smear

D) Repeat LEEP

E) Repeat the Pap smear as soon as possible

Answer 15.12.7 The answer is “A.” Since the HPV test was negative, there is no need for further testing at this time and screening should proceed as previously outlined above for her CIN III. However, further evaluation now WOULD be necessary if the HPV were positive or unknown.

All your partners are on vacation and you are covering all their patients’ test results. Suddenly you receive a STAT page from the pathology lab (a pathological emergency?). They wanted to notify you that they made a mistake when interpreting one of the Pap smear results on a 33-year-old patient and, in fact, the correct report should have been ASC-US (atypical squamous cells of undetermined significance) instead of ASC-H (atypical squamous cells, high grade). The lab technician is new here and is not quite sure if they can add on an “HPV test” to the Pap sample.

Question 15.12.8 As you prepare yourself to call the patient, what do you tell her is the next step?

- A) Repeat Pap smear in 1 year
- B) Ask the lab personnel to investigate if the HPV test can be done on that sample
- C) Contact your malpractice attorney
- D) Both A and B

Answer 15.12.8 The correct answer is “D,” according to current ASCCP guidelines. If you are able to do HPV co-testing and it returns negative, she could have repeat co-testing in 3 years. If you choose to repeat cytology only in 1 year and it returns normal, she may return to age-appropriate screening. If the cytology returns with any other abnormalities greater than or equal to ASC then a colposcopy is indicated. Colposcopy would also be indicated if the HPV test returns positive. Make sure that the Pap report does not actually read ASC-H (atypical squamous cells: cannot exclude high-grade SIL). In this case, colposcopy would be indicated no matter the HPV status in this patient’s age demographic. If the patient were pregnant, or between the ages of 21 and 24, management would be different. Making sure your malpractice insurance is current and up-to-date is always a good idea but probably is unnecessary in this case.

HELPFUL (MAYBE) TIP:

The guidelines for Pap smears are ridiculously complex and include differences based on patient age, pregnancy status, etc. We strongly recommend that you review the ASCCP guidelines and algorithms available at <http://www.asccp.org/Default.aspx>. There is also an app...but they charge you \$10.00. It is cheaper to memorize it all. Some brief pearls:

- There is no need to start doing Pap smears until age 21 regardless of sexual activity; the great majority of patients with an abnormal Pap before age 21 will have regression of any lesion. HIV is an exception; see the following.

- Age 21 to 29: Screen every 3 years with cytology alone (not HPV).
- Age 30 to 65: Screen every 3 years with cytology and reflex HPV testing or every 5 years with HPV testing alone. Another option is every 5 years with cytology plus HPV ("co-testing").
- Age over 65: No screening necessary if past three consecutive Paps were normal and no risk factors.
- Hysterectomy: No need for screening unless was done for cancer or precancerous lesions. For a history of CIN 2/3 or higher, surveillance is recommended (see ASCCP guidelines).
- HIV positive: Pap smear twice in first year after diagnosis (regardless of age or mode of HIV transmission) and then yearly for 3 years. If negative, change to every 3-year testing.

► **Objectives: Did you learn to ...**

- Manage an abnormal Pap test?
- Recognize the indications for colposcopy?
- Evaluate and manage cervical dysplasia?
- Recognize the risks and potential complications of LEEP?
- Manage the absence of endocervical cells on a Pap test?

► **CASE 15.13**

You are called to the emergency department to evaluate a patient with a 2-day history of abdominal pain. She is a 24-year-old G1 P1 female whose LMP was 1 week ago. On the "1–10" scale, her pain is a "12." She is on oral contraceptives for birth control. She has "never missed a pill" and "could not possibly be pregnant." Her pain is across her lower abdomen and a little more on the right side than the left. She has felt feverish. She has had some nausea but no vomiting. She denies bowel or bladder problems. Her pain improves with acetaminophen and worsens with activity.

On examination, she appears uncomfortable but not toxic. Her temperature is 38°C, but the rest of her vitals are normal. Her abdominal examination reveals decreased bowel sounds, with tenderness to palpation primarily across the lower quadrants. She has minimal guarding and no rebound tenderness. Her pelvic examination is remarkable for cervical motion tenderness. The uterus is of normal size and consistency with no masses.

Question 15.13.1 Which of the following diagnoses can be absolutely excluded from your differential at this point?

- A) Ectopic pregnancy
- B) Appendicitis
- C) Pelvic inflammatory disease (PID)
- D) Pyelonephritis
- E) None of the above diagnoses should be excluded based on the information available

Answer 15.13.1 The correct answer is "E." The differential for lower abdominal pain in a young female includes all of the previously mentioned and more. Even though your patient seems unlikely to be pregnant due to her consistent use of contraceptives and recent menses, you should not exclude pregnancy without a negative urine hCG. Emergency department studies consistently show that women who claim to never have been sexually active can be pregnant. Either virgin births are a lot more common than we think or patient history cannot always be trusted.

You obtain cultures/PCR for chlamydia and gonorrhea. The urine pregnancy test is negative ("I told you not to waste healthcare dollars—especially in this economy," your patient complains). The urinalysis is negative for nitrites and leukocytes, and the WBC is 15,600/mm³ with an increase in bands. She reports that she's had an appendectomy.

Question 15.13.2 What is the most appropriate next step?

- A) Consult surgery and gynecology to confirm your findings
- B) Admit for IV antibiotics and IV hydration
- C) Treat as an outpatient with antibiotics and schedule follow-up for 36 to 48 hours
- D) Treat with IV antibiotics on an outpatient basis utilizing visiting nurse care
- E) Obtain cultures, discharge the patient, and treat based on culture results

Answer 15.13.2 The correct answer is "C." The patient's history, examination, and diagnostic tests are most consistent with pelvic inflammatory disease (PID). PID is a clinical syndrome caused by the ascent of microorganisms from the lower genital tract (e.g., vagina) to the upper genital tract (e.g., endometrium). Most cases of PID can be managed in the outpatient setting. Indications for hospitalization are listed in Table 15-7.

HELPFUL TIP:

The diagnosis of PID is a **clinical** one and not laboratory based! Untreated PID has significant morbidity and mortality; empiric treatment is recommended by the

TABLE 15-7 CRITERIA FOR ADMISSION FOR THE TREATMENT OF PID

- Uncertain diagnosis
- Surgical emergencies (e.g., appendicitis) cannot be excluded
- Suspected tubo-ovarian abscess
- Concurrent pregnancy (due to high risk of maternal mortality, fetal loss, and preterm delivery)
- Severe illness, intractable nausea and vomiting, or high fever
- Patient cannot tolerate or follow an outpatient regimen (e.g., severe vomiting)
- Lack of clinical response to oral outpatient antimicrobial therapy

Adapted with permission from Gradison M. Pelvic inflammatory disease. *Am Fam Physician*. 2012;85(8):791–796. Copyright © 2012 American Academy of Family Physicians. All rights reserved.

CDC if the patient meets the following minimal diagnostic criteria:

- Uterine/adnexal tenderness **or**
- Cervical motion tenderness **and**
- No other cause for illness identified

Other helpful (but not necessary) criteria include:

- Temperature $\geq 38.3^{\circ}\text{C}$
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of an abundant number of white cells on saline microscopy of vaginal fluid
- Adnexal mass
- Laboratory evidence of gonorrhea or chlamydia infection
- Elevated C-reactive protein and/or ESR

Question 15.13.3 For empiric antibiotic therapy for PID in this patient, you prescribe:

- A) Amoxicillin 500 mg PO TID for 14 days
- B) Ceftriaxone 250 mg IM once **PLUS** azithromycin 1 g
- C) Ceftriaxone 250 mg IM once **PLUS** doxycycline 100 mg PO BID for 14 days
- D) A and B
- E) B and C

Answer 15.13.3 The correct answer is “C.” Recommendations for treatment of PID include ceftriaxone (Rocephin) 250 mg IM once **PLUS** doxycycline 100 mg PO BID for 14 (yes, 14) days. Metronidazole may be added to this regimen to cover anaerobic bacteria. *Note that single-dose azithromycin is not indicated for the treatment of PID, only for cervicitis.* Thus, 14 days of doxycycline are indicated.

The current (2015) CDC treatment guidelines for rectal, oral, cervical, or penile gonorrhea include ceftriaxone 250 mg IM once **PLUS** azithromycin 1 g or 7 days of doxycycline. This is true even if the patient has **ONLY** gonorrhea. This is to prevent the development of resistant gonorrhea and also due to the high co-infection rate of gonorrhea with chlamydia. If ceftriaxone is not available, cefixime 400 mg orally in a single dose **PLUS** azithromycin 1 g orally in a single dose is an appropriate alternative. Of note, patients who have been treated for gonorrhea should be re-tested 3 months after treatment regardless of whether they believe their sex partners were treated as there is a high incidence of re-infection (CDC, 2015).

You administer ceftriaxone and instruct her to finish a 14-day course of doxycycline. She presents for follow-up a week later, at which time her symptoms have completely resolved.

Question 15.13.4 Which of the following is a potential consequence of PID?

- A) Infertility
- B) Chronic pelvic pain
- C) Increased risk for ectopic pregnancy
- D) Recurrent PID
- E) All of the above

Answer 15.13.4 The correct answer is “E.” All the choices previously listed are potential sequelae of PID. Additionally, a tubo-ovarian abscess may develop.

HELPFUL TIP:

The etiology of PID is polymicrobial, although sexually transmitted infections, predominantly gonorrhea and/or chlamydia, are implicated in up to two-thirds of cases. Antibiotic regimens are chosen for broad coverage. The CDC no longer recommends the use of fluoroquinolones for treatment of PID or gonorrhea due to increasing resistance. Of note, there is ceftriaxone-resistant gonorrhea in Japan and elsewhere with intermediate-resistant gonorrhea in the United States. There is also azithromycin-resistant gonorrhea in the United States.

Later she returns for a health maintenance examination. She quit taking her oral contraceptive 3 months ago after separating from her husband (the jerk gave her chlamydia, after all!). Subsequently, her periods have been irregular. She is not obese, has minimal acne, and no hirsutism or galactorrhea. Her physical examination is essentially normal. Urine hCG is negative (you *did* immediately think of an hCG, didn't you?) and a serum TSH is normal.

Question 15.13.5 What is the most likely etiology of the irregular cycles?

- A) Anovulation
- B) Pituitary tumor
- C) Polycystic ovarian syndrome
- D) Premature ovarian failure
- E) Androgen-secreting tumor

Answer 15.13.5 The correct answer is “A.” OCPs work by suppressing ovulation. Resumption of ovulation after pill cessation can take up to 6 months. In the absence of abnormal history, physical examination, or laboratory findings, the other choices are unlikely to be the etiology of the irregular cycles in this patient.

Question 15.13.6 Each of the following is appropriate initial management of this patient's irregular menses EXCEPT:

- A) Expectant management
- B) Reestablishment of cycle regulation with OCPs
- C) Progestin-induced withdrawal cycles
- D) Colposcopy with cervical and endometrial biopsies

Answer 15.13.6 The correct answer is “D.” Anovulation is expected following OCP cessation; thus, expectant management is a reasonable option, as most people will resume regular cycling within 6 months. She could also opt to resume OCPs for cycle regulation if that is her goal. Withdrawal bleeds could be induced by cyclical progestin challenges. Colposcopy is not indicated in this patient as she has no cytologic abnormalities.

noted that would require follow-up with colposcopy and biopsy.

The patient is reluctant to resume “the pill” and elects expectant management. You next evaluate her 8 months later. Her last period was 7 weeks before. A urine pregnancy test is positive. Given her history of PID, you request a quantitative serum β -hCG and are considering a pelvic ultrasound to confirm intrauterine pregnancy.

Question 15.13.7 What is the minimum expected increase in quantitative hCG in early gestation in a normal pregnancy?

- A) 20% increase in 24 hours
- B) 66% increase in 48 hours
- C) 100% increase in 24 hours
- D) 10% increase in 48 hours
- E) 75% increase in 72 hours

Answer 15.13.7 The correct answer is “B.” hCG typically doubles (increases by 100%) every 48 hours in normal gestation. The minimum increase considered to be compatible with a viable pregnancy is 66% in 48 hours.

Question 15.13.8 If the quantitative serum β -hCG is 5,500 ng/mL and the pelvic ultrasound reveals no intrauterine pregnancy but a probable right tubal pregnancy, what would be the most appropriate management option?

- A) Medical management with methotrexate
- B) Laparoscopic surgery with evacuation of the products of conception
- C) Consultation with someone able to do a salpingectomy if necessary
- D) Dilation and curettage
- E) Hysterectomy

Answer 15.13.8 The correct answer is “C.” An ectopic pregnancy may rupture and become a life-threatening event at any point before complete resolution. If the patient becomes hemodynamically unstable, she will need emergent surgery. Thus, an early referral for management is warranted. Medical treatment with methotrexate may be indicated, but should be done under close supervision with surgical consultation available.

Question 15.13.9 If the quantitative serum β -hCG had come back at 1,000 ng/mL and no ultrasound were available, how would you have counseled the patient?

- A) Given the history of PID, this is most likely an ectopic pregnancy. She should abort the pregnancy at once
- B) Given the history of PID, she should remain on bed rest until a definitive diagnosis is made
- C) She should be educated about ectopic pregnancy and miscarriage
- D) She should have an urgent surgical consultation today for exploratory laparotomy

Answer 15.13.9 The correct answer is “C.” This β -hCG level is consistent with an early gestation given her history of irregular cycles. However, with her history of PID, she is at risk for ectopic pregnancy. Thus, she should receive ectopic pregnancy and miscarriage precautions. While a history of PID increases the risk of ectopic pregnancy by 7- to 10-fold, only 8% of such patients will ever have an ectopic. So, it is still highly probable that the patient has a normal intrauterine pregnancy. If you chose “E,” you may also want to hand her the pamphlet entitled “Choosing a Better Doctor.”

Well, those were interesting thought experiments, but in reality, her quantitative serum β -hCG is 6,000 ng/mL. A pelvic ultrasound confirms a viable intrauterine pregnancy at 8 and 4/7 weeks of gestation and everyone is happy. She names the baby after you but with the suffix “lars,” as in “Wilburlars.”

HELPFUL TIP:

Assisted reproductive technology substantially increases the risk of a heterotopic pregnancy (two pregnancies with only one inside the uterus) to about 1%, and in these patients, the rate of ectopic pregnancy is 4% to 8%, which is about fourfold higher than the general population. Having one ectopic pregnancy predisposes to having a subsequent one.

► Objectives: Did you learn to ...

- Evaluate a patient with pelvic pain?
- Diagnose and treat PID?
- Evaluate and treat irregular menses?
- Diagnose and manage ectopic pregnancies?

► CASE 15.14

A 52-year-old female patient of yours presents for a health maintenance examination and Pap smear. Her last menstrual period was 3 months ago. She has intermittent hot flashes and night sweats. Her examination is remarkable for mild vaginal atrophy. She wonders about “estrogen testing” to see if she needs hormone replacement therapy.

Question 15.14.1 How will you counsel her about the role of estrogen testing?

- A) Recommend against estrogen testing
- B) Recommend buccal swab testing as it is the most accurate
- C) Recommend fasting morning serum estradiol testing
- D) Recommend estrogen testing with FSH to ensure menopause status
- E) Recommend annual estrogen testing after the age of 55 years

Answer 15.14.1 The correct answer is “A.” In a woman of the right age with symptoms consistent with menopause, no testing is recommended. Testing is only recommended if the diagnosis is unclear (e.g., a patient younger than 35). It can also be useful when a patient on OCPs presents with symptoms suggestive of menopause. In this case, an FSH could be done after the patient has

discontinued hormonal contraception for 1 week (or on the last day of her placebo pills). If the FSH is high (>25 mIU/L), this indicates that the patient has likely entered the menopausal transition.

She jokes that you're probably getting kickbacks from the insurance company for ordering fewer tests, and then she asks, "How will you know if I'm going through menopause without an estrogen level?"

Question 15.14.2 How will you counsel her about menopause and its diagnosis?

- A) FSH is the definitive test
- B) There is no definitive test of menopause
- C) 6 months amenorrhea, elevated FSH, and decreased estradiol confirm the diagnosis
- D) 12 months amenorrhea, elevated FSH, and decreased estradiol are the definitive test
- E) 2 years of mood swings and hot flashes will clinch the diagnosis

Answer 15.14.2 The correct answer is "B." Menopause is a clinical syndrome characterized by the cessation of spontaneous menstrual periods along with associated symptoms of estrogen deficiency such as hot flashes, vaginal atrophy, and psychological symptoms. As such, there is no definitive test.

She is concerned about menopause and wonders if she needs hormone replacement therapy.

Question 15.14.3 All the following are benefits of estrogen-containing hormone replacement therapy (HRT) EXCEPT:

- A) Osteoporosis prevention
- B) Decrease in colon cancer risk
- C) Decrease in hot flashes and vasomotor symptoms
- D) Decrease in stroke risk

Answer 15.14.3 The correct answer is "D." We have learned a lot about HRT in postmenopausal women with data from the Women's Health Initiative. Here's a quick summary. Proven benefits of HRT are limited to the following:

- Reduced risk of osteoporosis and related fractures
- Improvement of vasomotor symptoms such as hot flashes
- Decreased colon cancer risk (**not** seen in estrogen only arm). Data now suggest that even though the number of colon cancers is reduced, they are diagnosed at a more advanced stage. HRT is not recommended for chemoprevention of colon cancer in women

HRT may increase the risk of the following (variable findings):

- Breast cancer (estrogen-only arm showed a paradoxical **reduction** in risk of breast cancer)
- Myocardial infarction (estrogen-only arm showed no increase risk)
- Venous thromboembolic events
- Stroke

Only women with vasomotor symptoms appear to have improved overall quality-of-life scores with HRT. Given the

significant excess risks with HRT usage, many practitioners now recommend short-term HRT use only for vasomotor symptoms and not for osteoporosis prevention or other purported benefits.

Question 15.14.4 An absolute contraindication to use of HRT is:

- A) Heart disease
- B) Breast cancer
- C) Endometrial cancer
- D) Previous thromboembolic event
- E) All of the above

Answer 15.14.4 The correct answer is "D." Previous thromboembolic disease is the only *absolute* contraindication to HRT. The others are *relative* contraindications. While HRT is not routinely recommended for women who have heart disease or a history of breast or endometrial cancer, it may be useful in women who have significant impairment in their quality of life from vasomotor symptoms refractory to other management methods. *Topical estrogens clearly have a lower risk of thromboembolic disease (vaginal rings or transcutaneous patches).*

You discuss menopause and the potential risks and benefits of HRT with your patient. She decides against HRT for now, but returns in 6 months with continued amenorrhea, hot flashes, and vaginal dryness—which seems to bother her the most.

Question 15.14.5 Options to treat the vaginal dryness include which of the following?

- A) Systemic HRT
- B) Vaginal estrogen
- C) Lubrication
- D) All of the above

Answer 15.14.5 The correct answer is "D." Systemic and local estrogen administration are both effective for treating vaginal dryness. Lubrication with vegetable/olive oil (preferably cold pressed, extra virgin, organic) and specifically manufactured lubricants can be effective.

HELPFUL TIP:

A new medication Ospena (ospemifene) is available for vaginal dryness and post menopausal dyspareunia. It claims to be "non-hormonal" but carries the same warnings about endometrial cancer and cardiovascular disorders as do the estrogens and is an estrogen receptor agonist/antagonist. It is about \$9.00/pill. "We won't get fooled again!"

Question 15.14.6 How is vaginal atrophy most rapidly and accurately diagnosed?

- A) Biopsy of vaginal mucosa
- B) Culture of vaginal swab
- C) Patient's history and physical examination
- D) Serum hormone levels
- E) KOH prep of vaginal swab

Answer 15.14.6 The correct answer is “C.” The diagnosis of urogenital atrophy is clinical, based on history and physical examination findings. Tests such as microscopic examination of the vaginal smear will reveal an abundance of basal and parabasal cells and a paucity of mature squamous epithelium. A biopsy is a bit extreme. “B” and “E” are incorrect since atrophy is not an infectious issue.

Despite your tepid endorsement of HRT, she wants to try it to reduce hot flashes. You also counsel her on other options to treat hot flashes.

Question 15.14.7 Further options to treat symptomatic hot flashes include which of the following?

- A) Progesterone alone
- B) Clonidine
- C) Exercise
- D) Trial of an SSRI
- E) All of the above

Answer 15.14.7 The correct answer is “E.” HRT is the most efficacious treatment for vasomotor symptoms with almost 90% of women responding. Other options include progestins such as medroxyprogesterone (Provera) or megestrol (Megace), SSRIs, clonidine, gabapentin (Neurontin), venlafaxine (Effexor), clonidine, exercise, and environmental modifications (e.g., thermostat settings, fans). *Note that we do not list estrogen alone. Unopposed estrogen can increase the risk of endometrial cancer and should be avoided unless the woman has had a hysterectomy.* There is no good evidence for the efficacy of vitamin E and black cohosh. Some phytoestrogens do reduce hot flashes (about one less per day) but not sweating, and the effect may not be clinically significant.

► **Objectives: Did you learn to ...**

- Evaluate menopausal symptoms?
- Describe hormone replacement therapy, including risks, benefits, and contraindications for its use?
- Diagnose and manage atrophic vaginitis?
- Treat menopausal symptoms?

► **CASE 15.15**

A 57-year-old postmenopausal patient presents for her annual examination. She is experiencing hot flashes and night sweats, as well as a recurrence of vaginal bleeding. Her medical history is otherwise unremarkable. She wants your opinion about resuming hormone replacement. Her pelvic examination is remarkable for atrophic vaginal mucosal changes, a stenotic cervix without lesions, normal size uterus, no adnexal masses, and no masses palpable on rectovaginal examination.

Question 15.15.1 All of the following are possible causes of her vaginal bleeding EXCEPT:

- A) Cervical cancer

- B) Uterine polyp
- C) Polycystic ovary disease
- D) Atrophic vaginitis
- E) Endometrial cancer

Answer 15.15.1 The correct answer is “C.” Polycystic ovarian disease does not cause vaginal bleeding in postmenopausal women. All the other choices are diagnostic considerations in a postmenopausal female with vaginal bleeding or spotting.

Question 15.15.2 Which of the following studies should you consider obtaining?

- A) Urinalysis
- B) Pap smear
- C) Endometrial biopsy
- D) Stool guaiac
- E) All of the above

Answer 15.15.2 The correct answer is “E.” The patient could mistake the source of the bleeding; thus, it is prudent to rule out a rectal or urinary source. Cervical and endometrial evaluations are necessary to rule out gynecological pathology, such as endometrial polyp, hyperplasia, or cancer.

Question 15.15.3 All of the following increase the risk of endometrial cancer EXCEPT:

- A) Smoking
- B) Obesity
- C) Unopposed estrogen
- D) Diabetes
- E) Hypertension

Answer 15.15.3 The correct answer is “A.” Endometrial cancer is believed to be caused by unopposed estrogen stimulation of the endometrium. Smoking decreases luteal phase estrogen and is epidemiologically linked to a **decrease** in the risk for endometrial carcinoma (of course, this risk is offset by the other adverse health effects of smoking—go figure!). Risk factors and protective factors for endometrial cancer are listed in Tables 15-8 and 15-9.

TABLE 15-8 RISK FACTORS FOR ENDOMETRIAL CANCER

Advancing age
Obesity ^a
Nulliparity
Early menarche
Late menopause
Chronic anovulation (e.g., PCOS)
Unopposed exogenous estrogen use
Tamoxifen
Hypertension
Diabetes
Estrogen producing tumor
Lynch Syndrome

^aObesity leads to increased estrogen levels from peripheral conversion of androstenedione. The presence of DM and HTN as risk factors may simply reflect the high incidence of obesity in patients with these disorders.

TABLE 15-9 PROTECTIVE FACTORS FOR ENDOMETRIAL CANCER^a

Progesterone
Oral contraceptives
Cigarette smoking
Multiparity
Child bearing at an older age

^aAll reduce exposure to unopposed estrogens.

You review your patient's test results: normal Pap smear and urinalysis, stool guaiac negative for blood, and endometrial biopsy with fragments of benign polyp.

Over the next 3 years, she continues to have rare occurrences of vaginal spotting. She has declined further evaluation given the infrequency of the episodes. However, over the past several months, she has experienced an increase in the amount and frequency of the bleeding. Other than an interval weight gain of 27 lb, there has been no change in her examination. Repeat endometrial biopsy reveals complex hyperplasia with atypia, and the pathologist cannot rule out endometrial cancer.

Question 15.15.4 Of the following, the most appropriate intervention is:

- A) Repeating the endometrial biopsy
- B) Performing a transvaginal ultrasound to assess endometrial thickness
- C) Starting high-dose progestin therapy
- D) Starting high-dose selective estrogen receptor modulator therapy (e.g., tamoxifen)
- E) Arranging for definitive management (e.g., hysterectomy)

Answer 15.15.4 The correct answer is "E." Her biopsy findings are highly abnormal and may indicate already existing carcinoma that was not contained in the sample examined. Referral to a gynecologist for definitive management is warranted at this time.

HELPFUL TIP:

In postmenopausal women, an endometrial stripe of greater than 5 mm on ultrasound is suggestive of endometrial cancer. With an endometrial stripe of 4 or 5 mm or less, malignancy is rare. In evaluation of postmenopausal women with vaginal bleeding, transvaginal ultrasound is an alternative to endometrial biopsy when an endometrial biopsy cannot be done. Further benefit of obtaining a transvaginal ultrasound, regardless of endometrial biopsy, is that it can detect structural lesions or masses. Often, both modalities are required to arrive at the right diagnosis for postmenopausal bleeding.

- Manage a patient with postmenopausal bleeding?
- Assess patient for risk of endometrial cancer?

CASE 15.16

A 15-year-old nulligravid female presents with her mother for evaluation of painful periods. Menarche was at age 14. Her periods are typically every 4 to 8 weeks and are associated with severe cramping. She has missed 1 to 2 days of school with each menses because of pain. She denies intercourse. She has never had a pelvic examination. Her review of systems is otherwise negative.

Question 15.16.1 What is the MOST LIKELY etiology of the irregular cycles in *this* patient?

- A) Pregnancy
- B) Endometriosis
- C) Anovulation
- D) Hyperthyroidism
- E) Imperforate hymen

Answer 15.16.1 The correct answer is "C." Abnormal uterine bleeding is common among adolescent girls who have reached menarche. The first few years of menstruation are often characterized by irregular cycles as a result of anovulation. Pregnancy and imperforate hymen ("A" and "E") lead to absence of menses, not irregular menses. While hyperthyroidism ("D") may lead to irregular cycles, it does not typically cause dysmenorrhea and is usually associated with other systemic complaints. Additionally, hyperthyroidism would be unusual, but not out of the question, in a patient of this age. Endometriosis ("B") may cause dysmenorrhea but is unlikely to occur in a patient this young; most cases of endometriosis present in patients aged 20s to 30s.

Question 15.16.2 What is the etiology of this patient's dysmenorrhea?

- A) Prostaglandin release
- B) Streptococcal endotoxin release
- C) Estrogen release
- D) Excessive testosterone production

Answer 15.16.2 The correct answer is "A." Dysmenorrhea is the term that describes excessive pain in association with menstruation. It is the most common gynecologic complaint, affects about half of all adolescent females, and is the leading cause of periodic school absenteeism. The pathogenesis of dysmenorrhea involves excess prostaglandin release, which causes prolonged, painful uterine contractions. It can be divided in two main subtypes: primary and secondary. Primary dysmenorrhea usually starts before the age of 20 and has a tendency to occur with menarche. It is caused by prostaglandin stimulation of the myometrium. Secondary dysmenorrhea typically arises after the age of 20 and is associated with pelvic pathology or other organic disease.

► Objectives: Did you learn to ...

- Evaluate postmenopausal bleeding?

You perform a physical examination, revealing normal vital signs, normal weight, a benign abdomen, Tanner stage V, and no signs of androgen excess.

Question 15.16.3 Which of the following is the best next step in caring for this patient?

- A) Offer reassurance and observation
- B) Initiate combined hormonal contraception
- C) Initiate a GnRH agonist
- D) Prescribe a narcotic analgesic
- E) Refer for diagnostic laparoscopy

Answer 15.16.3 The correct answer is “B.” OCPs offer cycle regulation and a reduction in dysmenorrhea. “A,” expectant management, is inappropriate, given the severity of symptoms and availability of safe and effective treatment. A further workup is not needed at this stage, as her history is straightforward, and her physical examination is reassuring. She certainly does not need surgery now (“E”). “C” is incorrect. GnRH agonists will induce amenorrhea, hot flashes, accelerated bone loss, are expensive, and require add-back estrogen when utilized longer than 6 months. Narcotic analgesics (“D”) do not help reduce prostaglandin levels and are not appropriate for pain control in this case. **NOTE:** Although not listed in the answers, NSAIDs are quite effective at treating dysmenorrhea and should be considered as a first-line drug. Anecdotal evidence suggests that mefenamic acid (Ponstel) may be more effective for dysmenorrhea than other NSAIDs. Acetaminophen is not as effective as NSAIDs.

HELPFUL TIP:

The average age of menarche is 12.8 years in the United States, with the range from 10 to 15 years.

Your patient and her mother opt to try hormonal regulation with birth control pills. She returns for follow-up in 4 months and is doing well. She admits to being sexually active.

Question 15.16.4 In addition to reviewing the use of birth control pills, she should be questioned or counseled about which of the following?

- A) Knowledge of sexually transmitted diseases and use of condoms
- B) Age of her boyfriend
- C) Consensual nature of her relationship
- D) HPV vaccination
- E) All of the above

Answer 15.16.4 The correct answer is “E.” Visits for contraception are great opportunities for you to discuss safe sexual practices with the patient. Such an interview should include evaluation for sexual assault, coercion, or abuse. Although she is a little late for starting HPV vaccination, “D” is still correct

(better late than never—truly!). The ACIP recommends the routine use of 9-valent HPV vaccine (Gardasil 9) in all individuals age 11-26. Vaccination can start as young as age 9. 9-valent vaccines are given in three doses (0, 2, and 6 months from first dose). If patient gets their first two vaccines prior to age 15, they only need the first two doses at 0 and 6 months. HPV vaccine should also be considered for those 27-45 where the benefit may still outweigh the risk.

HELPFUL TIP:

HPV is the most common viral sexually transmitted infection in the United States with point prevalence in females ranging from 26% to 64%. Many patients have serial infections with different HPV types. Recent data suggests that there is herd immunity to HPV. Keep pushing those vaccines!

HELPFUL TIP:

The best time to check a pregnancy test is after the first missed menses. Otherwise, you risk having a false-negative test. Even on day 1 of a missed menses, the sensitivity is only 90% (thus, patients can present with an ectopic pregnancy with a negative urine pregnancy test).

You lose touch with the patient, and she discontinues her OCP. Years later when she returns for a health maintenance examination—and you’re still paying off your student loans—she complains of increasing irritability along with intermittent bloating and swelling during the week before her period each month. Although she is annoyed by these symptoms, they are not so severe as to interfere with her usual activities. Her menses now occur monthly without intermenstrual spotting or missed periods.

Question 15.16.5 What is her most likely diagnosis?

- A) Major depression
- B) Premenstrual dysphoric disorder (PMDD)
- C) Premenstrual syndrome (PMS)
- D) Polycystic ovary syndrome (PCOS)
- E) Hypothyroidism

Answer 15.16.5 The correct answer is “C.” PMS is a constellation of physical, emotional, and behavioral symptoms. It is cyclical in nature, occurs during the second half of the menstrual cycle (luteal phase, 7–10 days before menses), and resolves soon after menses. A symptom-free interval occurs during the first half of the cycle (follicular phase). PMDD (“B”) is more severe but occurs during the same time frame as PMS. Symptoms of PMDD include: labile mood, depressed mood, irritability, feelings of hopelessness, hypersomnia or insomnia, and decreased interest in usual activities. PMDD

is diagnosed by DSM-V criteria and some functional impairment must be present.

HELPFUL TIP:

Premenstrual symptoms exist on a continuum with up to 90% of women affected by minimal PMS symptoms while 10% are severely affected. This group with more severe symptoms can be categorized as having PMDD.

Question 15.16.6 Each of the following is a key element of the diagnosis of PMS EXCEPT:

- A) Physical symptoms of bloating, swelling, and/or fatigue
- B) Elevated luteinizing hormone to follicle stimulation hormone (LH:FSH) ratio
- C) Restriction of symptoms to the luteal phase of the menstrual cycle
- D) Exclusion of other diagnoses that may better explain the symptoms

Answer 15.16.6 The correct answer is “B.” PMS is a clinical entity and no laboratory data exist to aid in diagnosis. All other options described above are correct. An elevated LH:FSH ratio of 3:1 in the face of appropriate symptoms is suggestive of PCOS.

Question 15.16.7 Each of the following is a possible treatment option for PMS and PMDD EXCEPT:

- A) Supportive therapy/counseling
- B) Aerobic exercise
- C) Selective serotonin reuptake inhibitors
- D) Thiazide diuretics

Answer 15.16.7 The correct answer is “D.” Thiazide diuretics are not helpful in PMS or PMDD, but all of the other options are potentially useful. Calcium has been used in the past, but the best data suggests that it is no more effective than placebo (30%). Treatment options that have been shown to help with PMS are listed in Table 15-10.

► Objectives: Did you learn to ...

- Evaluate concerns about menarche and describe normal early menstrual patterns?
- Evaluate and manage dysmenorrhea?
- Diagnose and treat PMS?

► CASE 15.17

A frantic 25-year-old patient calls you. She and her boyfriend were having intercourse and the condom broke at the time of ejaculation about 16 hours ago. She does not use any other form of contraception. Her last menstrual period was about 2 weeks ago. You tell her that 8% of women become pregnant

TABLE 15-10 TREATMENT OPTIONS FOR PREMENSTRUAL SYNDROME

Nonpharmacologic

Aerobic exercise
Increased intake of complex carbohydrates and fiber
Reduction in sodium, caffeine, and alcohol intake
Supportive psychotherapy

Pharmacologic

Anxiolytics such as buspirone and benzodiazepines
Calcium and vitamin D supplementation
Danazol
Hormonal treatment (combination OCPs, GnRH agonists, progestones)
NSAIDs
Serotonergic antidepressants such as SSRIs and venlafaxine
Spironolactone (NOT thiazide diuretics)
Vitamin B6 (pyridoxine)
Chasteberry

Adapted from Biggs W, Demuth RH. Premenstrual syndrome and premenstrual dysphoric disorder. *Am Fam Physician*. 2011;84(8):918–924.

after a single act of coitus. She is mortified, exclaiming, “I’ve always been in the top 8% of everything!”

Question 15.17.1 Appropriate methods of “emergency contraception” for this patient include:

- A) Levonorgestrel (Plan B)
- B) Ethinyl estradiol plus levonorgestrel (Yuzpe regimen)
- C) High-dose ethinyl estradiol (Ivanapyuk method)
- D) A and B only
- E) A, B, and C

Answer 15.17.1 The correct answer is “D.” Many OCPs are also effective if used at the right doses and within 72 hours (the Yuzpe method). Currently, only levonorgestrel (Plan B) and ulipristal (Ella) are FDA-approved for postcoital contraception. Plan B uses a high dose of levonorgestrel and is more effective than the combined OCPs for postcoital contraception. Plan B is available over the counter (in the United States). Ella (ulipristal) appears to be more effective than Plan B and may be taken up to 120 hours after unprotected intercourse but is only available by prescription. The Paraguard IUD (copper IUD) is another option and may be used up to 8 days after unprotected intercourse. “C” is incorrect as estrogen alone is not known to be effective as emergency contraception, and “Ivanapyuk” is a made-up name (but a good description of what happens to a patient who takes a massive dose of estrogen).

HELPFUL TIP:

Prescribe an antiemetic with postcoital OCPs as nausea and vomiting are common side effects. Plan B has fewer GI side effects. About the only contraindication to postcoital treatment is active pregnancy. Use a progestin-only regimen (Plan B) in women with a history of thromboembolism.

**HELPFUL TIP:**

Mifepristone (Mifeprex) is not approved in the United States **for postcoital pregnancy prophylaxis**, but is very effective (99–100%) and has a more favorable side-effect profile when compared with other regimens. Mifepristone is approved by the FDA to use in conjunction with misoprostol (Cytotec) for termination of early pregnancy (within 49 days of last menstrual period). Of note, there have been serious adverse events associated with this combination, including sepsis from *Clostridium* infections and even death. However, these events are very rare extremely rare and poses less of an overall risk than surgical abortion.

You recommend Plan B. Since she now trusts you, she schedules an appointment with you for evaluation of intermittent abdominal and pelvic pain. Her pain has gradually worsened over the last 2 years and is almost omnipresent. Now she complains of severe abdominal cramping and stabbing in the right lower quadrant. The pain radiates to the left lower quadrant at times and is worse during menstruation. Her periods have become heavier and occasionally irregular. She has no bowel or bladder symptoms. She has been missing work 1 or 2 days each month and is now concerned about her job.

Your examination reveals a well-developed woman who looks depressed and uncomfortable. Her abdomen is soft, nondistended, and diffusely tender to palpation in the lower quadrants. There is no evidence of guarding, rebound tenderness, or palpable masses. She has no back tenderness. The external genital and vaginal examinations show no lesions or erythema. There is a creamy discharge noted at the cervix. Bimanual reveals a retroverted uterus with uterosacral nodularity palpable. Both adnexal areas are tender to examination, but without masses.

You get a pregnancy test, cultures, and urinalysis, all of which are negative.

Question 15.17.2 Based on her symptoms and your physical examination, what is the most likely etiology of the patient's chronic pelvic pain?

- A) Irritable bowel syndrome
- B) Myofascial pain disorder
- C) Endometriosis
- D) Cervical dysplasia
- E) Painful bladder syndrome (the disease formerly known as interstitial cystitis)

Answer 15.17.2 The correct answer is "C." There were no bowel symptoms elicited on the history to suggest irritable bowel syndrome ("A"). There were no signs elicited on the examination to suggest a myofascial pain disorder ("B"). The patient's history and physical examination, including uterosacral nodularity, is consistent with a diagnosis of endometriosis ("C"). Dysplasia ("D") is typically asymptomatic. There were

no bladder symptoms elicited on the history to suggest painful bladder syndrome ("E"). *Be truthful; have you ever actually felt ligament nodularity?*

**HELPFUL TIP:**

If after a careful assessment the diagnosis of endometriosis is highly likely, empiric therapy is considered a viable alternative to laparoscopy and preferred by many experts. However, definitive diagnosis relies upon direct visualization of endometrial implants confirmed by histologic examination.

She does not want laparoscopy. You offer alternatives, and she elects to undergo cycle suppression with a 3-month trial of leuprolide (Lupron) and to complete a pain calendar. You see her in follow-up in 3 months, and she is feeling much better. The pain has been almost completely suppressed, and she has missed only 1 day of work since you last saw her—but that was for a Star Trek convention. After all, the future birthplace of Captain Kirk is located in Iowa (Riverside, Iowa). She has hot flashes, but they are minor.

Question 15.17.3 What is the most appropriate management at this point?

- A) Continue the Lupron for up to another 3 months (6 months total)
- B) Stop the Lupron and monitor
- C) Switch to a trial of cycle suppression using Depo-Provera (medroxyprogesterone acetate) or continuous low-dose OCPs
- D) Switch to a trial of Premarin (conjugated estrogens)
- E) A or C

Answer 15.17.3 The correct answer is "E." For pain relief, treatment with a GnRH agonist for 3 to 6 months is effective in most patients. Oral contraceptives, as well as oral or depo progestins (Depo-Provera), are more effective than placebo ("C"). Given the marked treatment success with the depo-Lupron, discontinuing treatment ("B") would likely result in recurrence of the patient's pain symptoms. Since endometriosis is estrogen dependent, use of estrogen (Premarin) ("D") theoretically could worsen symptoms. Another option is treatment with danazol. However, danazol is less well tolerated than GnRH agonists, Provera, or OCPs.

**HELPFUL TIP:**

NSAIDs are useful monotherapy in patients with mild endometriosis and are useful in combination with hormonal therapy (e.g., OCPs) for patients with more severe symptoms.

The patient is concerned about how endometriosis may affect her future fertility. You recall that she is 25 years old and has never attempted pregnancy (at least not intentionally). She has regular menstrual cycles.

Question 15.17.4 What will you tell her?

- A) “You are surely infertile. Look into adoption”
- B) “You just cannot know for sure until you have tried to conceive”
- C) “What are you worried about? There is no association between endometriosis and infertility”
- D) “Look at my face. See how tired I am? Do you really want kids?”

Answer 15.17.4 The correct answer is “B.” It is impossible to predict fertility and infertility based on the available information. Early-stage endometriosis is not likely to be associated with alterations in fecundity. If the patient is willing, a diagnostic laparoscopy may aid in visualization of anatomic pathology and allow one to render a guess as to possible tubal disease.

**HELPFUL TIP:**

Chronic pelvic pain is a *symptom*, not a specific disease. By definition, chronic pelvic pain refers to pain that has been present for more than 6 months and for which a thorough investigation has been negative. Here is a helpful starting guide for elucidating the underlying causes of chronic pelvic pain:

- **Is the pain cyclic?** It may be related to endometriosis, dysmenorrhea, adenomyosis, or other diseases that respond to hormones, such as irritable bowel syndrome and interstitial cystitis.
- **Is the pain noncyclic?** It may be urinary, constipation, a myofascial trigger point in the abdominal wall, etc.
- **Always ask about sexual and physical abuse:** There is a high correlation between chronic pelvic pain and a history of sexual abuse.
- To go by the textbook, the “diagnosis” of chronic pelvic pain requires a negative diagnostic laparoscopy. However, laparoscopy may not be performed in all cases.

► **Objectives: Did you learn to ...**

- Manage patients who desire emergency oral contraception?
- Define and evaluate chronic pelvic pain?
- Describe the ramifications, evaluation, diagnosis, and management of endometriosis?

**QUICK QUIZ: A “TRICHY” ONE**

A 19-year-old sexually active female presents to your urgent care center with a foul-smelling vaginal discharge. She has noted the discharge for about 3 days. On examination, she is in no acute distress, and her vital signs are normal. Her pelvic examination is remarkable for mild vaginal erythema and a frothy gray discharge. You note a malodorous discharge and suspect *Trichomonas* (bacterial vaginosis can also be malodorous, of course, with a fishy smell). A wet prep confirms your diagnosis.

At this point in time, you recommend that she also be tested for:

- A) Chlamydia and gonorrhea
- B) Herpes simplex
- C) Hepatitis A
- D) All of the above

The correct answer is “A.” Routine screening for chlamydia and gonorrhea infection is recommended for all sexually active adolescents. Given the presence of one STI, it is appropriate to offer testing for other STIs at this visit. Currently, herpes simplex virus (HSV) is not routinely tested for in asymptomatic persons, and the USPSTF recommends against serologic screening for HSV. Hepatitis A is not a sexually transmitted disease. Of note, *Trichomonas* has been found to be associated with a two- to threefold increase in acquisition of HIV (*Curr HIV Res.* 2012;10(3):202–210). Therefore, it would be appropriate to offer testing for hepatitis B, HIV, syphilis, etc., as individual cases dictate.

**QUICK QUIZ: PROLAPSE**

An 80-year-old woman presents for evaluation of a “bulge” she noted after gardening over the weekend ... or maybe it’s been there for years—she’s not sure. She has no discomfort and no difficulty with bowel or bladder elimination. On examination, you note her cervix extends 1 cm beyond the vaginal introitus with a Valsalva maneuver. There are no lesions or excoriations noted.

Of the following, what is the best initial treatment option?

- A) Hysterectomy
- B) Trachelectomy
- C) Pessary trial
- D) Bed rest
- E) Hormone therapy

The correct answer is “C.” Seventy percent of women who are fitted with a pessary are satisfied at 5-year follow-up. Hysterectomy and trachelectomy (removal of the cervix) are both unnecessarily invasive treatments without trying a conservative strategy.

**QUICK QUIZ: OVARIAN MASS 1**

What is the best way to manage an asymptomatic 4-cm ovarian cystic mass found initially on pelvic examination and confirmed by pelvic ultrasound as a simple cyst in a 22-year-old female who is otherwise healthy?

- A) Referral to a gynecologist
- B) Start hormonal therapy to reduce ovulation
- C) Expectant management with repeat ultrasound in 2 months
- D) Serum CA-125 level

The correct answer is “C.” A 4-cm ovarian mass likely represents a functional cyst in a woman who is cycling (reproductive

age). In general, premenopausal women with simple cysts 10 cm or smaller may be managed conservatively with serial ultrasonography in 4 to 12 weeks. Since the mass is asymptomatic and without concerning ultrasound findings (complex mass, septations, solid components), expectant management is the best option. No further evaluation is warranted at this time. CA-125 is a tumor marker for epithelial ovarian cancer, but it is not useful as a screening test.

QUICK QUIZ: OVARIAN MASS 2

What is the best first step in managing an asymptomatic palpable 4 cm adnexal mass in a 76-year-old postmenopausal woman (although why you are doing a pelvic exam on an asymptomatic 76 years old is a mystery)?

- A) Referral to a gynecologist
- B) Start hormonal therapy to suppress FSH and LH
- C) Expectant management with repeat examination in 2 months
- D) Serum CA-125 level
- E) Pelvic ultrasound

The correct answer is "E." Unlike a relatively small palpable ovarian mass in a reproductive-age woman, a palpable ovarian mass in a postmenopausal woman represents ovarian malignancy until proven otherwise. The best initial imaging study for evaluation of a pelvic mass is ultrasound. Ultrasound will not only identify the location of the mass but will also identify its internal consistency. Characteristics suggestive of cancer include bilaterality, solid and cystic components, thick septations, and the presence of ascites. CA-125 is a marker for epithelial ovarian cancer and may assist in evaluation, but it cannot be relied upon to rule in or to rule out cancer as a diagnosis. (Best case scenario, in appropriately selected patients, CA-125 has a sensitivity around 95% and a specificity around 90% for the diagnosis of ovarian cancer.) CA-125 is useful in follow-up of patients with a history of ovarian cancer.

QUICK QUIZ: GYNECOLOGIC CANCERS

What is the leading cause of death from a gynecologic malignancy in American women?

- A) Ovarian cancer
- B) Uterine cancer
- C) Cervical cancer
- D) Fallopian tube cancer
- E) Vaginal cancer

The correct answer is "A." Ovarian cancer is the leading cause of death from gynecologic malignancy, is the second most common gynecologic malignancy, and is the fourth leading cause of cancer death in women. Endometrial cancer is the most common gynecologic malignancy but also one of the most treatable. Cervical cancer is the third most common gynecologic

malignancy. Both fallopian tube and vaginal malignancy are relatively rare.

QUICK QUIZ: OVARIAN CANCER

How does ovarian cancer typically present?

- A) Early satiety
- B) Abdominal fullness and pain
- C) Urinary obstruction
- D) Asymptomatic mass noted on routine examination
- E) A and B

The correct answer is "E." There are no specific early symptoms of ovarian cancer. Thus, most patients present with symptoms associated with increasing tumor mass: early satiety, abdominal fullness or bloating, and abdominal pain. Unfortunately, ovarian cancer is rarely identified at an early stage on routine annual examination.

HELPFUL TIP:

An ovarian mass is more likely to be malignant if the patient is premenarcheal or postmenopausal. Other signs pointing to malignancy include mass greater than 10 cm in diameter and presence of solid or complex cystic features on ultrasound. Consider an ultrasound for otherwise unexplained bloating, abdominal distention, urinary frequency/urgency, abdominal or pelvic pain, early satiety, etc.

▶ CASE 15.18

While covering the emergency department on the graveyard shift, a 21-year-old college student presents sobbing with a friend. Her friend says, "She's been raped." Thankfully, your town has a rape crisis team who can come to the ED and provide emotional/psychological support, though they are not trained to do exams.

Question 15.18.1 Relevant history includes all of the following EXCEPT:

- A) Whether force was used and what type
- B) Physical characteristics of the assailant
- C) Details regarding penetration (vaginal, anal, oral)
- D) Number of sexual partners the victim has had in her lifetime
- E) Condom use

Answer 15.18.1 The correct answer is "D." The patient's past sexual history is not relevant in the evaluation of sexual assault. The other issues are pertinent to the case. Although it may be difficult for the patient to relive the experience, you should try to obtain a detailed history of the assault. In order to assess her risk for pregnancy and infection, you need to ask

about the area penetrated (e.g., vaginal, oral, or anal penetration) (“C”), whether the assailant ejaculated, and if a condom (“E”) was used. In a sexual assault case, your job is also to collect evidence, including pertinent historical elements (e.g., number of assailants, names, physical appearance, whether force was used and what type—threat, restraints, weapons, etc.) (“A” and “B”).

**HELPFUL TIP:**

Sexual assault includes genital, anal, or oral penetration by a part of the assailant’s body or by an object. By definition, it occurs without the victim’s consent (including inability to consent secondary to intoxication or drugs) and need not involve direct force or violence.

Question 15.18.2 Which of the following are important physical elements to collect for the forensic evaluation in this case?

- A) Combed specimens from the scalp and pubic hair
- B) Swabs of the oral, vaginal, and rectal mucosa
- C) The patient’s clothing
- D) Fingernail scrapings
- E) All of the above

Answer 15.18.2 The correct answer is “E.” All of the items listed will be important to the investigation. Evidence collection kits for sexual assault cases (“rape kits”) should be available in your emergency department.

.....
Although apparently inebriated, the patient is able to give a coherent history. When you broach the subject of physical examination, her friend says, “Look, she was raped an hour ago. Can’t you let her just recover a bit before you violate her all over again?”

Question 15.18.3 Which of the following is the most appropriate response?

- A) “Of course. Come back tomorrow after you have sobered up and taken a shower”
- B) “An examination is important for your health and in the event that this becomes a criminal case. The yield of the examination declines with time. Even if you don’t feel like prosecuting now, you may decide to do so in the future, and the best evidence is gathered early”
- C) “The examination has a fairly high yield even a week after the assault, so take your time on this”
- D) “Under federal law I am required to perform this examination”

Answer 15.18.3 The correct answer is “B.” The yield of a forensic examination declines with time. Even if a patient states that she does not want to prosecute the assailant, she should be encouraged to have the examination done in case she changes her mind. Also, you are concerned about her health, and she may be at risk for sexually transmitted diseases, pregnancy, and

traumatic injury. Despite the fact that yield does decline with time, reliable evidence may still be gathered up to 5 days after the assault. And remember that all patients with capacity have autonomy; you should not coerce or force someone to have an exam that they decline.

**HELPFUL TIP:**

“Rape trauma syndrome” generally occurs in three stages. The first includes anger, anxiety, guilt, shame, sleep disturbance, etc. The second stage includes somatic complaints (pelvic pain, other pain) and psychiatric complaints (depression, phobias, etc.). Some patients will resolve these issues while others will develop post-traumatic stress syndrome. The third stage is renormalization.

Question 15.18.4 Which of the following is the LEAST appropriate to offer this patient at this point in time?

- A) HIV antigen/antibody testing
- B) HSV antibody testing
- C) Prophylactic treatment for gonorrhea and chlamydia
- D) Mental health services referral
- E) Emergency contraception

Answer 15.18.4 The correct answer is “B.” Herpes virus antibody testing will only tell you if she has been exposed to HSV in the past. Further recommendations include syphilis testing, hepatitis B antibody testing, performing a wet prep of a vaginal sample, and checking a urine pregnancy test. Why HIV testing? You need to decide whether to provide prophylaxis. If the patient is HIV+, prophylaxis may just lead to resistance.

► **Objectives: Did you learn to ...**

- Evaluate a patient for sexual assault?
- Manage a patient who has been the victim of sexual assault?

► **CASE 15.19**

A 21-year-old woman presents to your office complaining of pelvic pain with intercourse, worse over the last 2 weeks. She also complains of not getting pregnant, even though she’s had several partners over her last 3 years of sexual activity and has been trying to get pregnant with the same partner for the past 6 months. She states she never has used birth control of any type—not even once. You commend her on commitment to her principles. She started her periods around age 14 but has only had a couple of periods since then. Apparently, this pattern of menstruation is normal for her family, as her mother was the same way.

On physical examination, you notice the patient is a centrally obese young woman, afebrile, with (culturally defined) excess hair noted down the side of her face and under her chin. She also has some erythematous pustules on her cheeks.

Question 15.19.1 Which of the following lab results would be most consistent with the history and examination findings?

- A) Positive urine pregnancy test
- B) Low TSH level
- C) Elevated CA-125 level
- D) Mildly elevated androgens
- E) Prolactin level more than three times normal

Answer 15.19.1 The correct answer is “D.” This patient gives a history and has an appearance consistent with polycystic ovarian syndrome (PCOS). The clinical features of PCOS include oligomenorrhea (90%), hirsutism (80%), obesity (50%), amenorrhea (40%), and infertility (40%). Early symptoms in an adolescent may consist only of irregular periods, acne, and central obesity. Clinical or laboratory evidence of androgen excess may be present, such as mildly elevated testosterone. Note that depending on the diagnostic criteria you are using for PCOS, an ultrasound may not be necessary. An LH:FSH ratio greater than 3:1 adds further support to the diagnosis. You should certainly do a pregnancy test, a TSH, and a prolactin level. However, this patient most likely has PCOS. There is no role for measuring CA-125 as this is a marker for ovarian cancer as per above.

HELPFUL TIP:

The most recent evidence points to insulin resistance as the underlying cause of PCOS, and these patients may have acanthosis nigricans. Insulin resistance can be quantified by calculating the ratio of fasting glucose to insulin. A ratio of less than 4.5 indicates insulin resistance. Insulin resistance stimulates ovarian androgen production, which leads to anovulation.

You proceed with the pelvic portion of the examination, noting the patient also has a diamond-shaped, rather than triangular-shaped, pubic hair pattern. You find no lesions on the vulva or in the vagina. However, the cervix appears reddened, with an almost strawberry texture. And, even though there is a generous amount of yellowish, malodorous leukorrhea in the vaginal vault, there is no notable pus at the cervical os. Bimanual examination is limited due to the patient's obesity.

Question 15.19.2 Of the following, which is the most likely cause of her cervicitis?

- A) HSV infection
- B) *Trichomonas vaginalis* infection
- C) *Candida albicans* infection
- D) PID
- E) Bacterial vaginosis

Answer 15.19.2 The correct answer is “B.” *Trichomonas* is a protozoan that is sexually transmitted and can cause urethritis in both sexes. However, in women, it most commonly causes ulceration of the cervical mucosa with punctate hemorrhages known as a “strawberry cervix.” Signs and symptoms also include

a malodorous discharge and occasional vulvar and vaginal irritation. The cervix can be somewhat tender to touch, either during examination or intercourse, and patients often complain of a nonspecific pelvic pain. Males are often asymptomatic.

The wet mount demonstrates *Trichomonas*; there is no evidence of yeast or clue cells. You send samples for chlamydia and gonorrhea tests as well as a Pap smear. You recommend testing for HIV, syphilis, and hepatitis B, and she agrees.

Question 15.19.3 For her *Trichomonas* vaginal infection, you prescribe:

- A) Flagyl (metronidazole) 2 g orally in a single dose
- B) MetroGel-Vaginal (topical vaginal metronidazole) 5 g applied nightly for 5 days
- C) Diflucan (fluconazole) 150 mg orally in a single dose
- D) Zithromax (azithromycin) 1 g orally in a single dose
- E) Levaquin (levofloxacin) 250 mg orally in a single dose

Answer 15.19.3 The correct answer is “A.” The best choice is oral metronidazole. Topical antibiotic gels, creams, or ovules—either metronidazole or clindamycin (Cleocin)—only treat bacterial vaginosis, as the concentration is insufficient to reach the protozoa in the glands and urethral areas. The remaining options are all incorrect for treating *Trichomonas*. See Table 15-11 for more on diagnosis and treatment of infectious vaginitis.

HELPFUL TIP:

As with other STIs, a patient with *Trichomonas* should have her partner tested and treated (or just treated depending whether or not this is allowable under your state law). Males with *Trichomonas* infections will have symptoms in about 25% of cases. Symptoms consist of dysuria and clear or white urethral discharge, which can sometimes last for months if left untreated. If you see a male patient with dysuria, pyuria on urinalysis/micro, and negative cultures (including chlamydia and gonorrhea), consider *Trichomonas*.

HELPFUL TIP:

While it makes sense that single-dose azithromycin would work better in treating Chlamydial cervicitis because of compliance issues, the cure rate is the same whether azithromycin or the doxycycline is used. There is about a 3% failure rate with azithromycin which isn't seen with doxycycline. Both are first line per the CDC.

You now return your attention to her PCOS (remember, way back then, the reason she came in?). Her lab results demonstrated a LH:FSH ratio >3 ; normal TSH and prolactin; slightly elevated testosterone, but still well below the normal male range; fasting glucose:insulin ratio <4.5 ; and slightly elevated total cholesterol and triglycerides. Her LH:FSH

TABLE 15-11 VAGINITIS DIAGNOSIS AND TREATMENT

Organism	Discharge	Odor	Microscopy	pH	Treatment
Bacterial vaginosis	Thin, gray, homogeneous	Fishy with positive "whiff test"	Clue cells	>4.5	Metronidazole 500 mg BID × 7 days or clindamycin 300 mg BID × 7 days or topical metronidazole 1 applicatorful intravaginally daily × 5 days (lower success rate)
Candida	Adherent, white, "cottage cheese" like	Neutral	Pseudohyphae but only 65–85% sensitive	<4.5	Fluconazole oral, topical clotrimazole, miconazole, etc.
Trichomonas	Copious yellow, gray, green, foamy. Friable "strawberry" cervix	Malodorous	Trichomonads	>4.5	Metronidazole 2 g PO once (recommended), or 500 mg BID × 7 days (alternative)

Adapted with permission from Hainer BL, Gibson MV. Vaginitis: diagnosis and treatment. *Am Fam Physician*. 2011;83(7):807–815. Copyright © 2011 American Academy of Family Physicians. All rights reserved.

ratio was consistent with the diagnosis of PCOS. She has not menstruated for 4 months. A urine hCG is negative, and a repeat fasting glucose is 120 mg/dL.

Question 15.19.4 Which of the following recommendations should you make now?

- A) Initiate metformin
- B) Attempt weight loss through a nutritious diet and increased exercise
- C) Initiate oral contraceptives to regulate menses
- D) A and C
- E) All of the above

Answer 15.19.4 The correct answer is "E." This patient has glucose intolerance (elevated fasting glucose and ratio of glucose:insulin <4.5), and it is reasonable to initiate dietary and medical therapy at this point in time. Another option is to start with lifestyle modifications and check fasting glucose again 3 to 6 months later. Due to increased risk of endometrial carcinoma in patients who have rare menses, it is important to regulate her cycles. OCPs ("C") can accomplish menstrual regulation.

HELPFUL TIP:

For hirsutism associated with PCOS, spironolactone is usually first-line therapy unless the patient has a contraindication; traditional hair removal techniques will still be required for the existing hair growth. Since spironolactone can result in feminization of a male fetus, patients taking spironolactone must be using reliable birth control.

HELPFUL TIP:

Not all women with PCOS are obese and hirsute. Many patients may be thin with sparse body hair and present with menstrual irregularities and fertility concerns.

► Objectives: Did you learn to ...

- Identify the clinical presentation of PCOS?
- Diagnose and treat *Trichomonas* infection?
- Diagnose and manage PCOS?

QUICK QUIZ: SCREENING IN TEENS

A 16-year-old female presents with her mother. They don't look happy. Her mother says, "She needs a Pap smear because she's been having sex with a couple of boys—in my house, I will have you know—for a year!" The patient rolls her eyes.

Consistent with published guidelines, you recommend:

- A) Pap smear
- B) Gonorrhea and chlamydia testing
- C) Pap smear and gonorrhea and chlamydia testing
- D) Return for a Pap after sexually active for 3 years (age 18 for this patient)
- E) A chastity belt

The correct answer is "B." It is now recommended to delay cervical cancer screening until age 21, even if the woman has been sexually active. The reasoning: although adolescent females are frequently infected with HPV, they also easily clear these infections, with 95% of lesions spontaneously regressing. Exceptions to this rule include patients who are immunocompromised (e.g., organ transplant, HIV infection). For this patient, ensuring that she has completed her HPV vaccination series and counseling on safe sexual behavior is also warranted.

QUICK QUIZ: AN ITCHY VULVA

A 65-year-old female presents for a health maintenance examination. She complains of a vulvar itching due to what she calls "recurrent yeast infections," and her symptoms have worsened over the last few months. She is sexually active with her husband

and has experienced dyspareunia with penetration lately. She always uses a water-based lubricant with intercourse. On examination, you find complete loss of the borders of the labia minora, constriction of the vaginal outlet, and several thin white plaques (like parchment paper) on the vulva. There is no other skin or mucosal involvement.

What is the most likely diagnosis?

- A) Lichen planus
- B) Lichen simplex
- C) Lichen sclerosus
- D) Vulvovaginal candidiasis
- E) Squamous carcinoma

The correct answer is "C." The clinical description above is characteristic of lichen sclerosus, which occurs more commonly in older women but also has a peak in young girls. Almost all lichen sclerosus is intensely pruritic. As lichen sclerosus progresses, there may be loss of labial architecture, stenosis of the introitus, and obliteration of the clitoris. The lesions are usually multiple and appear as thin, shiny, white, wrinkled patches or plaques. The rest are incorrect. However, "E," squamous carcinoma, occasionally can be confused for lichen sclerosus but is more likely to present with ulceration and induration and is less common (though if you are suspicious of cancer, a biopsy is indicated). Patients with lichen sclerosus have a squamous cell cancer risk of 3% to 7% and should have an examination every 6 to 12 months with biopsies as indicated for persistent and non-healing lesions.

HELPFUL TIP:

Initial treatment for lichen sclerosus involves local steroid ointment application. High-potency steroids are initiated and then tapered to the lowest effective potency and frequency that maintain symptom control. Testosterone creams have fallen out of favor due to lesser efficacy and secondary virilization. Vaginal dilators can be used if there is constriction of the vaginal opening causing dyspareunia and it is of concern to the woman.

QUICK QUIZ: VULVOVAGINAL CANDIDIASIS

A 48-year-old perimenopausal female presents with a 3-day history of vulvar pruritus. Her history is significant for mitral valve replacement and she is on warfarin with INR 2–3. A limited vulvar and vaginal examination reveals significant erythema with satellite lesions on the labia majora. Wet prep microscopy reveals abundant pseudohyphae and inflammatory cells. You somehow assemble all these clues into a diagnosis of candidal vulvovaginitis (and you can tell the patient is impressed when she says, "That's right, genius. I've got a yeast infection"). She enquires about use of oral therapy, as vaginal creams are "messy."

How will you counsel this patient regarding use of oral fluconazole (Diflucan)?

- A) "You have no contraindications to oral fluconazole"
- B) "Given your use of warfarin, you should not use oral fluconazole"
- C) "You will need to stop warfarin while taking oral fluconazole"
- D) "You should take extra warfarin if you take oral fluconazole"

The correct answer is "B." There are numerous drug interactions with oral fluconazole, including warfarin (both inhibit CYP3A4). The INR will increase after even one dose of fluconazole therapy. Similarly, the ubiquitous statins are affected by oral fluconazole with several case reports of rhabdomyolysis in the literature. In this case, stick with topical antifungals, although your patient satisfaction scores may plummet. (Incidentally, patient satisfaction has been inversely correlated with healthcare quality—although there appears to be a direct link between increased satisfaction and increased healthcare expenditure.) *Avoid fluconazole in pregnancy as well. A single dose can cause miscarriage or birth defects.*

CASE 15.20

A 27-year-old female presents with her husband seeking advice regarding pregnancy loss. She recently had a miscarriage. Your patient states that this was her third miscarriage in the last 2 years. All three occurred at about 9 weeks of gestation.

Question 15.20.1 Possible explanations for recurrent pregnancy loss in this patient include each of the following EXCEPT:

- A) Parental structural chromosome abnormalities
- B) Uterine anatomic abnormalities
- C) Anticardiolipin antibody syndrome
- D) Idiopathic (unexplained etiology)
- E) Conception while on oral contraceptives

Answer 15.20.1 The correct answer is "E." Conception while on oral contraceptives will not increase the risk of **recurrent** spontaneous miscarriages. Parental structural chromosome abnormalities (balanced structural chromosome rearrangement in one partner) are responsible for pregnancy loss in 2% to 4% of couples. Uterine anatomic abnormalities ("B") have been associated with 10% to 15% of pregnancy loss. "D" is true. The majority of couples with recurrent pregnancy loss will have an uncertain etiology despite extensive evaluation (>50%). See below for more on "C".

HELPFUL TIP:

Recurrent pregnancy loss is classically defined as loss of three or more **consecutive** pregnancies.

The couple desires testing for possible causes of the pregnancy losses.

Question 15.20.2 Of the following, which test(s) should be included in the evaluation?

- A) Cultures for bacteria
- B) Test for glucose intolerance
- C) Maternal anti-paternal antibodies
- D) Lupus anticoagulant and anticardiolipin antibody
- E) All of the above

Answer 15.20.2 The correct answer is “D.” Antiphospholipid syndrome is associated with pregnancy loss in 3% to 15% of women with recurrent pregnancy loss. The others are not useful. However, chromosomal testing of the parents (not given as an option in this question) may be useful. Other tests that can be considered include screening for thyroid abnormalities with anti-thyroid peroxidase (TPO) and TSH with free T4 as well as an ultrasound to look for uterine abnormalities

Evaluation of the recurrent pregnancy loss fails to identify a cause. Thus, like most couples with recurrent pregnancy loss, the etiology remains unexplained.

Question 15.20.3 What is the likelihood that this couple will have a successful pregnancy outcome in the next pregnancy?

- A) Highly unlikely, they should consider adoption
- B) Less than one in four chances of successful pregnancy
- C) 60% to 70% chance of successful next pregnancy
- D) You cannot hazard a guess. Amazingly, this has not been studied

Answer 15.20.3 The correct answer is “C.” Studies suggest that 60% to 70% of couples with *unexplained* recurrent pregnancy loss will have a successful next pregnancy.

► **Objectives: Did you learn to ...**

- Define recurrent pregnancy loss and discuss some of its epidemiologic aspects?
- Enumerate potential causes of recurrent pregnancy loss?
- Identify etiologies and the workup of recurrent pregnancy loss?

QUICK QUIZ: WEIGHT GAIN IN PREGNANCY

A 28-year-old primigravida female presents for an initial obstetric visit. Pelvic examination is consistent with a 6- to 8-week gestation uterus, and the remainder of the examination is unremarkable. As this is her first pregnancy, she has a number of questions. She wants to know how much weight gain is expected and whether she should “watch her weight.”

You calculate her BMI as 24 kg/m² and recommend the following:

- A) “Eat anything you want. You’re eating for two!”
- B) “Your BMI is normal. Your goal is to gain no more than 20 lb”
- C) “Your BMI is low. Your goal is to gain 40 lb”
- D) “Your BMI is high. Your goal is to gain no more than 15 lb”
- E) “Your BMI is normal. Your goal is to gain 30 lb”

The correct answer is “E.” The Institute of Medicine recommends weight gain in pregnancy based on pregravid BMI (see Table 15-12). In this patient, her BMI is in the normal range, so her goal for weight gain in pregnancy is 25 to 35 lb. Women with a normal pre-pregnancy BMI should gain about 1 lb per week during their second and third trimesters.

QUICK QUIZ: AMENORRHEA

A 32-year-old female is coming to see you for amenorrhea. She had regular menses until the last year when they became irregular. She has not had any menses for the past 6 months. She is somewhat distraught because she wants to have a family. Being the smart doctor that you are, you know that a pregnancy test is the first thing to do: it is negative. Being the smart doctor that you are, you also think about the female athlete triad, but she does not meet this profile. You take more of a history and find out the following:

- There is no additional stress in her life (such as starting college or a new job), weight loss, or illness, etc., which might lead to hypothalamic amenorrhea.
- She has no galactorrhea (prolactinoma).
- She has no hot flashes, vaginal dryness, etc. (premature menopause).
- She denies headaches, visual changes, fatigue, polydipsia, or polyuria (pituitary problems).
- She has no acne, hirsutism, etc., suggestive of PCOS.

Hey, did you notice how we are cleverly giving you the workup of secondary amenorrhea in the question?

As recommended, you check a TSH and prolactin; they are normal.

TABLE 15-12 PREGNANCY WEIGHT GAIN GUIDELINES

BMI (kg/m ²)	Goal Weight Gain (kg)	Goal Weight Gain (lb)
<18.5	12.5–18.0	28–40
18.5–24.9	11.5–16.0	25–35
25.0–29.9	7.0–11.5	15–25
>30	5–9	11–20

Adapted from Institute of Medicine, Resource Sheet, May 2009: Weight gain during pregnancy: reexamining the guidelines. Available at: <http://www.iom.edu/Reports/2009/Weight-Gain-During-Pregnancy-Reexamining-the-Guidelines.aspx>.

The next step in the evaluation of this patient's amenorrhea is:

- A) A progestin challenge
- B) Hysterosalpingogram to prove cervical patency
- C) A trial of oral contraceptives to prove cervical patency
- D) An LH to rule out menopause
- E) All of the above

The correct answer is "A." A progestin challenge should cause a withdrawal bleed if there is still adequate estrogen (thus ruling out premature ovarian failure). If the progestin challenge does not result in menses, the step following this would be to start a combination oral contraceptive. Failure to induce menses with a combination OCP suggests a mechanical blockage such as Asherman syndrome (scarring of the endometrial lining with intrauterine adhesions). Failure to induce menses with a combination OCP can be followed by a hysterosalpingogram or hysteroscopy to identify any mechanical problems.

You did it! You successfully worked up secondary amenorrhea.

HELPFUL TIP:

But wait, there is more! If the progestin challenge is negative (no menses), check an FSH. If this is high, it might indicate ovarian failure. **If the FSH is normal or low in the absence of circulating estrogen** (a negative progestin challenge), consider a pituitary cause of amenorrhea including possible hypothalamic-pituitary axis dysfunction from weight loss, stress, pituitary tumor, empty sella syndrome, etc. No pituitary? No FSH.

Clinical Pearls

- Do not perform elective deliveries (C-sections or inductions) that are not medically indicated prior to 39 weeks of gestation.
- Do not perform routine screening for ovarian cancer in asymptomatic, low-to-average risk women.
- Do not require a Pap and a pelvic examination to prescribe contraception. The only necessary requirement is to perform a detailed history to ascertain risk factors of using hormonal contraception, blood pressure check, and the performance of a urine pregnancy test to ensure the woman is not pregnant.
- Do not routinely perform episiotomies; there is no evidence that episiotomies reduce perineal trauma, postpartum dyspareunia, etc.
- In HIV-negative patients, do not begin cervical cancer screening before the age of 21 regardless of sexual activity status.
- Due to the increased risk of endometrial cancer, do not use unopposed estrogen in a woman unless she has undergone a hysterectomy.
- In a pregnant woman with third-trimester vaginal bleeding, do not perform a digital or speculum vaginal examination until you can rule out the diagnosis of placenta previa.

- Perform routine GBS screening on pregnant women between 35 and 37 weeks of gestation UNLESS the woman has a documented history of GBS bacteriuria during current pregnancy or prior history of infant born with invasive GBS infection, in which cases they would be treated anyway.
- Recommend folic acid in all women of childbearing age to prevent any risk of neural tube defects if she should become pregnant.
- Use the ASCCP guidelines to determine frequency of Pap smears and management of abnormal smears.

Men's Health

Aaron R. Kunz and Jason K. Wilbur

► CASE 16.1

A 58-year-old black male presents to your clinic complaining of urinary hesitancy, frequency, and three to four episodes of nocturia per night, which have been worsening over the past few years. His urinary stream is weaker than it was a few years ago, and he feels he does not empty his bladder completely. He denies any history of urinary tract infections (UTIs) or painful urination. He is otherwise well with no significant past medical or surgical history. Currently, he takes no medications and has no allergies. On reviewing his family history, he notes his father and older brother died of prostate cancer in their fifties. His general physical examination is normal, and a genital examination is unremarkable. Digital rectal examination reveals a smooth prostate with no nodules or tenderness.

Question 16.1.1 Based on this patient's history and physical examination, all of the following would be appropriate at this stage EXCEPT:

- A) Serum assay for prostate-specific antigen (PSA)
- B) American Urological Association (AUA) symptom score
- C) Post-void residual urine volume
- D) Transrectal ultrasound with prostate biopsies
- E) Urinalysis and microscopic examination of the urine

Answer 16.1.1 The correct answer is "D." Although your patient has an increased risk of prostate cancer, transrectal ultrasound with prostate biopsies is not indicated at this stage. This diagnostic test should be reserved for a higher suspicion of prostate cancer. Based on this patient's family history and the fact that he is black (black males have a 50% higher incidence of, and mortality from, prostate cancer compared with whites), PSA testing ("A") is appropriate in this setting, as opposed to general population screening, which is discussed later in the chapter. The AUA symptom score ("B") is a seven-item questionnaire about symptoms of urinary outlet obstruction, which can be used to assess severity and assist in management of prostate disease. It is not very useful for diagnosis, but, on the bright side, it is freely available online and can be used to follow the disease *symptomatically*. There is

also the International Prostate Symptom Score, which is remarkably similar but has an additional question regarding how symptoms affect the patient's quality of life. Since your patient may not empty his bladder well, a post-void residual urine volume and urinalysis will help determine if he is experiencing urinary retention ("C") or an infection ("E").

Question 16.1.2 When considering benign prostatic hyperplasia (BPH), you reflect on the common symptoms of this syndrome, which include all of the following EXCEPT:

- A) Urinary retention
- B) Post-void dribbling
- C) Frequency
- D) Nocturia
- E) Hematuria

Answer 16.1.2 The correct answer is "E." Hematuria is not usually associated with BPH. However, it can occur if a man's prostatic urethra is very enlarged and friable. Enlargement of the prostate often results in obstructive flow symptoms (e.g., hesitancy and slow, weak stream), which in turn can lead to irritative symptoms (e.g., frequency, urgency, and nocturia). Obstruction from an enlarged prostate alone can cause hypertrophy of the detrusor, or it can lead to an infection that results in detrusor instability—the cause of irritative symptoms. If irritative symptoms are present without obstructive symptoms, other diagnoses should be considered, including bladder cancer, urolithiasis, infection, and neurogenic bladder.

Your patient's urinalysis and PSA are normal. After emptying 250 mL of urine, the postvoid residual urine volume is 50 mL.

Question 16.1.3 With this information, you recommend which of the following strategies?

- A) Urodynamic studies
- B) Medical therapy
- C) Surgical therapy
- D) Scheduled bladder catheterization
- E) Biofeedback

Answer 16.1.3 The correct answer is “B.” You have enough information to diagnose symptomatic BPH and further studies (“A”) are not necessary. Depending on the patient’s preferences, the next step is to begin treatment, and, in most cases, medical therapy is initiated first. If medical therapy fails or if a patient has severe BPH with ongoing obstruction, retention of large volumes of urine, bladder stones, or recurrent UTIs, surgical therapy should be considered. The most commonly performed surgery is transurethral resection of the prostate (TURP), but other techniques can be employed as well, including transurethral incision of the prostate, minimally invasive procedures, and open surgery for very enlarged prostate glands. “D” is incorrect. Scheduled bladder catheterization is unlikely to benefit your patient since his post-void residual is not very large. A post-void residual greater than 200 mL is associated with an increased risk of UTIs, and such patients may benefit from scheduled catheterizations if medical or surgical interventions do not correct the problem or are contraindicated. Kegel exercises and biofeedback (“E”) may be used to treat incontinence but are not used in BPH. Biofeedback is helpful for voiding dysfunction due to incomplete urinary sphincter relaxation.

.....
Your powers of deduction lead you to the conclusion that the patient’s urinary symptoms are due to BPH. He has always been proud of his bladder capacity (men can be proud of just about anything) and is embarrassed that he is taking frequent bathroom stops when driving with his wife on their road trips; your patient desires treatment.

Question 16.1.4 To give him the most immediate relief, you prescribe which of the following?

- A) Finasteride
- B) Oxybutynin
- C) Tamsulosin
- D) Imipramine
- E) Furosemide

Answer 16.1.4 The correct answer is “C.” Timing and type of intervention should depend on how much the patient is bothered by his symptoms and whether complications of BPH are present. If the symptoms do not significantly interfere with your patient’s life, he may choose to wait and take no treatment once he is reassured that he does not have a life-threatening illness. In general, medical management begins with a selective alpha-1a receptor blocker, such as tamsulosin, which relaxes the prostate at the bladder neck. If the patient does not receive sufficient relief from maximum doses of an alpha-1a blocker, consider adding a 5-alpha-reductase inhibitor (e.g., finasteride, dutasteride). These drugs work by reducing the size of the prostate gland by interfering with the effects of androgens on prostate tissue. However, it may take up to 6 months for a 5-alpha-reductase inhibitor to result in a noticeable difference in symptoms (thus, “A” should not be the first treatment); the full benefit of an alpha-blocker will be apparent within 4 to 6 weeks. “B” and “D” are incorrect because these anticholinergic drugs are used for

incontinence due to detrusor instability and may make urinary retention worse in patients with outlet obstruction. Furosemide, “E,” is a potent diuretic and would be a cruel joke to play on this patient.

HELPFUL TIP:

Since 5-alpha-reductase inhibitors shrink prostate tissue, they reduce the production of prostate-specific antigen (PSA). Be aware that PSA levels decrease by approximately 50% within 6 months of initiating one of these drugs. Therefore, if for some reason you check a PSA in a man on finasteride or dutasteride, the value should be doubled for the first two years when comparing to normal ranges. It should be multiplied by 2.5 thereafter.

Question 16.1.5 Before you tear up the prescription for terazosin you accidentally wrote, you review its side effects. Potential side effects of alpha-blockers include all the following EXCEPT:

- A) Retrograde ejaculation
- B) Hypertension
- C) Intraoperative floppy iris syndrome
- D) Priapism

Answer 16.1.5 The correct answer is “B.” Hypotension (not hypertension) is the most commonly encountered problem with terazosin and other alpha-blockers, including the uroselective alpha-blockers, although to a lesser degree. In elderly males, the hypotension can be particularly problematic as the propensity for falling may increase. Additionally, alpha-blockers in combination with phosphodiesterase inhibitors (e.g., sildenafil) can cause dangerously low blood pressures. Retrograde ejaculation (“A”) and priapism (“D”) are not common but have been reported. And, as if we needed it, here is more evidence for a direct link between the male ocular and genital systems: intraoperative floppy iris syndrome (“C”) describes a flaccid iris that protrudes out through the surgical incision in those undergoing cataracts surgery and has been reported with alpha-blocker therapy. Yes, you may have thought we made this up, but we didn’t.

.....
You start tamsulosin. Unfortunately, the patient is not able to tolerate it due to dizziness. His symptoms are bothersome enough that he wishes to try something else. You consider finasteride.

Question 16.1.6 Which of the following is true of finasteride?

- A) It permanently reduces prostate volume, even after the drug is stopped
- B) It is approved by the Food and Drug Administration (FDA) for abnormal hair growth in women
- C) It may reduce the overall risk of developing prostate cancer, but increases the risk of developing high-grade prostate cancers
- D) It improves symptoms within 1 week of starting the drug
- E) None of the above

Answer 16.1.6 The correct answer is “C.” This is important: 5-alpha-reductase inhibitors lower the overall risk of cancer, but increase the risk of those cancers diagnosed being high grade (Gleason score of ≥ 7). Finasteride (and dutasteride) works by inhibiting 5-alpha-reductase, which is the enzyme that converts testosterone to dihydrotestosterone. Dihydrotestosterone stimulates hyperplasia of the prostate gland, and removing this stimulus results in decreased prostate volume. However, removal of finasteride allows hyperplasia to continue, and thus answer “A” is incorrect. “B” is also incorrect because finasteride is not approved by the FDA for hirsutism in women. Additionally, finasteride is category X in pregnancy, with potential teratogenic effects on the fetus. “D” is incorrect because finasteride takes time to work—a lot of time. As previously mentioned, its peak effectiveness is not seen for 3 to 6 months after starting the medication.

HELPFUL TIP:

In comparison trials with alpha-blockers, 5-alpha-reductase inhibitors have shown variable results. The addition of a 5-alpha-reductase inhibitor to an alpha-blocker does not seem to have additional benefit over alpha-blocker therapy alone in the *near term*, but combination therapy has shown reduced incidence of clinical progression of BPH in *longer trials*.

You decide to add finasteride. You see him again 2 months later when he presents with a febrile illness. He thinks that he might have the flu, but his BPH symptoms worsened at the same time. For the last 2 days, he has felt feverish with back pain, perineal pain, and generalized malaise. He complains of dysuria and worsening urinary frequency and urgency.

Question 16.1.7 During your examination, you make sure NOT to:

- A) Perform a rectal examination
- B) Massage the prostate
- C) Swab the urethra for chlamydia
- D) Perform urinalysis and microscopic examination of the urinary sediment

Answer 16.1.7 The correct answer is “B.” There is a risk of seeding bacteria into the bloodstream when an infected prostate is massaged. This patient has symptoms of prostatitis; thus, you should **avoid prostatic massage**. Nonetheless, you should perform a prostate examination. The following prostate examination findings are associated with prostatitis: tenderness, warmth, enlargement, and boggy.

You suspect prostatitis and obtain urine for analysis.

Question 16.1.8 All of the following laboratory abnormalities are consistent with the diagnosis of acute prostatitis EXCEPT:

- A) Leukocytosis
- B) Hematuria

- C) Bacteriuria
- D) Elevated creatinine
- E) Elevated PSA

Answer 16.1.8 The correct answer is “D.” Tests of renal function should not be abnormal in simple, acute prostatitis. Chronic partial or complete urinary outlet obstruction may cause abnormal renal function but not acute prostatitis. Abnormal serum BUN and/or creatinine in the setting of prostatitis should prompt further investigation. The urine often shows bacteriuria (“C”), pyuria (and, therefore, leukocytosis [“A”]), and hematuria. However, the urine may also be negative. Urine should be sent for culture and sensitivity to definitively determine the pathogen and direct further treatment. “E” is true: the PSA is often elevated in prostatitis. However, it is not necessary nor is it recommended to obtain a PSA to diagnose prostatitis. When the PSA is elevated due to acute prostatitis, it may not return to normal levels for 1 month or more after the resolution of inflammation.

On examination, you find an uncomfortable appearing male in no distress. His temperature is 38.4°C, and the rest of his vital signs are normal. The prostate on digital rectal examination is tender, enlarged, warm, and boggy. The remainder of the examination is unremarkable. Urinalysis is consistent with an infection. He has a sulfa allergy.

Question 16.1.9 Which of the following is the most appropriate treatment plan for this patient?

- A) Prescribe trimethoprim-sulfamethoxazole 160 mg–800 mg BID for 42 days
- B) Prescribe ciprofloxacin 500 mg orally BID for 21 days
- C) Admit for IV levofloxacin 500 mg daily for 14 days
- D) Admit for IV levofloxacin 500 mg daily, followed by completion of therapy with oral levofloxacin 500 mg daily for 14 days when the patient is stable
- E) Perform transrectal ultrasound to rule out prostatic abscess

Answer 16.1.9 The correct answer is “B.” The most appropriate treatment for this patient is a fluoroquinolone, such as ciprofloxacin, for at least 21 days. Some authorities recommend longer treatment (up to 6 weeks) to reduce the risk of chronic prostatitis. In patients who are not allergic, a sulfa antibiotic (“A”) could be considered as an alternative to a fluoroquinolone. In this case, “C” and “D” are overkill. Admission is appropriate for patients who appear septic, have not responded to oral antibiotics, or who have significant comorbidities. However, fluoroquinolones have 100% bioavailability PO. Thus, there is no indication for giving these drugs IV unless the oral route is unavailable (e.g., vomiting). Additionally, the treatment course for “C” and “D” is too short. “E” is incorrect because abscesses are rare and imaging for an abscess is only undertaken if the patient does not respond to appropriate antibiotics.

When you see this patient again, his symptoms of prostatitis have cleared, but he does not think that finasteride is really helping. His AUA symptoms score is 21 (severe). He is

wondering if a transurethral resection of the prostate (TURP) might help him, and he wants to discuss the downsides of the operation.

Question 16.1.10 Compared with watchful waiting, all of the following are observed at greater rates in men who undergo TURP EXCEPT:

- A) Erectile dysfunction
- B) Urinary incontinence
- C) Urethral stenosis
- D) Increased urine flow
- E) Decreased post-void residual urine volume

Answer 16.1.10 The correct answer is “A.” TURP is a commonly performed procedure for BPH. Indications for TURP include failure of medical therapy, recurrent infections, bladder calculi, renal insufficiency, and patient preference. Patients who undergo TURP typically experience decreased AUA symptom scores, increased urine flow rates (“D”), and decreased post-void residual volumes (“E”). There are downsides to TURP, including urinary incontinence (“B”), urethral stenosis (“C”), and the need to repeat the surgery. Strange as it may seem, several studies have shown that erectile dysfunction does NOT occur at increased rates in patients undergoing TURP compared with watchful waiting. However, men can have retrograde ejaculation status post-TURP.

HELPFUL TIP:

Daily low-dose Cialis (tadalafil) has been approved by the FDA for treating BPH. But, the benefit over placebo is only 2.3 points on a 35-point scale ... don't expect miracles.

Your patient is so happy with his care that he shared his story over a few beers, and his friend comes to see you. This patient is a 50-year-old male, in no apparent distress, who presents with a 6-month history of recurrent irritative voiding symptoms (frequency, urgency, etc.), low back and distal penile pain, and recurrent UTIs with the same organism. Today he is afebrile with a mildly tender prostate on digital rectal examination.

Question 16.1.11 Based on this patient's history and physical examination, all would be appropriate at this stage EXCEPT:

- A) Have the patient complete the NIH Chronic Prostatitis Symptom Index questionnaire
- B) Perform a two-glass pre- and post-prostatic massage test
- C) Obtain urine culture and if positive, treat based on sensitivities for at least 4 weeks
- D) Obtain a pelvic MRI

Answer 16.1.11 The correct answer is “D.” There is no indication for a pelvic MRI at this time. The two-glass pre- and post-prostatic massage test (“B”) is a very useful method of

diagnosing chronic prostatitis. A mid-stream voided urine specimen is collected and sent for culture. If the urinalysis has greater than 10 WBCs per high-power field, next prostatic massage is performed, and then the first 10 mL of voided urine after the massage that should include expressed prostatic secretions should be sent for culture. Treatment is based on the culture and sensitivity results. A 4- to 6-week course of treatment is recommended with an appropriate antibiotic with good tissue penetration. The most common organisms isolated in chronic bacterial prostatitis are *E. coli*, *Klebsiella*, *Proteus*, *Pseudomonas*, and Gram-positive *Enterococcus*. The NIH Chronic Prostatitis Symptom Index questionnaire (“A”) is a reliable, valid method to assess symptoms and quality of life impact in men with chronic prostatitis (<http://www.prostatitis.org/symptomindex.html>).

HELPFUL TIP:

To massage or not, that is the question. While there appears reasonable evidence not to massage the prostate in acute prostatitis (so as to avoid potentially seeding bacteria into the blood stream), prostate massage's role in chronic prostatitis remains evolving. Given the more multifactorial etiology of chronic prostatitis (which includes noninfectious etiologies), prostate massage's role in chronic prostatitis has been prevalent since the mid-1900s. Its benefits are thought to arise from draining theoretically occluded prostate ducts, improving circulation, and helping with antibiotic penetration. However, a 2018 Cochrane review noted uncertainty as to whether or not prostatic massage reduces or increases prostatitis symptoms compared with control (with a “very low quality of evidence” rating for the studies examined). Use your clinical judgment when recommending prostatic massage for your patients with chronic prostatitis.

► **Objectives: Did you learn to ...**

- Recognize the pattern of voiding dysfunction seen in BPH?
- Manage a patient with BPH and understand the potential adverse effects of medications used to treat BPH?
- Diagnose and treat acute prostatitis?
- Describe indications for and complications of TURP?
- Evaluate chronic prostatitis?

QUICK QUIZ: SEXUALLY TRANSMITTED INFECTIONS

A 21-year-old college student and self-described as a “ladies’ man” (interpret: jerk) presents because of a concerning spot that developed on his penis. He complains of pain at the spot but denies itching. He reports no fever. When asked further about his sexual practices, he reports no condom use because his partners are all “on the pill.” He had chlamydia in high school but is otherwise healthy. His review of systems is negative. On examination of the penis, you find a 1-cm tender, erythematous papule with a deep central ulceration at the glans penis. There is

FIGURE 16-1. Chancroid lesions secondary to *H. ducreyi*. Notice the sharply demarcated borders and strongly erythematous appearance of the lesions. While it may look like syphilis, history is the key to distinguishing between the lesions, as chancroid lesions are painful while a chancre due to syphilis is nonpainful. (Used with permission from Kang S et al, eds. *Fitzpatrick's Dermatology*. 9th ed. New York: McGraw-Hill, 2019, Fig. 172-3.)

some mild, tender lymphadenopathy in the inguinal area. The rest of the examination is unremarkable.

This lesion is most likely caused by:

- A) *Haemophilus ducreyi*
- B) *Neisseria gonorrhoeae*
- C) *Staphylococcus aureus*
- D) *Treponema pallidum*

The correct answer is "A." This is the lesion of *H. ducreyi*, otherwise known as chancroid. It can be confused with the chancre of primary syphilis, caused by *T. pallidum* ("D"), but the syphilis chancre is painless. Gram stain (Gram-negative rods in chains), culture, or biopsy may confirm the diagnosis. A few more notes: chancroid is rarely diagnosed in the United States and is probably under-diagnosed; it frequently co-infects with syphilis and tends to occur in clusters. A number of treatments are available including ceftriaxone (250 mg IM once), azithromycin (1 g PO once), ciprofloxacin (500 mg PO BID for 3 days), and erythromycin base (500 mg PO TID × 7 days). *Neisseria gonorrhoeae* ("B") and *Staphylococcus aureus* ("C") are incorrect because these pathogens do not form the type of lesion described in the questions stem. For more images of skin lesions associated with sexually transmitted infections, see Figures 16-1 through 16-7.

▶ CASE 16.2

A 22-year-old male presents complaining of a painless lump on his left testicle. He denies penile discharge, dysuria, or other urinary complaints. He underwent a left orchidopexy for an undescended testicle at age 6. Otherwise, his past medical history is unremarkable. On examination, the penis is circumcised with no lesion or discharge. There is adenopathy

in the left inguinal area. His testicles are descended bilaterally with a 1-cm palpable, irregular mass on the mid-lateral portion of the left testicle. His examination is otherwise unremarkable. Your patient is worried about testicular cancer and wants to know if he is at risk.

Question 16.2.1 All of the following are associated with an increased risk of testicular cancer EXCEPT:

- A) Vasectomy
- B) HIV infection
- C) Cryptorchidism
- D) Klinefelter syndrome
- E) Family history

Answer 16.2.1 The correct answer is "A." Epidemiologic data do not support an association between testicular cancer and vasectomy. As is true of some other malignancies, males with HIV infection ("B") have an increased risk of testicular cancer. Also, males with cryptorchidism ("C"), defined as failure of one or both testicles to descend into the scrotum, and Klinefelter syndrome ("D") are at increased risk of testicular cancer. About 25% of testicular cancers occurring in patients with cryptorchidism arise in the contralateral (in the normally descended) testicle. While testicular cancer does not have as strong of a hereditary component, a positive family history ("E") is a risk factor for testicular cancer. Of note, black males have a much **lower** incidence of testicular cancer than do white males.

Question 16.2.2 If your patient had not had an orchidopexy to repair the undescended testicle, he would be at risk for developing all of the following problems EXCEPT:

- A) Infertility
- B) Inguinal hernia
- C) Testicular torsion
- D) Testicular malignancy
- E) Impotence

Answer 16.2.2 The correct answer is “E.” Organic impotence is not a consequence of cryptorchidism. All of the other problems listed occur at an increased frequency in males with an undescended testicle. The best time to begin treatment for an undescended testicle to minimize future sequelae is between 6 and 18 months of age and preferably by the end of the first year. The consequence of not treating an undescended testicle is a 20% to 40% increased risk of developing a testicular malignancy, which often presents as a painless mass (although it is not clear that fixing the undescended testicle lowers the cancer risk). Therefore, the reasons to treat cryptorchidism are (1) to better palpate the testicle to assess for potential malignant transformation; (2) to decrease the risk of malignant transformation (maybe); (3) to improve chances of fertility; (4) to decrease risk of testicular torsion; (5) to decrease psychological effects from having an empty scrotum; and (6) to repair an inguinal hernia at the same time, if it is present.

HELPFUL TIP:

In patients with hypospadias and unilateral or bilateral empty scrotum, there is a higher rate of chromosomal anomalies.

Question 16.2.3 After an appropriate history and physical examination, which of the following tests is the initial diagnostic study of choice in your patient with a scrotal mass?

- A) CT scan
- B) Ultrasound
- C) Complete blood count (CBC)
- D) Alpha fetoprotein (AFP)
- E) Pelvic x-ray

Answer 16.2.3 The correct answer is “B.” The best initial diagnostic test would be a scrotal ultrasound to determine if this mass is cystic or solid. If it is determined to be a solid mass suspicious for malignancy, then other diagnostic studies would be warranted, such as β -hCG and AFP (“D”). In conjunction with a radical inguinal orchiectomy for testicular cancer, a CT scan would be indicated to evaluate for metastatic disease, but it is not the test of choice for initial diagnosis, so “A” is incorrect. CBC (“C”) would have a role in suspected infection. X-ray (“E”) has no role in the evaluation of this patient since this is a soft tissue mass.

HELPFUL TIP:

If the ultrasound of a scrotal mass is equivocal, MRI or urological referral should be considered next.

Question 16.2.4 In taking this patient's history, if he had described a *painful* lump in his scrotum, the LEAST likely cause would be:

- A) Chlamydia
- B) Inguinal hernia

- C) Hydrocele
- D) Testicular torsion

Answer 16.2.4 The correct answer is “C.” Spermatocoeles and hydroceles are usually not painful. When a young, sexually active male presents with a painful scrotal mass or swelling, epididymitis from chlamydia (“A”) or gonorrhea should be considered. Testicular torsion (“D”) often has a very abrupt onset of pain and is a surgical emergency. Inguinal hernias (“B”) can be intermittently painful if moving freely in the inguinal canal. However, if one becomes incarcerated, intense pain occurs. Of note, varicoceles are usually an incidental finding; however, large varicoceles may occasionally be painful. Likewise, testicular cancers are usually not painful but can become so if the tumor growth is rapid.

Your patient's ultrasound is concerning for testicular cancer, and you refer him to a urologist.

The next day the patient's 15-year-old brother presents with scrotal pain. You wonder if you are on the cusp of discovering an infectious cause of testicular cancer, but alas, it appears to be coincidence.

This patient's pain is on the right and he can localize it well to the front of the testicle. It has been present for 3 days and seemed to occur gradually over a few hours. There is no radiation of the pain. Running makes it worse, and cool packs seem to help. Yesterday he noticed a slight swelling of the scrotum on the same side. He denies trauma to the area, any history of sexual activity, other genitourinary complaints, fever, nausea, or vomiting. On examination you find normal vitals. He has a well-localized tender spot at the anterior superior right scrotum with a bluish discoloration under the skin ... as if it were some sort of sign ... a blue dot sign (Fig. 16-8).

FIGURE 16-8. Blue Dot Sign (link to case 16.2.5). Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds). *The Atlas of Emergency Medicine*. 4th ed. New York: McGraw-Hill, 2016, Fig. 8.7. (Photo contributor: Alan B. Storrow, MD.)

Question 16.2.5 Which of the following is the most likely diagnosis?

- A) Torsion of the appendix testis
- B) Torsion of the testicle
- C) Varicocele
- D) Abscess
- E) Spermatocoele

Answer 16.2.5 The correct answer is “A.” This is the classic presentation of a torsed appendix testis. The appendix testis is a pedunculated, vestigial structure at the anterior superior testicle. Torsion of the appendix testis is one of the most common causes of scrotal pain in children. The pain is usually well localized. There may be a reactive hydrocele. Diagnosis is confirmed by ultrasound. Unlike a torsed testicle (“B”), a torsed appendix testis is not an emergency. It may be treated by conservative therapy (rest, NSAIDs, ice) or surgical excision. The remainder of the options (“C,” “D,” “E”) do not present with features of bluish discoloration under the skin.

► Objectives: Did you learn to ...

- Recognize potential causes of a painless scrotal mass?
- Evaluate a testicular mass?
- Recognize the significance of cryptorchidism?
- Identify torsion of the appendix testis?

**QUICK QUIZ: HEMATOSPERMIA**

A 28-year-old male presents to your office looking quite concerned. Several days ago after sexual intercourse with his girlfriend, he noticed bloody ejaculate in the condom. Since then he has masturbated twice (“just to check”) and has not seen any more blood. He denies pain, hematuria, dysuria, fevers, night sweats, and weight loss. He reports that he is otherwise healthy. His examination, including genitourinary and rectal examination, is normal. A urinalysis is negative.

What is your next step in the evaluation and management of this patient?

- A) Reassurance and follow-up
- B) Scrotal ultrasound
- C) Pelvic CT scan
- D) Transrectal ultrasound
- E) PSA

The correct answer is “A.” Hematospermia, the name given to bloody penile ejaculate, is fairly uncommon. It can occur in men of any age and is perhaps most common after prostate biopsy or prostate surgery. In otherwise healthy young men, the cause is most often idiopathic and is almost always benign. History should focus on traumatic causes (e.g., a long bicycle ride), symptoms of prostate disease, and symptoms of infection. A genital and prostate examination should be performed. Urinalysis is helpful to exclude infection. Consider gonorrhea and chlamydia cultures in the appropriate patients, for example,

those with symptoms of urethritis. In this patient, reassurance is adequate. Persistent hematospermia, with symptoms present for over a month, may require further evaluation with PSA (“E”), imaging (“B,” “C,” “D”), and urologic consultation. Some experts recommend a more aggressive workup, especially in older males, but there is no evidence to support more extensive evaluations. Also, ask about recent travel, as schistosomiasis is a frequent cause of hematospermia and hematuria in other parts of the world. In most cases of hematospermia, semen analysis is not warranted, but it can be diagnostic in patients with schistosomiasis.

► CASE 16.3

A couple you have known for a few years comes to your office to announce that they are expecting and that they want you to be the baby’s doctor (strange that they didn’t ask you to be the mother’s doctor, but you let it slide). According to an ultrasound, the fetus is male. The couple is ambivalent about neonatal circumcision and wants your advice.

Question 16.3.1 You start the conversation by saying:

- A) “Circumcision is a relic of history and should be illegal”
- B) “All major medical organizations (e.g., AAFP, AAP, AMA) recommend routine neonatal circumcision”
- C) “The decision to perform circumcision is a personal one, influenced by a number of factors—but primarily by cultural, religious, and familial issues”
- D) “Do whatever you want. I don’t really care what you do with a tiny piece of skin”

Answer 16.3.1 The correct answer is “C.” One of the strongest predictors of whether a newborn in the United States will be circumcised is the circumcision status of the father. There are other reasons cited by parents as well (discussed later in the case). “A” is incorrect simply because the statement is effused with emotion and lacks logic. “B” is incorrect. The AAFP has no policy statement on circumcision. In 2012 the American Academy of Pediatrics changed its statement on circumcision to the following: *the health benefits outweigh the risks, and circumcision should be made available to all families who choose it. However, ‘routine’ universal circumcision is still not recommended.* If you chose “D,” you need to work on your bedside manner!

Question 16.3.2 Consequences of circumcision include which of the following?

- A) Overall reduction in mortality of circumcised infants compared with uncircumcised infants
- B) Reduction in UTIs in the first year of life
- C) Reduction in the number of sexual partners
- D) All of the above

Answer 16.3.2 The correct answer is “B.” The rate of UTIs in uncircumcised males in the first year of life is about 10 times greater than the rate for circumcised males. In order

to prevent one UTI in the first year of life, about 100 circumcisions need to be performed. The effect of circumcision on rates of UTI later in life is not well studied. The rate of UTI may be higher shortly after circumcision (within the first 2 weeks). “A” is incorrect because there is no data showing any difference in mortality between circumcised and uncircumcised infants. “C” is incorrect; some surveys have shown increased frequency and variety of sexual practices in circumcised males compared with uncircumcised (note that this is an association, not a causal relationship).

HELPFUL TIP:

Circumcision reduces the rate of cervical cancer in the female partners of males who were circumcised and previously had six or more sexual partners. This is thought to be due to decreased rate of HPV transmission. Of course, it is now recommended to provide vaccination to all young men and women with the HPV vaccination series. See the Chapters 13 and 14 for more information.

Question 16.3.3 Neonatal circumcision is associated with all of the following EXCEPT:

- A) Risk of hemorrhage with the procedure
- B) Psychological trauma and decreased sexual satisfaction later in life
- C) Reduced risk of infection with STIs, such as HIV
- D) Reduced risk of penile cancer

Answer 16.3.3 The correct answer is “B.” Despite what some anti-circumcision websites maintain, circumcision does not appear to result in any significant psychological trauma or decreased sexual satisfaction for most men later in life. “A” is true. There is a small but real risk of hemorrhage with the procedure, and this occurs mostly in patients who have an unknown or unrealized coagulopathy. In fact, abnormal bleeding after circumcision is a common way in which sporadic cases of hemophilia are discovered (including one case discovered this way by one of the editors—and he still feels bad!). “C” is true. Several studies have demonstrated that circumcised men are less likely to have HPV infection. The data for the risk of other sexually transmitted infections (STIs) are somewhat contradictory, but generally favor a reduced risk of STIs in circumcised males. “D” is true. There is evidence that circumcision may decrease the transmission of HPV and penile cancer. Retrospective studies have shown that the rate of squamous cell carcinoma of the penis is about threefold higher in uncircumcised men, at least in the United States. However, penile cancer is exceedingly rare (about 0.6 cases/100,000) and the number of circumcisions needed to prevent one case of penile cancer is about 300,000. However, the American Cancer Society does **not** recommend routine neonatal circumcision for the prevention of penile cancer, but it does recommend that all risk factors be addressed.

HELPFUL TIP:

It is abundantly clear that circumcision reduces the transmission of HIV. This has led to a call for routine circumcision in high-risk populations (e.g., some parts of sub-Saharan Africa, etc.).

HELPFUL TIP:

In addition to uncircumcised status, risk factors associated with penile cancer include smoking, risky sexual behavior, poor hygiene, and genital warts.

You have a nice, long conversation with the couple, discussing the potential benefits and risks, and they decide to have their son circumcised. After the birth, you are performing a thorough examination when you find something slightly abnormal with the penis.

Question 16.3.4 Neonatal circumcision is indicated for:

- A) Congenital phimosis
- B) Micropenis
- C) Hypospadias
- D) Ambiguous genitalia

Answer 16.3.4 The correct answer is “A.” Significant congenital phimosis rarely occurs and is an indication for circumcision. Phimosis is defined as the inability to retract the foreskin (prepuce) over the glans. This is a **normal** finding in uncircumcised infants. However, **significant** congenital phimosis may completely cover the urethra and not allow the normal passage of urine. “B,” “C,” and “D” are reasons to **avoid** routine circumcision and to call on the aid of a urologist.

HELPFUL TIP:

When performing circumcision, local anesthetic is recommended, and either dorsal penile nerve block or subcutaneous ring block is preferred. Other pain control modalities may be used as well, including pre-procedure acetaminophen, sucrose-coated pacifier, calming music, swaddling, etc.

► Objectives: Did you learn to ...

- Discuss the benefits and risks of circumcision with parents?
- Identify indications and contraindications for neonatal circumcision?
- Employ appropriate pain control measures for the procedure of circumcision?

► CASE 16.4

A 32-year-old male presents to discuss permanent sterilization. He clearly states that he wants a vasectomy, and sooner is better than later. He is married and has three children at home.

His wife just gave birth to twins. He is healthy and takes no medications. He looks tired and anxious. You examine him and find no abnormalities. The vas deferens is easily isolated bilaterally.

Question 16.4.1 What is your next step?

- A) Refer him for psychological counseling as he is clearly under a great deal of stress
- B) Provide him with detailed counseling on vasectomy, give him written material on the procedure, and ask him to discuss it with his wife
- C) Do the vasectomy right now; the next patient can wait
- D) Tell him that he is not an appropriate candidate for vasectomy because of his history of hypertension

Answer 16.4.1 The correct answer is “B.” Patient education, counseling, and selection are very important aspects of vasectomy. When you counsel him on vasectomy, you should explore his reasons for wanting the procedure. You should not schedule a vasectomy without providing counseling and assuring that he understands the procedure in detail (thus, “C” is incorrect). This patient appears to be fatigued—an issue that should be explored further—and he has newborn twins at home (who the heck wouldn’t be tired?). So, immediate referral for psychological counseling without investigating the underlying cause (“A”) is not appropriate.

Question 16.4.2 While counseling this patient, you discuss which of the following issues?

- A) Partner’s desire for permanent sterility
- B) Effect of the procedure on sexual function
- C) Reversibility of the procedure
- D) Complications
- E) All of the above

Answer 16.4.2 The correct answer is “E.” All these issues are important to discuss prior to scheduling the procedure. It is important that the couple agree on this procedure because it is *the couple*—not just your patient—who will be sterile. Aside from psychological effects of vasectomy, the procedure should not directly affect sexual function, orgasm, or ejaculation. Patients should be aware that vasectomy results in permanent sterility and that reversal procedures are only successful about half of the time. Potential complications include failure and unwanted pregnancy, infection, pain, bleeding, hematoma, etc.

Your patient decides to “get snipped” (as he puts it). You perform the vasectomy using a no-scalpel technique. The procedure was fairly easy, and the patient tolerated it well. One month after the procedure, the patient calls to complain about a painful swelling that has developed superior and slightly posterior to the left testis. He has no other symptoms.

Question 16.4.3 Which of the following is the most likely diagnosis?

- A) Hematoma
- B) Varicocele

- C) Congestive epididymitis
- D) Abscess

Answer 16.4.3 The correct answer is “C.” Without any further information, congestive epididymitis is the most likely cause of this patient’s current complaint. Congestive epididymitis occurs in about 3% of patients post-vasectomy, and the onset is usually within weeks to months after the procedure. “A,” hematoma, can be avoided in most cases if hemostasis is achieved during the procedure and the patient does not overexert himself immediately post-operation. A hematoma is more likely to develop early rather than a month later. Likewise, an infection (“D”) would be unlikely so far out from the procedure. “B” is incorrect because varicoceles do not develop after vasectomy (unless you are operating far away from where you are supposed to be). Overall, the most common scrotal pathology after vasectomy is sperm granuloma, which occurs in up to 40% of patients but is generally asymptomatic.

HELPFUL TIP:

The treatment of congestive epididymitis can be frustrating. Most men who have a vasectomy will have some element of congestive epididymitis, but most will have minor swelling without pain. For patients with painful congestive epididymitis, a trial of NSAIDs and sitz baths for several months is indicated. Failing conservative therapy, steroid injection or surgery may be indicated.

Two months after the vasectomy, your patient returns with a semen sample, showing no sperm. His surgery was successful, but failures do occasionally occur.

Question 16.4.4 Vasectomy failure is usually due to:

- A) Failure to identify and transect the vas at the time of surgery
- B) Recanalization
- C) Infection
- D) Immaculate conception

Answer 16.4.4 The correct answer is “B.” Although “redundant systems” (removing a segment of the vas deferens, clipping or suturing the free ends, cauterizing the transected vas, suturing fascia around one free end while leaving the other outside the fascia) are employed to avoid this complication, recanalization can occur. A new pathway can form between the free ends of the transected vas deferens, allowing sperm into the ejaculated semen. Therefore, all patients should return post-vasectomy for semen analysis. “A” and “C” are potential, but infrequent, causes of failure. As to “D,” only God knows.

Your patient is ultimately pleased with his vasectomy results. He returns to see you several years later because of concerns that he is balding. On examination, you find non-scarring hair loss at the vertex. The scalp appears normal otherwise.

Question 16.4.5 You should entertain all of the following diagnoses EXCEPT:

- A) Androgenetic alopecia (yes, it is “androgenetic” and not “androgenic”)
- B) Telogen effluvium
- C) Alopecia areata
- D) Hypothyroidism
- E) Tinea capitis

Answer 16.4.5 The correct answer is “E.” Hair loss is common in males, affecting up to two-thirds of all men. Alopecia is often divided into scarring and non-scarring forms. Most infectious causes of hair loss (e.g., tinea capitis and folliculitis) are scarring if not treated, whereas the other causes listed (“A” through “D”) are non-scarring. Without any signs of inflammation or hyperkeratosis, tinea capitis (“E”) is unlikely. “A,” androgenetic alopecia, is quite common in adult males (male balding). “B,” telogen effluvium, presents with diffuse hair loss usually secondary to metabolic (including dieting) or emotional stress. This occurs as an abnormal percentage of hair enters the telogen phase during which they are shed. Grab some hair: if more than five hairs in telogen phase come out, you have your diagnosis. “C,” alopecia areata, results in patchy hair loss in round or oval shapes. Metabolic conditions should also be in the differential diagnosis of hair loss, and these might include hypothyroidism (“D”), hyperthyroidism, and iron deficiency.

HELPFUL TIP:

Secondary syphilis causes a non-inflammatory, non-scarring hair loss that may be patchy or diffuse. Consider testing for syphilis in appropriate patients.

The patient reports a strong family history of baldness. On your examination, the patient has thin hair at the vertex and recession of the hairline in an “M” shape at the frontotemporal area. On the basis of the history and examination, you diagnose androgenetic alopecia. He would like to do something about his hair loss.

Question 16.4.6 Regarding androgenetic alopecia, which of the following statements is true?

- A) Minoxidil must be used for at least 2 years to achieve permanent hair regrowth
- B) Lower doses of 5- α -reductase inhibitors (e.g., finasteride) are used in treating androgenetic alopecia compared with BPH
- C) Hair transplant should be avoided unless all other therapeutic attempts have failed
- D) Topical steroids are an effective therapy for androgenetic alopecia
- E) A toupee looks great on anyone

Answer 16.4.6 The correct answer is “B.” Finasteride (Propecia) is FDA approved for androgenetic alopecia, and the dose is 1 mg/day rather than the 5 mg/day dose used to

treat BPH symptoms. Minoxidil applied to the scalp is also an effective therapy for androgenetic alopecia. Both minoxidil and finasteride must be continued indefinitely to be effective (thus, “A” is incorrect). Hair transplant is a viable option for men and women with androgenetic alopecia, and it is sometimes used as a first-line therapy. Thus, “C” is incorrect. Topical steroids (“D”) are not effective for this type of hair loss. “E” is clearly wrong; there are a lot of bad toupees out there.

► **Objectives: Did you learn to ...**

- Provide pre-vasectomy counseling?
- Recognize complications of vasectomy?
- Identify causes of hair loss in men?
- Describe current treatment options for androgenetic alopecia?

QUICK QUIZ: DEATH RATES IN MEN

For all the following causes of death, the age-adjusted death rate is higher for males than for females EXCEPT:

- A) Liver disease
- B) Alzheimer disease
- C) Coronary artery disease
- D) Suicide
- E) Cancer

The correct answer is “B.” When it comes to Alzheimer disease, men get a break; the death rate is higher for females. All of the other causes of death listed have greater death rates in males. For example, compared with women with liver disease, same age men with liver disease are twice as likely to die of their liver disease.

QUICK QUIZ: MORE ABOUT DEATH IN MEN

The relative risk of death for males is greater throughout the life span. Compared with same age females, at what age range is the relative risk of death greatest for males?

- A) <1 year
- B) 5 to 14 years
- C) 15 to 24 years
- D) 25 to 34 years
- E) >85 years

The correct answer is “C.” Unfortunately, males aged 15 to 24 years have a relative risk of death of greater than 2.5 compared with same age females (usually preceded by a cry of, “Hey! Look what I can do!”). Mother Nature has a way of making up for boys and young men dying: more male fetuses are conceived than female. However, the miscarriage rate is also greater for male fetuses. Nonetheless, about 105 males are born in the United States for every 100 females. By age 35, enough males have died off that the number of males and females at that

age is about equal, and thereafter the number of females exceeds the number of males (in other words, the singles scene improves markedly for the remaining males).

► CASE 16.5

A 14-year-old male presents with his mother, who is worried that he has growing breasts. Over the last 2 or 3 months, the patient has developed swellings beneath both nipples. He denies discharge or pain, but the nipples are tender at times.

Question 16.5.1 You can tell this patient that physiologic gynecomastia (subareolar breast tissue) is a condition that affects:

- A) Newborns
- B) Adolescents
- C) Elderly males
- D) All of the above

Answer 16.5.1 The correct answer is “D.” The incidence of physiologic gynecomastia is trimodal, with peaks in the neonatal period, adolescence, and old age. Data can be contradictory at times, but clinically palpable breast tissue (either fat or true breast tissue) may be present in more than 50% of males in each of these three age groups.

Question 16.5.2 Which of the following hormones is responsible for the proliferation of breast tissue?

- A) Testosterone
- B) Estrogen
- C) Androstenedione
- D) Growth hormone
- E) Progesterone

Answer 16.5.2 The correct answer is “B.” Estrogens induce ductal hyperplasia and growth of glandular tissue. Testosterone (“A”) and androstenedione (“C”) inhibit the actions of estrogens on the breast tissue. Some men with gynecomastia have increased sensitivity of breast tissue to circulating estrogens. Others may have an increased proportion of estrogens compared with androgens. And others still may have a mixture of both processes or another process altogether.

Question 16.5.3 Potential causes of gynecomastia include all of the following EXCEPT:

- A) Renal failure
- B) Marijuana use
- C) Testicular cancer
- D) Hypothyroidism
- E) Phenothiazines

Answer 16.5.3 The correct answer is “D.” Hyperthyroidism, not hypothyroidism, can cause gynecomastia through increased aromatization of testosterone to estradiol and androstenedione to estrone. A number of drugs are associated with gynecomastia,

including marijuana (“B”), alcohol, 5-alpha-reductase inhibitors, phenothiazines (“E”), tricyclic antidepressants, androgens, estrogens, growth hormone, calcium channel blockers, and spironolactone. Other causes of gynecomastia include: hypogonadism, hyperprolactinemia, testicular tumors (some secrete estrogens), renal failure (“A”), and liver diseases (cirrhosis). Obesity is associated with gynecomastia, but obese patients may also appear to have gynecomastia while simply having excess fat deposition in the area of the breast (sometimes called “pseudogynecomastia”).

A thorough drug history is negative. On physical examination, you find palpable, nontender tissue beneath the nipples, with slightly more prominent tissue mass on the right. The tissue is about 2 to 3 cm in diameter, and no discrete masses are palpable. There is no nipple discharge. An adult male’s hair growth pattern is evident in the axillary and inguinal areas. The testicles are normal size without masses.

Question 16.5.4 At this point in time, you recommend which of the following?

- A) Observation
- B) Referral to a surgeon
- C) Limited laboratory studies, including thyroid-stimulating hormone (TSH), testosterone, and liver enzymes
- D) Biopsy of the tissue
- E) Mammogram and/or ultrasound

Answer 16.5.4 The correct answer is “A.” As previously mentioned, physiologic gynecomastia is quite common in adolescent males. The findings on examination are reassuring. This patient does not display any other signs of testosterone deficiency, and further workup (“C,” “D,” “E”) is not indicated at this time. If there are no discrete masses on examination, a mammogram, ultrasound, or biopsy is not likely to be helpful. Referral to a surgeon is premature (“B”), as 90% of these patients experience spontaneous involution of the breast tissue over 3 years.

HELPFUL TIP:

In adolescent males with gynecomastia, further evaluation with laboratory studies and imaging is indicated if the breast tissue is rapidly enlarging or is greater than 5 cm in diameter, a mass (not normal breast tissue) is palpable, or other signs of under androgenization are present. Should the breast tissue be glandular, nonmalignant, and is causing significant embarrassment or pain, a trial of the selective estrogen-receptor modulator tamoxifen for gynecomastia may be reasonable, given its efficacy and safety profile. However, patients should be warned that use of this medication may not result in complete regression of the breast tissue despite potentially helping with pain.

You provide the patient and his mother with reassurance and have them return in a year. At follow-up, there is no palpable tissue. When you see the patient again, he is 17 years old.

He told his mother that he was having abdominal pain, but really he is worried that he may have contracted an STI. He has become fairly promiscuous and does not use condoms (after the gynecomastia disappeared, his mojo returned). In the last week he has developed dysuria and a yellowish urethral discharge. He has no other symptoms.

Question 16.5.5 Which of the following is the most likely diagnosis?

- A) HPV
- B) Syphilis
- C) Gonorrhea
- D) Trichomonas
- E) Herpes simplex

Answer 16.5.5 The correct answer is “C.” This patient’s symptoms are typical of gonococcal urethritis. However, *N. gonorrhoeae* may be present in the urethra without any symptoms and *Chlamydia trachomatis* can present with a purulent discharge that is classically thought of as gonorrhea. Gonorrhea and chlamydia cannot be reliably distinguished on clinical grounds. “A” is incorrect as HPV causes genital warts, not urethritis. “B,” syphilis, may present as a painless ulcer (primary syphilis). “D” is incorrect because most men infected with *Trichomonas vaginalis* are asymptomatic, although some will have mild urethritis. Finally, “E,” herpes simplex, presents with painful vesicles at the area of inoculation.

You obtain urine for PCR for gonorrhea and chlamydia. You discuss other STIs and decide to perform some other tests (e.g., HIV, hepatitis B, syphilis antibody).

Question 16.5.6 At this point in time, you are compelled to do all of the following EXCEPT:

- A) Recommend safer sexual practices
- B) Inform the public health services if he tests positive
- C) Treat him with antibiotics now
- D) Encourage him to contact his partners and tell them to get tested
- E) Inform his mother of your findings

Answer 16.5.6 The correct answer is “E.” In general, adolescents can seek care for STIs and be treated without parental consent. However, clinicians should refer to the laws of the state in which they practice for ultimate legal authority in this matter. Of course, the time of diagnosis and treatment should be used as an opportunity to educate the patient regarding safer sexual practices (“A”). “B” is true. Gonorrhea and chlamydia are reportable diseases in every state. Again, clinicians should refer to the laws of their state and the reporting protocols of the clinic in which they practice. Empiric treatment is the rule here, so “C” is correct. “D” is also correct since all of this patient’s partners should be contacted, tested, and treated. There are several ways to contact the partners and allowing the patient to do so is only one way. The clinician or the public health authorities could contact the partners as well.

HELPFUL TIP:

Expedited partner treatment, in which the patient being treated for an STI is also given medication for his/her partner(s), is recommended by the Centers for Disease Control and Prevention (CDC) and others. See <http://www.cdc.gov/std/ept/> for more information and the legality of the practice in your state.

Question 16.5.7 Which of the following methods maintains a high degree of sensitivity and is also the quickest and least expensive way to diagnose gonococcal urethritis in a symptomatic male?

- A) Culture
- B) Gram stain
- C) Serologic antibody assay
- D) PCR
- E) NAAT (nucleic acid amplification testing)

Answer 16.5.7 The correct answer is “B.” In symptomatic males, Gram stain of a urethral sample can identify Gram-negative diplococci (*N. gonorrhoeae*) with a sensitivity of about 90% to 95%. The sensitivity drops to about 70% in asymptomatic males. If the materials and expertise are readily available, a Gram stain is quick and inexpensive. Culture (“A”) of a urethral specimen on Thayer–Martin agar takes longer and false-negative tests can occur with high frequency (due to the need to have a CO₂-rich environment and to keep the culture in a narrow temperature range). PCR (“D”) and other nucleic acid testing are more sensitive than cultures but still not 100%. PCR is particularly attractive as a screening test, as it can be performed on urine specimens instead of urethral swab specimens. Serologic assays (“C”) for gonorrhea would not be helpful in diagnosing urethritis. “E,” NAAT is actually the most sensitive technique for detecting gonorrhea. It can be used in asymptomatic individuals, is completed in hours, and works with patient-collected specimens (urine, self-collected vaginal swab). Overall it is the preferred test. But it is not as fast as a Gram stain and is more expensive.

HELPFUL TIP:

When obtaining urine for testing of gonorrhea and chlamydia, remind the patient to perform a first-catch urine and NOT a midstream clean-catch urine. A 20 to 30 mL sample should suffice. For men-who-have-sex-with-men, urethral, oral, and rectal samples should be sent.

Question 16.5.8 Your clinical suspicion of gonorrhea is high. What is your next step?

- A) Single doses of ceftriaxone 125 mg IM
- B) Single dose of penicillin G 1.2 million units IM and erythromycin 500 mg orally QID for 7 days
- C) Tetracycline 500 mg orally QID for 10 days
- D) Single doses of ciprofloxacin 500 mg orally and cefixime 400 mg orally
- E) Single dose of ceftriaxone 250 mg IM and azithromycin 1 g orally

Answer 16.5.8 The correct answer is “E.” If there is any concern for compliance, it is best to treat the patient in the office if you have access to the appropriate antibiotics. As of 2015, the CDC recommends ceftriaxone 250 mg IM as a single dose (rather than 125 mg, due to increasing resistance) PLUS azithromycin 1 g PO for uncomplicated gonococcal urethritis. The azithromycin is given for two reasons: increasing resistance among gonococcal isolates and to cover for possible chlamydia co-infection. If ceftriaxone is not available, cefixime 400 mg PO is an acceptable alternative. **Fluoroquinolones are not recommended for gonorrhea due to high rates of resistance in some communities.** “A” is incorrect because ceftriaxone alone will not provide empiric coverage for chlamydia, and the dose is too low anyway. “B” is incorrect because penicillin should never be used to treat gonorrhea (due to the prevalence of penicillinase-producing strains of the bacteria). “C” is incorrect. Tetracycline antibiotics provide adequate coverage for chlamydia and some strains of *N. gonorrhoeae*, but other strains of *N. gonorrhoeae* are resistant to tetracyclines, so these drugs are not used as first-line agents in treating gonorrhea. “D” is incorrect because fluoroquinolones are not recommended for gonorrhea and it contains nothing for the treatment of chlamydia.

**HELPFUL TIP:**

Another equally effective regimen for chlamydia is doxycycline 100 mg BID for 7 days. This is equal in efficacy to azithromycin despite the fact that some doses may be missed. Of note, doxycycline has been in short supply periodically.

You treat this patient with ceftriaxone and azithromycin and tell him to contact his partners so that they can get treated. When your patient returns to discuss his lab tests, he is feeling much better. You tell him that he was infected with both gonorrhea and chlamydia but that the rest of his tests were negative. He is relieved that he does not have HIV, but he wonders what problems chlamydia can cause.

Question 16.5.9 *C. trachomatis* has been implicated in which of the following?

- A) Reiter syndrome
- B) Lymphogranuloma venereum
- C) Proctitis
- D) Epididymitis
- E) All of the above

Answer 16.5.9 The correct answer is “E.” A small percentage of men with chlamydia urethritis develop reactive arthritis, and a subset of these will go on to have the triad of Reiter syndrome (urethritis, arthritis, and uveitis). Lymphogranuloma venereum is also due to a particularly virulent strain of *C. trachomatis*, but it produces genital ulcers and lymphadenitis and is generally seen in tropical areas. Lymphogranuloma venereum is treated with extended courses of doxycycline (100 mg PO BID for 21 days) or azithromycin (1 g PO weekly for 3 weeks). Chlamydia

proctitis occurs almost exclusively in homosexual men and presents with rectal pain, bleeding, and discharge. Diagnosis is confirmed by rectal swab, and the treatment is the same as for chlamydia urethritis. Epididymitis is most often the result of infection with *C. trachomatis* or *N. gonorrhoeae* in younger individuals (contrast to *E. coli* and *Pseudomonas* in those over the age of 35). Urethral strictures are also commonly related to prior STIs.

**HELPFUL TIP:**

The majority of males (and females) who are infected with chlamydia and/or gonorrhea **do not have symptoms**. Therefore, there is a good argument to be made for screening asymptomatic males (and females) in high-risk populations (e.g., adolescents, young adults, and those with multiple sexual partners). For females, see Chapter 15.

► **Objectives: Did you learn to ...**

- Define gynecomastia and understand its causes?
- Identify when to initiate further evaluation in a patient with gynecomastia?
- Recognize symptoms of gonorrhea and chlamydia?
- Initiate treatment in a male with urethritis?
- Recognize manifestations of chlamydia infection in men?

**QUICK QUIZ: AN INFLAMED GLANS**

A 36-year-old male diabetic patient presents with a 3-day history of irritation, itching, dysuria, and redness at the tip of his penis (Fig. 16-9). He is monogamous with his wife, and he denies any history of high-risk sexual behavior or STIs. On examination, you find an afebrile patient in no acute distress. The penis is circumcised, and the glans penis is red, tender, and edematous. There are numerous small, white papules on the glans.

Which of the following is the most appropriate treatment?

- A) Sitz baths and improved hygiene
- B) Oral doxycycline
- C) Topical bacitracin
- D) Topical miconazole
- E) Topical steroids

The correct answer is “D.” This patient has balanitis, which is defined as an inflammatory condition of the glans penis (balanoposthitis is the name applied to inflammation of the glans and foreskin). Some authors believe that balanitis is a noninfectious, inflammatory condition. Others implicate infectious causes. Of infectious causes, the most common is *Candida albicans*, especially in diabetic patients. This patient has classic findings of candidal balanitis and is diabetic. Therefore, the most appropriate therapy is a topical antifungal agent, such as miconazole (“D”). Fluconazole is an option. Topical and oral antibiotics (“B”, “C”) will not help, and topical steroids (“E”) should be avoided. Sitz baths and improved hygiene (“A”) should be encouraged, but they should not be employed without an antifungal agent.

FIGURE 16-9. Candidal Balanitis. Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds). *The Atlas of Emergency Medicine*. 4th ed. New York: McGraw-Hill, 2016, Fig. 8.33. (Photo contributor: Kevin J. Knoop, MD, MS.)

▶ CASE 16.6

While covering the emergency department (ED), a 40-year-old male presents with a painful erection that began 4 hours ago “out of the blue” (perhaps after he took too many little “blue pills”).

Question 16.6.1 Which of the following is true regarding priapism and normal erections?

- A) Normal erections can last up to 12 hours, so this is not priapism
- B) Abnormally prolonged sexual desire can “convert” a normal erection into priapism
- C) The corpus spongiosum and glans penis are not involved in priapism
- D) Acute urinary retention may lead to priapism and vice versa
- E) All of the above are true statements

Answer 16.6.1 The correct answer is “C.” Priapism is defined as the prolonged engorgement of the penis (or—rarely—the clitoris in females), unrelated to sexual desire or stimulation. The word priapism comes from the Greek god Priapus, apparently well known for his lasciviousness and generous genital endowment. In most cases of priapism, the corpus spongiosum and glans penis are not involved. Only the corpora cavernosa are engorged and rigid. Priapism typically lasts longer than 6 hours (thus making “A” incorrect), whereas normal erections

TABLE 16-1 DRUGS ASSOCIATED WITH PRIAPISM

Psychotropics

- Trazodone
- Chlorpromazine

Agents used to treat erectile dysfunction

- Intracavernosal injections (e.g., papaverine)
- Phosphodiesterase inhibitors (e.g., sildenafil)

Antihypertensives

- Hydralazine
- Prazosin

Anticoagulants

- Heparin

Drugs of abuse

- Alcohol
- Cocaine
- Marijuana

last minutes to hours. With normal erections, detumescence occurs after ejaculation or after the stimulus is removed. This is not the case with priapism, and sexual desire does not play a role in the development of priapism; thus, “B” is incorrect. “D” is also incorrect. Urinary retention is not thought to cause priapism, and priapism does not lead to urinary retention.

Question 16.6.2 Priapism may be secondary to all of the following EXCEPT:

- A) Sickle cell disease
- B) Penile trauma
- C) Leukemia
- D) Iron deficiency anemia
- E) Trazodone use

Answer 16.6.2 The correct answer is “D.” A number of different disease states and drugs have been implicated in the etiology of priapism. In one way or another, these diseases and drugs affect the balance of blood flow into the penis, leading to increased arterial blood flow and/or decreased venous outflow. Local malignancies, such as bladder and prostate cancers, can cause obstruction. Likewise, any condition that increases blood viscosity (e.g., sickle cell disease, polycythemia, leukemia) or results in thromboembolic phenomena (e.g., vasculitis) can cause priapism. Penile trauma that results in laceration of penile arteries can cause priapism. Numerous drugs have also been implicated (see Table 16-1), but, in most cases, the cause of priapism is not identified.

Question 16.6.3 What is your next step in management of this patient?

- A) Reassurance
- B) Call for emergent urologic consultation
- C) Give oral alpha-blockers
- D) Engage patient in guided imagery to lead his thoughts away from sex

Answer 16.6.3 The correct answer is “B.” Priapism is a urologic emergency and needs to be treated ASAP. All the other answers (“A,” “C,” “D”) could result in your undesired new title of “defendant.” Until the urologist arrives, conservative measures

are probably best, and you should try to make the patient comfortable using analgesics, oxygen, and hydration. Check a CBC since leukemia can rarely present with priapism. Some patients will respond to analgesics and ice packs. Oral or subcutaneous terbutaline may be helpful. Some authors recommend sedatives, such as benzodiazepines.

HELPFUL TIP:

If a urologist is not available and/or you are comfortable performing the procedure (and you have a good lawyer), you can attempt detumescence. A needle is inserted into the corpora cavernosa and blood is withdrawn. Then a vasoactive agent (e.g., phenylephrine) is injected. This procedure is repeated every 5 minutes until detumescence occurs. It should go without saying that the patient's vital signs must be closely monitored during this intervention because they will likely need sedation.

HELPFUL TIP:

After recovery, about 50% of men with priapism suffer erectile dysfunction. Penile implants are an option.

► Objectives: Did you learn to ...

- Recognize priapism and its causes?
- Manage a patient with priapism?

QUICK QUIZ: DEPRESSION AND SUICIDE

Which of the following groups has the highest rate of death by suicide?

- A) Black males
- B) White males
- C) Black females
- D) White females
- E) Hispanic males

The correct answer is "B." In the United States, white males make up about 70% of all deaths due to suicide. Although females account for more suicide attempts, males are at greater risk of death from suicide. Men tend to use deadlier means, such as guns, hanging, and car collisions. In other words, men are very efficient at suicide. White men older than 85 years have one of the highest rates of death due to suicide: 59/100,000 (with the rate in the general public being 10.6/100,000). As a group, black males have the second highest rate of suicide. Of those groups listed above, black females have the lowest risk of death from suicide.

► CASE 16.7

A 78-year-old male presents for follow-up after an emergency department visit last week. He sustained a fall that resulted in a T11 compression fracture. You obtained a

DEXA scan to confirm that he has osteoporosis and found that his T-score is indeed osteoporotic-range. Just to be on the safe side, you order a bunch of laboratory tests, all of which are normal except for serum testosterone. Lo and behold, his testosterone level is very low. He's also been tired, felt weak, and lost his libido. Because he knows we need to cover testosterone supplementation in this book, he asks you, "Should I be on one of those fancy testosterone supplements?"

Question 16.7.1 Which of the following testosterone supplementation products would you AVOID?

- A) Transdermal testosterone patches
- B) Buccal testosterone tablets
- C) Oral testosterone tablets
- D) Intramuscular testosterone injections
- E) Transdermal testosterone gel

Answer 16.7.1 The correct answer is "C." Oral testosterone should be avoided due to significant first-pass metabolism and potential liver toxicity. The other choices listed are viable options for testosterone replacement (see Table 16-2). The IM option is not the best for a steady state, but patients often like it due to the peaks.

TABLE 16-2 TESTOSTERONE SUPPLEMENTATION PRODUCTS

Agents	Dosages	Comments
Buccal tablet (Striant)	Dosed 30 mg BID and must be kept beside buccal mucosa	The product does not dissolve completely
Transdermal gels (Androgel, Fortesta, Testim)	Dosed daily	Cover the application area to reduce risk of spreading by contact with others
Transdermal patch (Androderm)	Applied daily	Rotate sites to reduce skin irritation
Scrotal patches (Testoderm)		Now rarely used due to scrotal irritation and more acceptable alternatives
Intramuscular injections (Depo-testosterone, Delatestryl)	Dosed every 2–4 weeks	Serum testosterone levels fluctuate significantly between doses
Subcutaneous pellets (Testopel)		These are implanted (like Norplant) and are rarely used for supplementation
Oral agents (methyltestosterone)		Not available in the United States; significant first-pass metabolism, fluctuating serum levels, and risk of liver toxicity

**HELPFUL TIP:**

If a male patient with osteoporosis has testosterone deficiency, testosterone supplementation may be a reasonable treatment option, but the efficacy of testosterone in this scenario is **not** well established. Although testosterone contributes to peak bone mass in young men and low testosterone is associated with an increased fracture risk in older men, testosterone for the treatment of osteoporosis has been **disappointing**.

Question 16.7.2 Which of the following is true regarding testosterone supplementation in older men with testosterone deficiency?

- A) Testosterone supplementation has markedly beneficial effects on depression
- B) The effects of testosterone supplementation in young hypogonadal males and older testosterone-deficient males are the same
- C) In testosterone-deficient older males with erectile dysfunction, testosterone supplementation dramatically improves erections
- D) In testosterone-deficient older males with poor libido, testosterone supplementation improves libido
- E) Testosterone supplementation has no effect on lean muscle mass or grip strength

Answer 16.7.2 The correct answer is “D.” In testosterone-deficient older males, testosterone supplementation does improve libido. Unfortunately, “C” is incorrect: its effects on erectile dysfunction are not impressive. Even in testosterone-deficient men with erectile dysfunction, a phosphodiesterase inhibitor (e.g., sildenafil) is more likely to be successful. In terms of the neuropsychiatric effects of testosterone, many questions are as yet unanswered. However, testosterone supplementation does not appear to significantly affect depression, so “A” is incorrect. Furthermore, testosterone replacement does not replace the need for antidepressants if depression is the cause of symptoms. “B” is not true. Young hypogonadal males who are treated with testosterone have increased peak bone mass and virilization. But the effects on older males are different: older males have improved strength, libido, and sense of well-being without some of the effects seen in the young hypogonadal males. “E” is incorrect because testosterone has been shown to consistently improve lean muscle mass and grip strength.

**HELPFUL TIP:**

Hypogonadal males should **not** take testosterone replacement while trying to impregnate their partners because it will further decrease their sperm counts (due to the effect of exogenous testosterone feeding back on the hypothalamic–pituitary–gonadal axis). To improve fertility in these patients, unproven empiric therapy is often used, including clomiphene, human chorionic gonadotropin, and gonadotropin-releasing hormone.

**HELPFUL TIP:**

Topical testosterone can have an androgenizing effects on women and children if they come in contact with the gel on a male's skin. Patients should be warned of this.

You have a conversation with your patient about starting testosterone therapy. He would like to try it. Those direct-to-consumer marketing campaigns really work!

Question 16.7.3 You tell him about adverse effects and monitoring and tell him it is important to periodically check:

- A) Hematocrit
- B) Potassium
- C) Alanine aminotransferase
- D) A and B
- E) A and C

Answer 16.7.3 The correct answer is “E.” There are good reasons behind the recommendation for periodic monitoring with certain serum tests. Testosterone increases erythropoietin production and can cause erythrocytosis. In fact, testosterone should not be started in a patient with a hematocrit greater than 50% (or severe heart failure or untreated sleep apnea). Testosterone can cause elevated liver enzymes, increased cholesterol, and growth of prostate and breast tissue, including prostate and breast cancers. Prostate examination and PSA are recommended prior to starting therapy and periodically while on testosterone. Of course, it makes sense to periodically monitor serum testosterone levels to assure that the patient is in the normal range and not sub- or supratherapeutic. Potassium (“B”) is not directly affected and no monitoring is recommended.

**HELPFUL TIP:**

In 2015, the FDA required updated labeling of testosterone products to add information about the possible increased risk of cardiovascular events. The risk–benefit ratio of testosterone products appears to NOT weigh in their favor.

► **Objectives: Did you learn to ...**

- Identify testosterone replacement products and discuss how older males might benefit (or not) from them?
- Recognize some of the risks associated with testosterone supplementation?

► **CASE 16.8**

A 50-year-old male presents for a “get acquainted” visit. He has a history of hyperlipidemia treated with lovastatin. He takes no other medications and states that he is otherwise healthy. After watching a television feature called “What’s

Killing Us Now: Prostate Cancer,” he thought he should be screened.

Question 16.8.1 In order to assess his risk for prostate cancer, you should take into account all of the following factors EXCEPT:

- A) Age
- B) Race
- C) Family history
- D) Cigarette smoking
- E) Ultraviolet light exposure

Answer 16.8.1 The correct answer is “E.” Ultraviolet light exposure increases the risk of skin cancer but not prostate cancer (after all, it is located where “the sun don’t shine”). Advancing age (“A”) is strongly and directly associated with the development of prostate cancer. Between ages 50 and 70 years, the incidence of prostate cancer more than quadruples, and it continues to increase thereafter. Black ancestry (“B”) and positive family history (“C”) carry the strongest associations with prostate cancer. Cigarette smoking (“D”) has been linked to an increased risk of prostate cancer, but not with the strength of association of age or family history. Interestingly, dietary factors may have a role in the development of prostate cancer, although the associations are not strong and studies conflict. A diet rich in fish and vegetables and low in red meat may reduce the risk of prostate cancer.

.....
Your patient is Caucasian and denies any family history of prostate cancer. He has no urinary symptoms and denies sexual dysfunction.

Question 16.8.2 If he did have urinary symptoms, which of the following could be used to reliably distinguish BPH from prostate cancer?

- A) Urgency
- B) Nocturia
- C) Frequency
- D) Hesitancy
- E) None of the above

Answer 16.8.2 The correct answer is “E.” A male who presents with urinary symptoms of urgency, nocturia, frequency, and/or hesitancy is more likely to have BPH and not prostate cancer. These urinary symptoms are incredibly common in older persons in general and most often are benign in nature. In fact, “BPH symptoms” (better termed lower urinary tract symptoms or “LUTS”—really) are common in older women as well. However, urinary tract cancers (including prostate and bladder cancers) can present with these symptoms and must be considered. The point is that we cannot always attribute urinary symptoms in an older male to BPH.

.....
You discuss prostate cancer screening with him, presenting the controversial and conflicting guidelines, discussing positive and negative values of lab tests (and what they

signify) using a dry erase board and giving a mini-lecture. Twenty minutes later he says, “It’s just a blood test right? I think I want one ounce of prevention, you understand, Doc.” He gets “the works”: digital rectal examination and PSA. The examination is remarkable for a slightly enlarged, smooth, nontender prostate without nodules. The PSA level is 16 ng/mL (reference range for your lab 0–4 ng/mL).

Question 16.8.3 The most appropriate next step is to:

- A) Repeat the PSA in 3 to 6 months
- B) Order a transrectal ultrasound of the prostate
- C) Refer to urology for further evaluation and prostate biopsy
- D) Repeat the rectal examination and try to find the nodule that you missed
- E) Order a free PSA

Answer 16.8.3 The correct answer is “C.” To use the Monopoly® line: go directly to the urologist; do not pass GO. If he had symptoms of prostatitis, you might try treating with an appropriate antibiotic for 4 weeks and repeating the PSA to confirm elevation before referral. But this patient is completely asymptomatic. He is at relatively high risk of having prostate cancer based on his PSA level (16—that’s high, in case you were uncertain) and age at presentation. Sending him to a urologist for prostate biopsy is the most prudent step. Follow-up PSA alone (“A”) would be more defensible if the PSA level were <10 ng/mL and/or the patient were much older. “B,” a transrectal ultrasound, is likely to miss more than it would find in this case. With this patient’s PSA and current life expectancy, ultrasound should only be used as part of a larger urologic evaluation, including biopsy. “D,” repeating the rectal exam, is just nuts. There is no need for this. Did you miss a nodule? Maybe. Would it hurt your ego? Who cares! You will eventually get over it. More likely, there was no palpable nodule. This patient could have stage T1 prostate cancer in which, by definition, no nodules are palpable. He could have a nodule located anteriorly in the prostate—a location you cannot palpate. He also may have a PSA elevation for reasons other than prostate cancer. Finally, “E” is incorrect. The free PSA is most helpful when the total PSA is in the intermediate risk zone (4.01–10 ng/mL). When the PSA is higher (>10 ng/mL), the risk of cancer is too great to make the free PSA useful. The fraction of PSA that is “free” (not bound to plasma proteins) is inversely proportional to risk of prostate cancer: the lower the free PSA compared with total PSA, the greater the risk of prostate cancer (cutoff percentages vary from 10% to 25%).

HELPFUL (OR NOT SO HELPFUL) TIP:

The determination of when to send a patient for prostate biopsy is made on clinical grounds and must take into account the patient’s risk, comorbidities, examination findings, PSA level, possibility of false-positive or -negative tests, patient’s preference, etc. This decision cannot be made based on an arbitrary PSA value.

Question 16.8.4 Which of the following is true of the PSA test when used for screening purposes?

- A) The positive predictive value approaches 100%
- B) Since PSA testing has become widespread, prostate cancer incidence and mortality have increased
- C) The false-negative rate is 20% to 25%
- D) Age-specific cutoff values for PSA have proven to increase positive predictive value and specificity
- E) Race-specific cutoff values for PSA have proven to increase positive predictive value and specificity

Answer 16.8.4 The correct answer is “C.” There is a substantial false-negative rate—from 20% to 25%—limiting the use of PSA for screening purposes. “A” is incorrect by a long shot. The positive predictive value (likelihood of a positive test indicating true prostate cancer) ranges from about 20% to 60%, depending on the PSA level. The positive predictive value increases with increasing PSA level. “B” is incorrect. Since the PSA test has come into widespread use, the incidence of prostate cancer has increased, but mortality due to the disease has decreased. The reason for these trends has not been completely explained, and the role of the PSA test in these trends is not known. “D” and “E” are incorrect. Since older males seem to have higher PSA values in the absence of prostate cancer and black males tend to have prostate cancer found at lower PSA levels, age-specific and race-specific cutoff values have been proposed and investigated. However, the use of age-specific and race-specific PSA cutoff values is of questionable value.

HELPFUL TIP:

The 5-year survival rate of prostate cancer is about 99%. While the lifetime prevalence of prostate cancer is about 14%, the lifetime risk of dying of prostate cancer is less than 3%. For older men, we often hear, “You are more likely to die **with** prostate cancer than **of** prostate cancer.” This saying appears rooted in reality.

Once again, your winning personality and reputation for thorough care has won you a referral! Your patient refers a friend to you. Your new patient is a 60-year-old male who presents to your clinic for advice regarding treatment after recently being diagnosed with prostate cancer. A urologist recommended surgery but he wants to know what you think. (Don't let it go to your head.)

Question 16.8.5 Possible treatment options for prostate cancer include all the following EXCEPT:

- A) External beam radiation
- B) Saw palmetto
- C) Active surveillance
- D) Robotic prostatectomy

Answer 16.8.5 The correct answer is “B.” While over-the-counter saw palmetto is sometimes taken by patients for BPH even though it has not been proven to be effective, it is not

used for prostate cancer treatment. External beam radiation (“A”), brachytherapy, surgery (open, laparoscopic, or robotic prostatectomy [“D”]), and androgen deprivation therapy are options considered for higher-risk prostate cancers. Watchful waiting and active surveillance (“C”) are options considered for lower-risk prostate cancers. Active surveillance consists of scheduled PSA testing and digital rectal examinations every 3 to 6 months and repeat prostate biopsies at 1- to 3-year intervals.

HELPFUL TIP:

It is important to realize that there is great controversy over the role of digital rectal examination and PSA in screening for prostate cancer. They are not considered “good” screening tests (high rate of false positives and false negatives), but there is nothing else to offer at this time. In 2013, the American Urological Association (AUA) changed their guidelines to screening ages 55 to 69 every other year, and continue to recommend this over yearly screening in this population as of their 2018 review (though they note re-screening can be individualized based on a baseline PSA level). In 2012, the US Preventive Services Task Force recommended against prostate cancer screening. However, as of a 2018 update, USPSTF adopted a tiered screening approach like the AUA, with both organizations recommending: (1) a weighing of risks and benefits of prostate cancer screening between patient and healthcare provider to arrive at a shared decision on the matter for men ages 55 to 69 and (2) not routinely screening men > 70 years old. The AUA also notes screening should not be done for a man with a less than 10- to 15-year life expectancy as well as men ages 40 to 54 at average risk and any man <40 years old. The two largest studies of prostate cancer screening with PSA (the Prostate, Lung, Colon, and Ovarian Cancer Screening Trial [PLCO] and the European Randomized Study of Screening for Prostate Cancer [ERSPC]), done to answer the question of how PSA screening affects mortality, arrived at opposite conclusions (PLCO showed no mortality effect with screening, while the ERSPC showed a prostate cancer-specific mortality reduction with PSA screening). However you approach this issue, you're not alone, and the company you keep is just as confused.

► **Objectives: Did you learn to ...**

- Identify risk factors for prostate cancer?
- Discuss prostate cancer screening with a patient?
- Interpret an elevated PSA?
- Recognize the limitations of prostate cancer screening?
- Recognize various treatment options for prostate cancer?

► CASE 16.9

A 32-year-old male accompanied by his wife presents for evaluation of infertility. They have been married for 5 years and have been attempting conception for 3 years without success. The patient's wife has a 7-year-old daughter from a previous marriage. The patient has no significant past medical or surgical history. He does not smoke, but he drinks a six-pack of beer and one cup of coffee daily—not necessarily in that order. He relaxes after work and on weekends by sitting in their hot tub for hours at a time. His BMI is 32 kg/m². He has normal facial and body hair and his testicles are descended bilaterally and of normal size. You note a moderate-sized varicocele on the left.

Question 16.9.1 Which of the following is *not* a modifiable risk factor for male subfertility?

- A) Alcohol intake
- B) Hot tub usage
- C) Varicocele
- D) Tobacco use
- E) Obesity

Answer 16.9.1 The correct answer is “D.” We should note that the study of infertility risk factors and treatments is complicated by inconsistent outcome measures (e.g., sperm count, sperm motility, conception, pregnancy resulting in live birth). However, there are no conclusive studies correlating tobacco use with male subfertility. The other answers are modifiable risk factors and have been directly linked to subfertility, either in decreased sperm count or in decreased sperm motility. It is important to ask about alcohol use (“A”). Other drug use, such as marijuana, should be investigated as well since it can affect sperm quality and motility (poor little guys can’t swim straight when stoned). “B” is true. Hot tub usage, febrile illnesses, and the presence of a varicocele raise the temperature of the testicles, thereby decreasing the optimal environment for the maturation of sperm. But how about the boxers versus briefs controversy? Type of underwear does not seem to affect scrotal temperature significantly, and more to the point, tight underwear is not associated with decreased fertility. The presence of a varicocele (“C”) is an interesting issue. It is certainly modifiable in that the patient could undergo a varicocelectomy, which might help if the varicocele is moderate to large in size. However, the degree to which a varicocele contributes to infertility is not well-known. Varicoceles are noted to occur more commonly in infertile men, but they also occur in 10% to 15% of the normal, fertile male population. Obesity (“E”) contributes to the increased peripheral aromatization of testosterone into estradiol in fatty tissue. Other factors that contribute to subfertility/infertility include a history of cryptorchidism, hypospadias, viral orchitis after puberty, prior chemotherapy or radiation, intake of calcium channel blockers, and retrograde ejaculation associated with diabetes and multiple sclerosis.

HELPFUL TIP:

Infertility in a couple is defined as inability to conceive despite 1 year of frequent (how frequent is not defined), unprotected sexual intercourse. In the United States, the prevalence of infertility is 7% to 15% depending on how the statistic is measured.

Question 16.9.2 You order a seminal fluid analysis (SFA), and the sperm density is 12 million/mL with a motility of 35%. This finding is:

- A) Normal for both sperm count and motility
- B) Normal for sperm count but abnormal for motility
- C) Abnormal for sperm count but normal for motility
- D) Abnormal for both sperm count and motility
- E) Scary; that seems like a lot of sperm

Answer 16.9.2 The correct answer is “D.” As a general rule, normal sperm concentration for fertility is considered to be 15 million/mL or greater. However, as they say, it only takes one sperm to make a baby, so men with lower sperm counts can be fertile. At least 40% or more should be motile. Another finding of importance on SFA is the sperm morphology. Using strict criteria, normal morphology should be 4% or more (yes, unfortunately for men, only 4%).

You repeat the SFA 2 weeks later, and again it is abnormal. His testosterone level is low for his age, and his FSH and LH are high.

Question 16.9.3 Which of the following is most likely to be the cause of his decreased fertility?

- A) Congenital absence of the prostate gland
- B) Primary hypogonadism
- C) Bilateral complete vas deferens obstruction
- D) Androgen resistance

Answer 16.9.3 The correct answer is “B.” A low testosterone level accompanied by elevated LH and FSH could indicate testicular failure (primary hypogonadism). “A” is not a known cause of infertility, and in fact it is not a known disorder as far as the editors can determine. The prostate gland’s only important function is to provide a subject for an endless debate over screening so that epidemiologists have something to do. Just kidding... The prostate gland actually has a role in producing important substances that are part of the seminal fluid and assist sperm in their migration through the female genital tract. However, prostate problems do not seem to cause infertility. “C,” an obstruction of the vas deferens, would most likely result in azoospermia with normal or high testosterone levels. “D” is incorrect. You would expect to see elevated testosterone levels in patients with androgen resistance. See Table 16-3 for a list of causes of infertility in males.

TABLE 16-3 A PARTIAL LIST OF CAUSES OF MALE INFERTILITY

Mechanism	Specific Examples
Hypothalamic–pituitary disorders	Congenital disorders (Kallmann syndrome), pituitary tumors, pituitary infarction, hormonal or psychotropic drug use
Primary hypogonadism	Klinefelter syndrome, cryptorchidism, alcohol use, chemotherapeutic agents, testicular torsion, hyperthermia
Disorders of sperm transport	Congenital absence of the vas deferens, epididymal dysfunction, spinal cord injury
Idiopathic infertility	Unexplained satisfactorily by history, examination, and laboratory evaluation

Question 16.9.4 How can you now best help this patient achieve fertility, assuming that there are no problems with his partner?

- A) Empiric treatment for gonorrhea and chlamydia
- B) Empiric treatment with testosterone injections
- C) Empiric treatment with gonadotropin-releasing hormone
- D) Referral to an infertility treatment center

Answer 16.9.4 The correct answer is “D.” At this point of time, you have performed a reasonably complete evaluation and even arrived at a potential cause of infertility. However, treatments for male infertility are the subject of much debate, and the patient is probably best served by referral to an infertility treatment specialist. “A” is incorrect. Genital infections are not thought to play a major role in male subfertility/infertility, so, without clear evidence of gonorrhea and/or chlamydia, treating for these diseases is not recommended. “C” is incorrect because this patient does not appear to have a hypothalamic source for his infertility. “B,” testosterone injection, can actually make the problem worse. The most effective therapy for patients with infertility and primary hypogonadism (i.e., this patient) may be sperm retrieval for intracytoplasmic sperm injection (not typically thought of as an office procedure for the family physician).

You refer this gentleman to an infertility treatment center in your neck of the woods. He is so pleased with your attention to detail and well-reasoned approach that he refers his best friend to you for the same problem—infertility. This new patient reports never conceiving, although his wife has had one child from a previous marriage. On physical examination, you note a thin frame, mild symmetric gynecomastia, and small, firm testicles. He has complete azoospermia on two semen analyses (Fig. 16-10).

FIGURE 16-10. Klinefelter syndrome in a 20-year-old male. This photo demonstrates classic features of the syndrome, including gynecomastia, small penis, sparse body hair, and female pubic hair distribution. Used with permission from Gardner DG, Shoback D. *Greenspan's Basic & Clinical Endocrinology*, 10th ed. New York: McGraw-Hill Education, 2018, Fig. 12-7.

Question 16.9.5 His most likely diagnosis is:

- A) Cystic fibrosis
- B) Psychosomatic azoospermia
- C) Klinefelter syndrome
- D) Testicular cancer
- E) Turner syndrome

Answer 16.9.5 The correct answer is “C.” The triad of small firm testicles, gynecomastia, and azoospermia are classic findings in patients with Klinefelter syndrome. Klinefelter syndrome occurs in 1 in 1,000 live male births and is responsible for 14% of cases of azoospermia. The most common (90%) chromosomal abnormality in Klinefelter syndrome is 47,XXY. “A” is incorrect. Although males with cystic fibrosis can have congenital absence of the vas deferens, these patients usually have normal-sized testicles and no gynecomastia. “B” is, of course, not a real thing. “D” is incorrect. Patients with testicular cancer usually have an enlarged testicle with a mass on the surface or inside the testicle. Although the treatments for testicular cancer may result in infertility, patients with testicular cancer do not typically present with infertility. “E” is incorrect. Turner syndrome (45,X) is associated with unambiguously female genitalia with no breast development.

► **Objectives: Did you learn to ...**

- Define modifiable risk factors for male subfertility/infertility?
- Recognize the significance (or lack of significance) of a varicocele?

- Identify the appropriate indications for obtaining laboratory studies in male patients with infertility concerns?
- Recognize some important causes of infertility?

▶ CASE 16.10

A 63-year-old male with a history of insulin-dependent diabetes complains of decreased libido and difficulty maintaining an erection, worsening over the past few years. He does have occasional erections sufficient for penetration and awakens with an erection at times. His medical history is also significant for hypertension and an appendectomy. His medications include insulin, lisinopril, and hydrochlorothiazide. He has been married for 30 years and has two grown children, ages 24 and 26.

Question 16.10.1 Which of the following historical elements is NOT likely to contribute to this patient's erectile dysfunction?

- A) Diabetes
- B) Depression
- C) Hypertension
- D) History of appendectomy
- E) Antihypertensive medications

Answer 16.10.1 The correct answer is "D." We're checking to see if you're still awake. All the other options could cause some degree of erectile dysfunction. Any disease process that affects the nervous, vascular, endocrine, or smooth-muscle systems can result in erectile dysfunction. A partial list of other risk factors for erectile dysfunction includes advancing age, prostate disease or prostate surgery (if the nerves are cut ... not an issue with TURP), pelvic fracture, alcohol or other substance abuse, medications (addressed later), spinal radiculopathy or spinal cord injury, multiple sclerosis, endocrine disorders (e.g., hypothyroidism, hyperthyroidism), smoking, cardiovascular disease, chronic renal failure, and Peyronie disease (a localized plaque-like fibrosis leading to possible erectile dysfunction, penis curvature, shortening of the penis).

HELPFUL TIP:

There are two categories of erectile dysfunction—psychogenic and organic. In men younger than 35 years, psychogenic erectile dysfunction is much more common. In contrast, men older than 50 years are more likely to have an organic cause for their erectile dysfunction.

Question 16.10.2 What further historical element(s) is/are useful in the evaluation of erectile dysfunction?

- A) Rapidity of onset of sexual dysfunction
- B) Presence of nocturnal erections
- C) Status of relationship with the sexual partner
- D) Partner's interest in sex
- E) All of the above

Answer 16.10.2 The correct answer is "E." Further history should involve all the elements listed. Patients with a sudden onset of erectile dysfunction often have a primary psychogenic erectile dysfunction. The presence of nocturnal erections establishes that the patient's neurologic and vascular mechanisms work to produce an erection. An organic disorder may still be playing a role, but the circuit is working. The status of the relationship with the patient's partner, his attraction to that partner, and the partner's interest in sex are important. If the patient and his partner are having relationship problems outside of the sexual arena, counseling may be the best first step in trying to address the erectile dysfunction.

Question 16.10.3 All of the following drugs or classes of drugs can adversely affect male sexual function EXCEPT:

- A) Cimetidine
- B) Chlorthalidone
- C) Prednisone
- D) Clonidine

Answer 16.10.3 The correct answer is "C." There are many drugs, prescription and recreational, which affect sexual function, and some of these include antihypertensives, antidepressants, antipsychotics, anxiolytics, hormonal agents (e.g., antiandrogens, estrogens, progestational agents, and anabolic steroids), and the H₂ blocker cimetidine (but apparently not ranitidine or famotidine). The effects range from decreased libido to impotence and/or ejaculatory dysfunction. Various recreational drugs such as alcohol, marijuana, heroin, and cocaine may initially cause a state of disinhibition and enhanced libido. However, excessive or chronic use leads to erectile dysfunction. Prednisone is not known to cause significant erectile dysfunction.

On physical examination, you find normal genitalia, normal femoral and dorsalis pedis pulses, appropriate virilization, and slightly diminished sensation at the plantar aspects of the feet with an otherwise intact neurological examination.

Question 16.10.4 Which of the following will be most useful in evaluating a cause for his erectile dysfunction and directing further therapy?

- A) BUN and creatinine
- B) TSH
- C) PSA
- D) Nocturnal penile tumescence study
- E) Arterial and venous Doppler studies

Answer 16.10.4 The correct answer is "B." With the advent of safe and efficacious therapy for erectile dysfunction, many clinicians proceed directly to a medication trial without laboratory studies. In many patients, this approach is acceptable. Other patients may benefit from a limited laboratory evaluation—especially those men with other symptoms and/or comorbidities. Initial labs might include TSH, testosterone, and prolactin. If not done already, screening for diabetes and vascular risk (e.g., lipids) is appropriate. The role of nocturnal penile tumescence

is debated, but it is not necessary prior to a therapeutic trial (additionally, this patient reported having nocturnal erections anyway). BUN and creatinine ("A"), and PSA ("C") are not likely to be helpful. Doppler flow studies ("E") of femoral vessels are unlikely to change therapy as long as the physical examination demonstrates normal distal blood flow. You know this patient has vascular disease (remember his diabetes, hypertension, and now erectile dysfunction), so his treatment should already involve lowering his vascular risk factors.

Question 16.10.5 Concurrent use of which of the following drugs is an absolute contraindication to taking a phosphodiesterase type 5 inhibitor (e.g., tadalafil, vardenafil, sildenafil)?

- A) Hydrochlorothiazide
- B) Isosorbide dinitrate
- C) Testosterone
- D) Finasteride
- E) Saw palmetto

Answer 16.10.5 The correct answer is "B." In patients who take nitrates for coronary heart disease, phosphodiesterase inhibitors are contraindicated. The combination has been shown to cause hypotension, in rare cases severe enough to result in stroke. While concurrent use of finasteride ("D") is safe, the alpha-blockers used to treat BPH are another story (see below). Drugs that inhibit cytochrome P450 isoenzyme (such as cimetidine, erythromycin, clarithromycin, itraconazole, ketoconazole, and HIV protease inhibitors) may warrant phosphodiesterase inhibitor dosage reductions. Caution with phosphodiesterase inhibitors is advised in patients with uncontrolled hypertension, recent stroke or myocardial infarction, life-threatening arrhythmias, unstable angina, or heart failure. Other potential medical therapies for erectile dysfunction include testosterone supplementation ("C") and yohimbine. There are even more treatment modalities: sex therapy, vacuum erection devices, intracavernosal injection therapy, intraurethral pharmacotherapy, arterial revascularization (not routinely performed strictly for ED), penile prosthesis implantation, and combined therapy.

HELPFUL TIP:

There is not much difference between the various phosphodiesterase inhibitors on the market. The efficacy is about the same. Side-effect profiles are similar. Onset of action is about the same. Tadalafil has the longest half-life. In December 2017, sildenafil became generic, and in October 2018, tadalafil became generic. However, pills remain expensive even for generic medications—up to \$25 to \$50 per tablet, though coupons can reduce the price of the medication down to as little as \$5 to \$6 per tablet (prices per time of writing of this book). Want to be tricky? Prescribe the 20-mg tablets of sildenafil that are used for pulmonary hypertension. They are only about \$1 each. Have your patient take three to five tablets. They will need to pay out-of-pocket, but they will very likely save money.

You start the patient on sildenafil. He discovers love again, but his wife finds out. Now you're in trouble!

► Objectives: Did you learn to ...

- Evaluate a patient with erectile dysfunction?
- Describe various etiologies of erectile dysfunction?
- Identify medications that affect erectile function?
- Recognize indications, contraindications, and side effects of therapeutic modalities for erectile dysfunction?

Clinical Pearls

- Do not delay an urgent urological consult for the treatment of priapism as this is a urological emergency.
- Do not perform prostatic massage if there is a suspicion for prostatitis due to the risk of seeding bacteria into the bloodstream.
- Do not use oral testosterone replacement therapy as there is a significant first-pass metabolism and potential for liver toxicity.
- Engage in a shared discussion about the use of PSA in screening for prostate cancer, potential benefits, and potential negative consequences prior to deciding to perform screening. Do not offer screening PSA to patients with life expectancy less than 10 years.
- Routinely screen young male patients for high-risk behaviors as trauma is the leading cause of death in young men.
- Screen for potential secondary causes of erectile dysfunction prior to prescribing medication.
- Screen young boys for cryptorchidism by doing a genital and testicular examination at well-child visits.

Dermatology

Megan H. Noe and Karolyn A. Wanat

Since dermatology is a visual science, take a look at pictures at www.dermnet.org.nz/sitemap.html or www.dermnet.com. We are not able to include pictures of every disease mentioned. See Table 17-1 for commonly used dermatology terms.

► CASE 17.1

A 37-year-old white female presents to clinic for her annual well-adult physical examination. After a complete skin examination, you find a suspicious lesion on her back (Fig. 17-1). It measures 16 mm × 8 mm. She has approximately 20 nevi that appear normal. The patient reports never performing self-skin examinations and does not know if the lesion is new. She denies any symptomatic lesions. Her family history is remarkable for “skin cancer” on her father’s side. Many family members have

“tons of moles.” She frequented a tanning parlor in college (too much free time ... probably majored in communications) and occasionally still does so before social events (didn’t learn much about skin health in college).

Question 17.1.1 How do you evaluate the lesion?

- A) Take a photograph and see her back in 2 months
- B) Take a shallow shave biopsy of the lesion
- C) Excise the entire lesion with 1- to 2-mm margins
- D) Excise the entire lesion with 3-cm margins
- E) All of the above are equally valid approaches

Answer 17.1.1 The correct answer is “C.” This lesion is worrisome for malignant melanoma because of the different pigmentation colors and irregular borders. Any time you suspect melanoma, you are obligated to completely remove the entire lesion and send it for pathology either with a punch biopsy or excisional biopsy. “A” is not an option; if you suspect melanoma, the earlier you make the diagnosis the better. A shallow shave biopsy (“B”) is also not recommended because in a shallow biopsy the deep margins are not visible, which is the most important factor in staging melanoma. Partial removal of a lesion may lead to a sampling error, which is why excisional biopsy with narrow (e.g., 1–2 mm) margins is preferred. “D” is preferable to “A” and “B”;

TABLE 17-1 DERMATOLOGY TERMS

Abrasion:	Partial-thickness loss of the epidermis
Abscess:	Localized collection of purulent exudate
Annular:	Grouped in a circular arrangement
Bulla:	Fluid-filled cavity greater than 1 cm
Crust:	Dried exudate on the skin surface; can be serous (yellow or honey-colored) or hemorrhagic (red-brown); when related to an infection the term impetiginization can be used
Desquamation:	Skin cells coming off in scales or flakes
Erythema:	A red color change that is blanchable with pressure
Herpetiform:	Grouped in a dermatomal distribution
Macule/Patch:	Circumscribed area of color-change without elevation or depression; a “macule” is <1 cm in diameter and a “patch” is >1 cm in diameter
Nodule:	A solid subcutaneous mass
Nummular:	Coin-shaped or circular
Papule/Plaque:	A palpable, (elevated) skin lesion; a “papule” is <1 cm in diameter and “plaque” is >1 cm in diameter
Purpura:	Bleeding into the skin; does not blanch with pressure
Pustule:	A papule with purulent exudate
Ulcer:	Full-thickness loss of the epidermis
Vesicle:	A fluid-filled cavity in the skin less than 1 cm
Wheal:	A round or irregular-shaped edematous plaque that tends to be transient (hive)

FIGURE 17-1. Malignant Melanoma.

however, it would be unnecessary to remove the lesion with such large margins when the histopathology is not yet known.

You excise the entire lesion with a small border. The pathology report reveals a malignant melanoma.

Question 17.1.2 Which of the following lesion characteristics will determine your patient's prognosis?

- A) The depth and ulceration
- B) The diameter of the lesion
- C) The number of colors in the lesion
- D) Whether or not it arose in a pre-existing mole
- E) The number of lymphocytes in the biopsy

Answer 17.1.2 The correct answer is "A." As alluded to previously, the depth of the melanoma is the most important prognostic indicator. Breslow tumor thickness is most commonly used to arrive at a prognosis. Breslow tumor thickness measures the depth of the melanoma from the granular layer in the epidermis to the base of the melanoma in millimeters. A thinner melanoma correlates with a better prognosis, and melanomas with a Breslow depth <0.75 mm generally have the best prognosis. Ulceration is associated with more aggressive cancers and a poorer prognosis. Clark level (invasion based upon the anatomic structure of the skin) is still reported but is not as important in regards to prognosis as the Breslow depth. The diameter of the lesion ("B," or the size observed on the skin) has not been associated with prognosis (e.g., superficial spreading melanoma may be large but generally carries a good prognosis). A very large, clinically atypical pigmented lesion can often be benign. Melanomas can also be of one color, many colors, or nonpigmented; color does not correlate with prognosis. Up to two-thirds of melanomas arise in normal skin. They can be just as aggressive as those arising from moles. The number of mitoses in a lesion can help predict the outcome; the more the mitoses, the worse the prognosis. The number of lymphocytes observed within a lesion can provide some information regarding the inflammatory response, but does not possess the same prognostic value as the Breslow depth.

HELPFUL TIP:

If there is regional or distant spread of disease, the overall survival drops to less than 50% for regional metastases and less than 10% for distant metastases.

Question 17.1.3 In the United States, the lifetime risk of developing melanoma in a Caucasian is approximately:

- A) 1/10
- B) 1/38
- C) 1/105
- D) 1/1500

Answer 17.1.3 The correct answer is "B." The lifetime probability of developing melanoma for Caucasians is approximately 1 in 38. The lifetime risk is 1 in 172 for Hispanic Americans and 1 in 1,000 for African Americans.

Your biopsy reveals a melanoma in situ. You excise the entire lesion with 0.5-cm margins. There is no penetration of the epidermis.

Question 17.1.4 What additional evaluation is necessary?

- A) Chest x-ray
- B) CT scan of the chest
- C) Serum lactic acid dehydrogenase (LDH)
- D) All of the above
- E) None of the above

Answer 17.1.4 The correct answer is "E." If the melanoma has not extended beyond the epidermis, it is referred to as a melanoma in situ. If excised with 0.5- to 1-cm margins, the long-term survival at 5 and 10 years approaches 100%. Therefore, any additional workup is not necessary according to the 2010 and 2017 reports from the American Joint Commission on Cancer. When the melanoma depth is greater than 1 mm, further workup may be performed depending on symptoms and stage of disease. A sentinel lymph node biopsy, although there is no proven therapeutic benefit, can provide additional prognostic information for melanomas with a depth >1 mm and is a diagnostic consideration. A CT scan of the chest and pelvis and MRI of the brain can be ordered if clinical symptoms exist or metastatic disease is suspected, but these studies are not routinely recommended. Metastatic disease has not been reported with melanoma in situ.

Question 17.1.5 Which of the following has NOT been associated with an increased risk of the development of melanoma?

- A) Blistering sunburns in childhood
- B) Sister with melanoma
- C) Red or blonde hair color
- D) More than 50 moles on a person's body
- E) Smoking

Answer 17.1.5 The correct answer is "E." A history of blistering sunburns, melanoma in first-degree relatives, light hair, and more than 50 moles are all associated with an increased risk of developing melanoma. Also, high socioeconomic class (too much time to lay in the sun or tanning booth) and immunosuppression appear to be risk factors. Smoking has not yet been linked to malignant melanoma—unlike many other malignancies.

Question 17.1.6 The most common subtype of melanoma in people of African descent is:

- A) Superficial spreading melanoma
- B) Lentigo maligna melanoma
- C) Nodular melanoma
- D) Acral lentiginous melanoma
- E) Amelanotic melanoma

Answer 17.1.6 The correct answer is "D." There are four classical subtypes of malignant melanoma. The subtype does not predict prognosis. **Superficial spreading melanoma ("A")** is

the most common type in fair skin populations. It can occur at any site and clinically presents as a brown macule with irregular, notched borders. It grows radially (outward) initially. **Nodular melanoma** (“C”) is the second most common type in fair skin individuals and, as the name suggests, is an exophytic nodule and often associated with deeper level of invasion and a vertical (downward) growth phase. **Amelanotic melanoma** (“E”) is a subtype of nodular melanoma that presents with little to no pigment and may be red or pink in color. **Lentigo maligna melanoma** (“B”) most often occurs in the elderly on sun-exposed areas, such as the face and hands and presents as a brown macule or patch with hue variations that spreads outward slowly. When there is dermal invasion, lentigo maligna is referred to as lentigo maligna melanoma. **Acral lentiginous melanoma** (“D”) is the least common type in Caucasian populations but is the most common type in races with pigmented skin, such as people of African descent. Acral lentiginous melanoma occurs on the palms, soles, or near the nails. This is what killed Bob Marley.

► **Objectives: Did you learn to ...**

- Evaluate a patient with suspected melanoma?
- Describe how the prognosis of melanoma is determined?
- Recognize the lifetime risk of malignant melanoma in the United States?
- Identify risk factors for the development of melanoma?
- Recognize the four classic subtypes of melanoma and which are the most common in African and Caucasian populations?

QUICK QUIZ: ITCHY ELBOWS

A 22-year-old female presents with a pruritic rash on her elbows and extensor forearms. She’s studying for finals, so she’s been indoors for days eating Wheat Thins and drinking Mountain Dew. She has a history of celiac disease, but is otherwise healthy and takes no medications. On examination, she is afebrile and has 2- to 4-mm diameter vesicular lesions with numerous excoriations in a bilaterally symmetrical pattern on her extensor forearms, knees, and buttocks.

The most likely diagnosis is:

- A) Dermatitis herpetiformis
- B) Poison ivy (contact dermatitis)
- C) Herpes simplex
- D) Neurotic excoriations

The correct answer is “A.” Dermatitis herpetiformis is the most common skin condition to occur in association with celiac disease (gluten enteropathy). This patient seems to have lapsed in her gluten-free diet, and her skin eruption has worsened as a result. Dermatitis herpetiformis presents with excoriated vesicles that are extremely pruritic. It can be confused with scabies. Often, only excoriations (and no blisters) are seen on examination. Dermatitis herpetiformis is also commonly symmetrical (as opposed to HSV) and may involve several body areas, most commonly extensor surfaces of the extremities. The cornerstone of treatment is a gluten-free diet. Dapsone can also help speed up

resolution of the rash, but a strict gluten-free diet will also lead to disease resolution. In this case, “B” is unlikely due to symmetric and diffuse eruption without linear lesions and no reported exposure to poison ivy (we didn’t tell you this, but her college is located in Antarctica, making poison ivy very unlikely). “C” is incorrect since the eruption is diffuse and there is no pain. Neurotic excoriations (“D”) do not present with vesicles.

► **CASE 17.2**

A 7-month-old male is brought to clinic for a “rash all over.” Six weeks ago, his parents noticed him rubbing his legs against his crib and scratching his head frequently. They are concerned because they find blood on his sheets in the morning, and he has become increasingly irritable. He is eating and drinking normally. His past medical history is unremarkable. His father has sensitive skin and hay fever, but no one else in the family currently has a rash. He does not attend a daycare. On skin examination, you find lichenified and erythematous patches of skin with fissures and bleeding on the ventral heels, dorsal feet, hands, and a few areas on the scalp. His cheeks are bright red with scale. His diaper area is uninvolved and there are no lesions in the web spaces of the hands and feet.

Question 17.2.1 Based on the description, which of the following is the most likely diagnosis?

- A) Seborrheic dermatitis
- B) Atopic dermatitis
- C) Scabies
- D) Tinea corporis
- E) Tinea versicolor

Answer 17.2.1 The correct answer is “B.” The most likely diagnosis is atopic dermatitis, also known by the moniker “eczema.” Atopic dermatitis is characterized by intense pruritus and an associated rash. Atopic dermatitis is often referred to as the “itch that rashes.” It occurs in characteristic locations. In younger infants, the cheeks and neck are involved. As they begin to crawl, their extensor surfaces are involved. The diaper area, because it is moist, is not usually involved. In older children, the flexural areas, such as the antecubital and popliteal fossae, are involved. Seborrheic dermatitis (“A”) is common in infants (cradle cap) and is usually seen on the scalp and face, although it can involve the whole body. Seborrheic dermatitis is usually associated with a yellow, greasy scale and is less erythematous than atopic dermatitis. Scabies (“C”) typically affects certain locations (web spaces, wrists, waist, etc.) and uncommonly involves the scalp, except in infants or immunocompromised patients. Also, in this question, he does not appear to have any exposure to scabies. Tinea corporis (“D”) presents with a ring of advancing erythema and a central clearing (“ringworm”). Finally, tinea versicolor (“E”) typically involves the trunk and extremities with hypo- or hyperpigmented patches with superficial scale. It does not involve the scalp and is not very pruritic.

You diagnose the patient with atopic dermatitis.

Question 17.2.2 Which of the following is true about atopic dermatitis?

- A) The prevalence of atopic dermatitis appears to be decreasing worldwide
- B) Atopic dermatitis tends to worsen with use of emollients
- C) In some patients, skin infections can exacerbate atopic dermatitis
- D) Positive skin prick tests and RAST testing correlate highly with food challenges (e.g., those with positive tests will have worsening of their rash when given a food challenge)
- E) In most infants, atopic dermatitis will not significantly improve or resolve by school age

Answer 17.2.2 The correct answer is “C.” Skin infections (Staph or Strep infections) can be associated with worsening atopic dermatitis, and when children flare, impetiginization (superinfection) should be considered. In these situations, a course of antibiotics may improve the overall clinical course (cephalexin is often a good choice). Sixty percent of atopic dermatitis appears in the first year of life, usually after 2 months of age; and it will usually get somewhat better by school age. The cause of atopic dermatitis is not yet known. The role of specific allergens is controversial. In some patients, a food allergy can worsen the disease but is not thought to be the cause. However, in severe, unresponsive atopic dermatitis, food allergens should be evaluated. Most patients who have positive allergy testing to foods do not have improvement in their skin with removal of the allergen (“D”). Atopic dermatitis does tend to improve as the affected child ages (“E”), and the use of emollients (“B”) is a cornerstone of therapy.

HELPFUL TIP (OR NOT):

The link between allergies of any kind, including food and environmental, and atopic dermatitis has been called into question. It does seem that a subset of patients have atopic dermatitis that flares in response to exposure to certain food and environmental triggers, but these patients are the minority. Random elimination diets are to be discouraged. Only patients with proven food allergy **and** an immediate worsening of symptoms when exposed to that food should eliminate that particular food from their diet.

Question 17.2.3 The clinical features of impetiginized atopic dermatitis include:

- A) Lichenification of the skin
- B) Pruritus and relapsing nature
- C) Associated asthma or allergic rhinitis
- D) Elevated IgE serum levels
- E) Redness of the skin with honey crusting

Answer 17.2.3 The correct answer is “E.” Although all of the above can be associated with atopic dermatitis, honey crusting implies a secondary bacterial infection (impetigo), which is common in atopic dermatitis and needs to be recognized and treated to get atopic dermatitis under control. Oral antibiotics and bleach baths can be used to help control the superinfection. However, bleach baths and emollients **in the bath** are not particularly effective. (Ann Allergy Asthma Immunol. 2017;119(5):435., BMJ 2018;361:k1332). Waxing and waning pruritus is what defines this common skin condition. Chronic scratching often leads to thickened skin with accentuation of skin lines (lichenification). Early lesions will not have lichenification, however. Asthma and allergic rhinitis can be associated with atopic dermatitis. This common hypersensitivity triad is referred to as atopy (although in most patients atopic dermatitis is not actually allergic in nature). “D,” elevated IgE, does occur in patients with atopic dermatitis, and higher levels of serum IgE are associated with more extensive disease of greater chronicity. However, an elevated IgE level is merely an association and is not pathognomonic of atopic dermatitis. Erythema of the skin is a nonspecific sign of inflammation and is seen in many skin disorders.

Question 17.2.4 Your initial recommendation should include which of the following in the management of atopic dermatitis:

- A) Daily use of thick emollients such as white petrolatum
- B) Bathing with lukewarm water and mild cleansers
- C) Topical corticosteroids or topical immunomodulators
- D) Oral antibiotics if there is evidence of superinfection
- E) All of the above

Answer 17.2.4 The correct answer is “E.” The protective barrier of the skin is broken down in patients with atopic dermatitis. By frequently applying a protective barrier, such as petrolatum, the skin becomes less pruritic resulting in less itching-induced skin trauma and rash, thus decreasing the “itch-scratch cycle.” This is the most important aspect of long-term management. Topical steroids and immunomodulators work well to decrease the inflammation in the skin and are first-line anti-inflammatory treatment; however, the goal is to protect the skin with thick emollients to re-moisturize and restore the barrier function of the skin. Daily bathing with mild cleansers and cool water followed by the application of emollients is recommended. Patients with atopic dermatitis have a higher bacterial count of *Staphylococcus aureus* on their skin. By bathing for short periods daily, the bacterial count is decreased, thus decreasing the risk of secondary infection. Oral antihistamines cause some level of sedation, which is often helpful at night when the child is awake and itching. Interestingly, there is almost no evidence to support the use of antihistamines in the treatment of atopic dermatitis, except small studies that have shown nonsedating antihistamines to be no better than placebo. If you choose to recommend an antihistamine, use an older drug (e.g., diphenhydramine) **but use extreme caution in children under 2 years of age**—there is no proven benefit for any indication in this age range and infants are more sensitive than adults and older children to the CNS depressant effects of diphenhydramine.

**HELPFUL TIP:**

Mid-potency steroid (e.g., triamcinolone) ointments are the mainstay of pharmacotherapy for atopic dermatitis flares. For the face, low-potency steroid (e.g., hydrocortisone) ointments can be used for a maximum of 2 to 3 weeks at a time. For severe, acute flares, systemic steroids can be employed for 10 to 14 days.

**HELPFUL TIP:**

Topical calcineurin inhibitors (e.g., tacrolimus, pimecrolimus) are recommended for use as a steroid-sparing agent in treatment of atopic dermatitis. They are generally safe and well tolerated; however, they carry a “black box warning” related to a theoretical risk of lymphoma. Studies since the black box warning was issued have failed to demonstrate a causal relationship between topical calcineurin inhibitors and lymphoma. They are not approved for children under the age of 2. However, the American Academy of Dermatology recommends **off-label use** of 0.03% tacrolimus or 1% pimecrolimus for patients with atopic dermatitis under 2 years of age if needed. Crisaborole (Eucrisa), a topical phosphodiesterase-4 inhibitor that is FDA-approved for mild-to-moderate eczema, can also be used as a steroid sparing agent. It is also only approved for children over 2 years of age. The NNT=8–14 is versus placebo vehicle and it is rather expensive.

A recent ear infection has caused your patient’s skin to worsen. He returns to clinic and your physical examination reveals the skin lesion seen in Figure 17-2. He has appreciably enlarged cervical lymph nodes. The patient has no known drug allergies.

Question 17.2.5 Which of the following oral antimicrobials would be the best initial choice for this patient?

- A) Cephalexin
- B) Ciprofloxacin
- C) Metronidazole
- D) Tetracycline
- E) No systemic treatment is necessary at this time

Answer 17.2.5 The correct answer is “A.” Patients with atopic dermatitis are prone to certain skin infections that may exacerbate their disease. Ninety percent of patients with atopic dermatitis will grow *S. aureus* on swab cultures of their crusted lesions. By decreasing the bacterial count, inflamed lesions often heal faster. Depending on your community susceptibilities, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) may be of concern. However, first-generation cephalosporins are a reasonable initial antibiotic choice for impetiginized atopic dermatitis because of excellent skin penetration and activity against Gram-positive cocci (both *Staph* and *Strep*). Tetracycline is another option for impetiginization; however, this should be

FIGURE 17-2. Lichenified, impetiginized, atopic dermatitis (Courtesy of Drs. Karolyn Wanat and Megan Noe.)

avoided in young children, as should fluoroquinolones (except in rare cases such as cystic fibrosis). Systemic therapy is necessary at this time due to clinical worsening and presence of lymphadenopathy.

**HELPFUL TIP:**

A subset of patients with severe, treatment refractory atopic dermatitis may require treatment with immunomodulatory agents including cyclosporine, azathioprine, methotrexate or mycophenolate mofetil, under the care of a specialist. Additionally, dupilumab (Dupixent), a monoclonal antibody that targets the IL-4 receptor, is a biologic medication FDA-approved for moderate-to-severe atopic dermatitis. Tofacitinib (Xeljanz), an oral janus kinase inhibitor, is another emerging therapy for severe atopic dermatitis.

Your patient’s culture results are consistent with methicillin-sensitive *S. aureus* (MSSA). With the appropriate antibiotics, the patient improves markedly. Time to rest on your laurels ... Wait ... there’s this little thing called continuity of care, and 3 months later, your patient returns with a new eruption. Clinical appearance is shown in Figure 17-3.

Question 17.2.6 Which of the following is the most appropriate treatment at this time?

- A) Acyclovir
- B) Cephalexin
- C) Ciprofloxacin
- D) Metronidazole
- E) A and B

Answer 17.2.6 The correct answer is “E.” Patients with eczema may also develop **eczema herpeticum**, a particularly severe form of disseminated herpes simplex with punched

FIGURE 17-3. Eczema herpeticum.

FIGURE 17-4. Allergic contact dermatitis.

out erosions and rapid spread of HSV within the areas of eczema. Patients can develop both eczema herpeticum and impetiginization, so treatment of both is important. The characteristic look of punched-out erosions requires immediate therapy with acyclovir, and often requires intravenous medications as the disease may be fatal. Treatment with cephalexin should be given, especially because the patient improved previously.

As the patient grows, he improves significantly. However, his skin continues to be sensitive to many products. As a teenager, he presents with a recurring rash near his wrist that is intensely pruritic. He has recently started wearing a bracelet ... and he won't take it off despite the rash because he's too cool ... (see Fig. 17-4).

Question 17.2.7 The test most likely to confirm your presumptive diagnosis is:

- A) Potassium hydroxide (KOH) of a skin scraping
- B) Tzanck preparation
- C) Patch testing
- D) Serum thyroid-stimulating hormone level
- E) Serum IgE levels

Answer 17.2.7 The correct answer is "C." The patient most likely has an allergic contact dermatitis to the nickel in the metal bracelet on his wrist. Patients with a history of atopic dermatitis are more likely to have contact hypersensitivities. Nickel is a common contact allergen and can also be seen with contact to earrings, optical glasses, and buttons on jeans. Patch testing ("C") is a test for delayed-type hypersensitivity reactions that can identify many of the common contact allergens. KOH application to a skin scraping ("A") is used to identify fungal elements. KOH dissolves keratin, the protein in skin, to better identify the fungal elements. Tzanck preparations ("B") stain keratinocytes from the base of bullae to evaluate lesions suspicious for mucocutaneous herpes, primary varicella, or herpes zoster. Thyroid disease can cause many skin conditions but is not a known cause of allergic contact dermatitis. An abnormality in the TSH level ("D") is least likely to yield a diagnosis in this case. As to "E," serum IgE levels may be elevated in atopic patients, but this is not diagnostic as IgE can be elevated in many states (Iowa, Wyoming, New York.)

► **Objectives: Did you learn to ...**

- Recognize atopic dermatitis by its classic presentations?
- Identify the hallmarks of atopic dermatitis?
- Manage a patient with atopic dermatitis and its complications?
- Recognize that eczema herpeticum in those with atopic dermatitis?

► **CASE 17.3**

A 49-year-old obese white male with poorly controlled diabetes mellitus, hypertension, and hyperlipidemia presents to clinic for a regularly scheduled visit. He complains that his left and right legs are extremely red and painful. He denies constitutional symptoms. His vital signs are within normal limits. He has warm legs with circumferential erythema extending from the ankle to the mid-calves with 2+ pitting edema bilaterally with hemosiderin staining (brownish macular lesions) of the ankles. There is no lymphadenopathy. There are no open sores or minor trauma noted (see Fig. 17-5). His complete blood count with differential is within normal limits. You send him for Doppler studies that fail to reveal venous thrombosis. You prescribe 7 days of oral antibiotics and send him home, confident that your therapy will not fail.

He returns 3 days later with modest improvement in the redness. After completing the antibiotic course, he presents to clinic 3 weeks later complaining of return of the redness. (Why don't patients just get better with a pill like they are supposed to?)

FIGURE 17-5. Chronic venous stasis (lipodermosclerosis).

Question 17.3.1 The most appropriate next step in the care of this patient is to:

- A) Prescribe another course of oral antibiotics for 14 days
- B) Admit the patient to the hospital for intravenous antibiotics
- C) Send a punch biopsy of skin for bacterial culture
- D) Recommend daily leg elevation and use of compression hose
- E) Prescribe a diuretic (e.g., furosemide)

Answer 17.3.1 The correct answer is “D.” This patient has a characteristic history of stasis dermatitis, a condition that is often misdiagnosed as recurrent or chronic cellulitis. **Remember cellulitis is almost always a unilateral disease.** Stasis dermatitis is a dermatitis of the lower extremities that results from chronic edema. It can start relatively abruptly and be unilateral or bilateral. The pitting edema with hemosiderin staining is a clue that there is chronic fluid extravasation from the vessels of the lower extremities. Ectatic veins may also be present. The goal of therapy is directed at resolution of the edema. Patients must lose weight and employ a strict routine of compression hose and leg elevation. In the short term, topical corticosteroids can improve the inflammation. In general, diuretics should

not be used simply to treat edema, as these drugs have numerous systemic effects. Paradoxically, diuretics can actually make edema worse in the long term by causing low circulating volume and renal retention of sodium and water to make up for the diuretic-induced hypovolemia. Chronic lower extremity edema can lead to local tissue necrosis, resulting in ulceration. With long-standing venous insufficiency, more chronic changes can also occur including lipodermosclerosis (which is “woody” fibrosis-bound down skin) as well as overlying retention of the king and verrucous features (elephantiasis nostra verrucosum).

From years of diabetic nephropathy, the patient’s kidneys eventually fail leading to transplantation (and use of immunosuppressants). After 5 years of stable renal function and improved control of his diabetes, he develops a new nonhealing lesion on the left forearm.

Question 17.3.2 What cutaneous malignancy is he at the highest risk of developing?

- A) Basal cell carcinoma
- B) Malignant melanoma
- C) Squamous cell carcinoma
- D) Metastases from an undiagnosed internal malignancy
- E) Kaposi sarcoma

Answer 17.3.2 The correct answer is “C.” All primary cutaneous malignancies are increased in immunosuppressed patients. However, squamous cell carcinoma is the most common in transplanted, immunosuppressed patients, surpassing basal cell carcinoma, which is most common in the general population. Depending on sun exposure and length of immunosuppression, the incidence of squamous cell carcinoma in transplant populations is as high as 45%. Any nonhealing lesion should be further investigated with a biopsy. There are also significantly increased rates of Kaposi sarcoma in immunocompromised patients.

You removed the lesion, which was indeed squamous cell carcinoma. Good job! The patient develops a shallow ulcer superior to the medial malleolus. “Is that another one of them cancers, Doc?” your patient asks.

Question 17.3.3 The most common cause of an ulceration at this location is

- A) Arterial insufficiency
- B) Diabetic neuropathy
- C) Chronic venous stasis
- D) Pyoderma gangrenosum
- E) Prolonged pressure (e.g., “decubitus” ulcer)

Answer 17.3.3 The correct answer is “C.” Your patient is at risk for many of the above diagnoses; however, venous ulcerations classically occur over the medial lower leg. In contrast to this patient’s venous ulceration, arterial insufficiency ulcers (“A”) classically have a punched-out appearance and occur over bony

prominences (e.g., malleoli) or distal aspects (e.g., tips of toes) and are extremely painful (in the absence of neuropathy) and usually dry. Poor peripheral pulses, cool extremities, and hairlessness are clues to arterial insufficiency. Abnormal ankle-brachial indices help to confirm peripheral artery disease. Neuropathic ulcers (“B”), such as those associated with diabetic neuropathy, also occur over pressure points including the plantar surface of the foot. The patient may complain of burning or tingling of the foot, but the ulcer is asymptomatic (because of lack of pain sensation from diabetic neuropathy). Pyoderma gangrenosum (“D”) is a rare cause of ulceration associated with systemic diseases including inflammatory bowel disease, connective tissue diseases, and hematologic malignancies. Pressure ulceration (“E”) is common and results from tissue ischemia from prolonged pressure, usually over bony prominences, such as the sacrum, coccyx, and heels.

As you start to exit the examination room, the patient states “Oh by the way, Doc, can you do anything for my toenails?” Your examination reveals three, yellow heaped-up nails on the left foot. You suspect a dermatophyte infection.

Question 17.3.4 What do you do next?

- A) Perform a KOH examination of toenail scrapings
- B) Empirically treat with an oral antifungal
- C) Empirically treat with a topical antifungal
- D) Tell the patient that his nails are the least of his worries

Answer 17.3.4 The correct answer is “A.” The cost of antifungal therapy has declined substantially over the past few years with generic options becoming available. Some experts now argue that “B,” empiric therapy, is reasonable in otherwise healthy patients without contraindications. However, a board examination is not real life, and “A” would be the best choice. Here’s the argument for testing prior to treating: all that looks fungal is not necessarily fungal. Dystrophic nails can mimic onychomycosis and may be the result of psoriasis, eczema, trauma, or other inflammatory conditions. KOH is an inexpensive and easy test to perform in the clinic setting. If it is negative, then a toenail clipping can be sent for fungal culture or pathologic study with periodic acid–Schiff staining if desired.

The KOH is negative, so you send a toenail clipping for culture. It grows a *Candida* species.

Question 17.3.5 Which of the following would be the LEAST efficacious medication?

- A) Amphotericin
- B) Fluconazole
- C) Nystatin
- D) Terbinafine
- E) Voriconazole

Answer 17.3.5 The correct answer is “D.” All the above medications have some *Candida* species coverage, but terbinafine (Lamisil) has the least yeast coverage. Of note, amphotericin would be the most toxic (but still would work well) and should

be avoided. *A plea from your editors:* the topical “paint-on” nail antifungals are relatively expensive, have a marginal benefit, and the recurrence rate tends to be high. Besides, who is really going to paint their nails everyday for a year?

HELPFUL TIP:

Terbinafine (Lamisil) is effective against most dermatophyte infections of the nails (except *Candida*). Most cases of onychomycosis are sensitive to terbinafine. Complete cure rates for systemic antifungals range from 50% to 75% (terbinafine has the highest rate), while cure rates for topical antifungals are less than 10% even under ideal conditions. For all-comers, recurrence after clearance is as high as 50%.

Another patient comes in with toenail fungus, but this time he has white changes, most prominent on his proximal nailfolds.

Question 17.3.6 You would like to test him for:

- A) Diabetes mellitus
- B) Kidney disease
- C) Lupus erythematosus
- D) HIV
- E) Yum, let’s go eat mushrooms

Answer 17.3.6 The correct answer is “D.” This pattern of dermatophyte infection, proximal white subungual onychomycosis, is characteristic of immunosuppression and particularly HIV disease. Testing for underlying HIV is important with this clinical presentation. Other nailbed changes can be seen with diabetes, kidney disease, and lupus. As to “E,” mushrooms might have this appearance but don’t grow on toes—we hope. As an aside, there is a great restaurant in Jogjakarta, Indonesia, where everything is made out of various types of mushrooms (shelf fungus, etc.). It is pretty yummy. If you are in the area check out “Je Jamuran.”

► **Objectives: Did you learn to ...**

- Recognize the presentation of stasis dermatitis and describe its etiology?
- Treat stasis dermatitis?
- Recognize the cutaneous malignancies seen in transplanted, immunosuppressed patients?
- Differentiate between common causes and sites of lower extremity ulcerations?
- Diagnose and treat onychomycosis?

► **CASE 17.4**

You are working in the student health clinic at the local university when a previously healthy 19-year-old female presents with malaise for 3 weeks and a severe sore throat for 3 days. Yesterday, she took some old amoxicillin that her roommate

gave her. Today, she developed a diffuse macular, red skin eruption, starting on her chest and spreading to involve her extremities. Her mucous membranes, palms, and soles are free of lesions, but she has enlarged tonsils with exudates and large cervical lymph nodes, including prominent posterior nodes. A rapid *Strep* test is negative.

Question 17.4.1 You suspect:

- A) An allergic reaction to the amoxicillin
- B) An Epstein–Barr virus infection (mononucleosis)
- C) An enterovirus infection
- D) A gonococcal infection
- E) Scarlet fever

Answer 17.4.1 The correct answer is “B.” All of the above infections except for enterovirus can present with an exudative pharyngitis; enterovirus presents with gastrointestinal or meningeal symptoms. The clinical scenario describes the usual course of infectious mononucleosis: a college-age student, a few week prodrome of malaise, and posterior cervical lymphadenopathy. Amoxicillin or ampicillin given to patients with infectious mononucleosis can result in a macular, diffuse rash. This is not an allergy but can be mistaken for one. Scarlet fever, which this patient does not have, is a complication of group A streptococcal infection, which presents with an erythematous, coarse (“sandpaper”) rash, strawberry tongue, and skin desquamation.

Later that same day, a (precocious) 16-year-old male presents with a mildly pruritic rash on his trunk. He had a cold a few weeks earlier but is otherwise healthy. He denies high-risk sexual activity or IV drug abuse (of course, your definition of “high-risk” and his may not be the same!). Your examination reveals the findings in Figure 17-6.

Question 17.4.2 You tell the patient:

- A) This skin condition is usually chronic and relapsing
- B) That topical corticosteroids are needed to speed up the healing
- C) That the rash usually resolves within 6 to 8 weeks without treatment
- D) That the rash is likely to be fatal
- E) That he is living a Kafkaesque nightmare and slowly metamorphosing into an insect

Answer 17.4.2 The correct answer is “C.” The rash is consistent with pityriasis rosea (PR), which is an acute, often asymptomatic, eruption on the trunk and proximal extremities. The etiology is (still) unknown. Secondary syphilis, which is on the rise in some areas of the United States, can mimic PR. A sexual history is necessary, and appropriate laboratory studies should be undertaken if a patient is sexually active, especially if high-risk behaviors have occurred or if local syphilis rates are high. PR, unlike syphilis, often resolves within 8 weeks without treatment and does not usually recur. Topical steroids are not necessary for healing but may be helpful in the minority of patients

FIGURE 17-6. Pityriasis Rosea (Courtesy of Drs. Karolyn Wanat and Megan Noe.)

who experience itching. “E” is incorrect. This rash just isn’t that serious.

HELPFUL TIP:

Pityriasis rosea starts with a “herald patch,” a salmon-colored, 2- to 5-cm oval-shaped lesion on the back, neck, or chest. The herald patch may clear a bit and scale and is then followed by numerous smaller lesions that crop up mostly on the trunk. These lesions tend to be oval in shape and are oriented along skin lines, giving a “Christmas tree” appearance.

Your next patient is a 20-year-old female complaining of “a rash down there.” You confirm that she is talking about a vulvar rash and ask about her sexual history. She says that she had not been sexually active with anyone for about 1 year until a recent spring break fling in Florida. On examination, you find a rash over the pubic region and extending into the inguinal areas and medial thighs. There is no pain or pruritus (see Fig. 17-7).

Question 17.4.3 Which of the following is FALSE?

- A) These lesions are transmitted in adults only by sexual contact
- B) If not treated, the lesions may resolve on their own
- C) Topical corticosteroids do not improve this skin condition
- D) The lesions are contagious and can spread readily and rapidly
- E) The skin lesions are a result of a viral infection

FIGURE 17-7. Molluscum contagiosum.

Answer 17.4.3 The correct (and false) answer is “A.” These lesions, referred to as molluscum contagiosum, result from a pox virus. Molluscum is commonly spread via sexual contact in adults; however, **any** physical human contact can also spread it. Molluscum is extremely common in children in daycare settings. The lesions generally resolve in time without treatment. Because they can be auto-inoculated, the molluscum lesions can rapidly increase in number, and it is for this reason that treatment is recommended. Treatment consists of destructive methods, such as cryotherapy or curetting. The immune modulator imiquimod has been used, but is not approved by the Food and Drug Administration (FDA) for molluscum, and only small trials have been undertaken. Topical steroids are not indicated. In immunocompromised patients, molluscum lesions can be widespread and persist much longer.

HELPFUL TIP:

Other molluscum therapies appear effective in small trials but are not FDA approved, including podofilox 0.5%, KOH 5% to 10%, and cantharidin.

Your next patient is a healthy 18-year-old male who presents for treatment of plantar warts. He has tried topical salicylic acid 17% at home. He used it for a few weeks without significant improvement.

Question 17.4.4 Which of the following can be used for therapy for plantar warts (verruca plantaris)?

- A) Cryotherapy (liquid nitrogen)
- B) Duct tape occlusion
- C) Imiquimod
- D) Candida antigen injection
- E) All of the above

Answer 17.4.4 The correct answer is “E.” No therapy for cutaneous warts (plantar or otherwise) has been proven superior, and all of the options can be used with different pros and cons.

“A,” cryotherapy, is easily performed in the office and is quick but may be too painful for children to tolerate. Also, cryotherapy may result in hypopigmented scarring in dark-skinned patients. As we all know, duct tape can be used for anything (e.g., holding your muffler together, preventing poison gas exposure) and has been used to treat warts, but the evidence is conflicting. “C,” imiquimod, is initially painless, can lead to a brisk inflammatory response, and unlikely to cause scarring, so it is a good choice for facial warts or dark-skinned patients. However, it is the most expensive option. “D,” candida antigen injection, is a therapy that aims at stimulating an immune response to the warts. Mumps antigen has been used as well. In the antigen injection studies, only one wart was injected to achieve treatment for all of a patient’s warts. This can be effective but is a painful injection. Destructive methods are all approximately 70% effective at eradicating warts. It is important to remind patients that no single method is more likely to work than another, and warts can resolve on their own. In immunocompetent patients, most warts resolve in time without treatment. For young children, this is an important issue, since they cannot understand the pain associated with most treatment modalities.

HELPFUL TIP:

To use duct tape for warts, the patient should put a piece of duct tape on the wart and leave it on for 6 days. On day 7, remove the duct tape, soak, and abrade the wart with a pumice stone. Reapply the duct tape the next day.

► **Objectives: Did you learn to ...**

- Recognize that ampicillin/amoxicillin given to patients with mononucleosis will often result in a macular rash?
- Diagnose pityriasis rosea (PR) and recognize secondary syphilis as a mimic?
- Recognize and treat molluscum contagiosum?
- Describe the treatment modalities for verruca plantaris?

QUICK QUIZ: HYPERSENSITIVITY REACTION

Which of the following represents a type IV hypersensitivity reaction?

- A) Serum sickness reaction
- B) Contact dermatitis to poison ivy
- C) Urticaria
- D) Vasculitis

The correct answer is “B.” Contact dermatitis has a geometric appearance and a characteristic immune-mediated reaction; someone may not react when they first encounter the agent and then develop stronger inflammatory responses with subsequent exposures. Contact dermatitis is an example of a delayed-type hypersensitivity reaction. The pruritus from contact dermatitis usually *does not* respond well to diphenhydramine or hydroxyzine. It is not histamine mediated. Serum sickness (“A”) is a

FIGURE 17-8. Erythema toxicum neonatorum.

FIGURE 17-9. "Blueberry muffin" appearance from CMV (but also caused by Rubella, Parvovirus B-19, etc.)

type III immune complex reaction. Urticaria ("C") is a type I hypersensitivity response, mediated by mast cell degranulation. Vasculitis ("D") can be either immune complex, antibody, or complement mediated.

HELPFUL TIP:

Auto-eczematization or "id" reactions represent a hypersensitivity response of the body to a significant infection or dermatitis in another part of the body. For example, patients with severe tinea pedis can develop eczematous lesions on other parts of the body and treatment of the tinea pedis will resolve the eczematous eruption (or "id" reaction).

▶ **CASE 17.5**

You are rounding in the newborn nursery. A healthy 2-day-old term infant has a new rash characterized by yellow pustules on an erythematous base (Fig. 17-8) involving the trunk and extremities but sparing the palms and soles.

Question 17.5.1 What is the diagnosis?

- A) Transient neonatal pustular melanosis
- B) Herpes simplex
- C) Miliaria
- D) Erythema toxicum neonatorum
- E) Epidermolysis bullosa

Answer 17.5.1 The correct answer is "D." Erythema toxicum neonatorum is a common, benign, self-limited rash seen in term infants. Lesions usually appear after 24 to 48 hours of age. Lesions may begin as erythematous macules that progress to yellow pustules on an erythematous base, may be sparse or numerous, and involve the trunk and extremities, sparing the

palms and soles. The etiology is unknown and the diagnosis is clinical. Transient neonatal pustular melanosis ("A") usually affects term African-American infants presenting at birth with pustules on a hyperpigmented macule that may involve the palms and soles. Neonatal herpes ("B") presents with blisters or erosions and an ill-appearing child. Diagnosis is made via a Tzanck preparation demonstrating multinucleated giant cells, viral culture, or direct fluorescent antibody for HSV 1 or 2. Commonly seen in warm climates, miliaria ("C") or "prickly heat" is due to blocked sweat ducts presenting as non-inflamed pinpoint clear diffuse vesicles. Epidermolysis bullosa ("E") is a chronic blistering disease presenting as blisters at sites of mild trauma.

HELPFUL TIP:

Neonatal acne presents as a pustular, facial eruption with a mean onset at 2 to 3 weeks of life. It is asymptomatic and diagnosed clinically. Fungal organisms have been found in some pustules. Treatment for acne is not necessary as most lesions resolve in several weeks; if severe, topical "azole" antifungals can be used. Besides, we doubt neonatal acne will affect the child's chance of landing a daycare prom date.

While taking care of the neonate in the newborn nursery, you notice a child in isolation. His skin catches your eye (see Fig. 17-9).

Question 17.5.2 The most common cause of this rash in newborns in the United States is:

- A) Cytomegalovirus (CMV)
- B) Rubella
- C) Langerhans cell histiocytosis
- D) Rh incompatibility
- E) Parvovirus B19

Answer 17.5.2 The correct answer is “A.” All of the listed can present as a “blueberry muffin baby”; however, CMV is the most common cause in the United States. CMV is the most common congenital viral infection, affecting about 1% to 2% of all births. Rubella was the most common cause in the pre-vaccination era (which, unhappily, seems to be returning). In most cases, the purple plaques represent extramedullary hematopoiesis.

Later that same morning, a previously healthy 2-month-old neonate presents to your clinic with peeling of the skin and a fever (Fig. 17-10). She had appeared well until 2 days ago when she became more irritable. Her mother noted a decrease in her urine output. The child was born vaginally without complications and has no known medical conditions. On physical examination, you notice a well-nourished, crying infant with large sheets of desquamating skin on her extremities. Her mucus membranes appear normal. You order complete blood count and urine analysis.

Question 17.5.3 The most likely diagnosis is:

- A) Toxic epidermal necrolysis (TEN)
- B) Burns
- C) Staphylococcal scalded skin syndrome (SSSS)
- D) Diffuse cutaneous mastocytosis

Answer 17.5.3 The correct answer is “C.” This is Staphylococcal scalded skin syndrome (SSSS), which results from a distant Staphylococcal infection (often involving urinary tract, nasopharynx, eyes, perianal areas). The key features of SSSS in Figure 17-10

FIGURE 17-10. Staphylococcal scalded skin syndrome (Courtesy of Drs. Karolyn Wanat and Megan Noe.)

are bright red erythema with impending desquamation in the neck folds and periorificial areas with sparing of the oral mucosa. So what differentiates “C” from “A”? TEN presents with shedding of sheets of skin **and often has mucosal involvement that separates it clinically from SSSS**. Both can present with significant skin pain. However, TEN is a result of drug hypersensitivity or bacterial sepsis (in the case of the neonate children); and neonates with TEN are quite ill compared with children with SSSS. In TEN, a biopsy would show full-thickness necrosis of the epidermis versus an intraepidermal split in SSSS. Burns (“B”) can mimic SSSS, but burns would not be likely to cause a diffuse red eruption and will often have a specific shape depending on what burned the skin. “D,” diffuse cutaneous mastocytosis, can present with hemorrhagic blisters and erosions, but these are usually focal areas, not sheets of skin loss. Keep reading for more information on SSSS.

Question 17.5.4 In this case of SSSS, peeling of the skin is a result of:

- A) Necrosis of the entire epidermis from lymphocyte attack
- B) A widespread bacterial skin infection
- C) Histamine released in the skin with edema and blistering
- D) Toxin-mediated skin blistering from nonskin source of infection

Answer 17.5.4 The correct answer is “D.” This clinical scenario describes SSSS, which is an epidermolysis toxin-driven disease. Extreme tenderness of the skin precedes superficial, widespread desquamation. The skin is usually bright red with areas of flakiness. Radial wrinkling of the mouth, giving an “old, sad man” appearance, is common. The source of infection is not the skin but rather an occult site such as nasopharynx, eye, perianal area, or urinary tract; therefore, investigation for a causative infection should be undertaken (e.g., blood, nares, ocular, perianal, and urine cultures).

► **Objectives: Did you learn to ...**

- Recognize neonatal benign cutaneous eruptions?
- Identify a “blueberry muffin” neonate and know the common causes?
- Recognize SSSS and consider its differential diagnosis?

QUICK QUIZ: NAILS

Which of the following nail findings–systemic disease pairing is INCORRECT?

- A) Muehrcke nails–nephrotic syndrome
- B) Nail pitting–psoriasis
- C) Periungual fibroma–tuberous sclerosis
- D) Splinter hemorrhages–infective endocarditis
- E) Koilonychia–systemic lupus erythematosus

The correct answer is “E.” Koilonychia, otherwise known as “spoon nail,” is a result of softening and thinning of the nail plate and is found in patients with long-standing iron deficiency anemia, Plummer–Vinson syndrome, Raynaud disease, hemochromatosis, and trauma. It can also be inherited as an

autosomal-dominant trait. Connective tissue diseases, such as lupus, are more commonly characterized by nail fold abnormalities, such as nail fold telangiectasias, rather than koilonychia. Muehrcke nails (“A”) have paired narrow horizontal (meaning perpendicular to the long axis of the finger) white bands, separated by normal nail, which remain static as the nail grows. They are most often seen in patients with nephrotic syndrome, and their presence reflects the degree of hypoalbuminemia. When you see onycholysis (separation of the nail plate from the nail bed that appears opaque), consider trauma, onychomycosis, psoriasis, and other systemic disease. Nail pitting can be associated with several conditions including psoriasis, atopic dermatitis, and alopecia areata. A periungual fibroma (“C”) should prompt evaluation for tuberous sclerosis with brain imaging for tuberous lesions. Splinter hemorrhages (“D”) are usually a result of trauma but can be a sign of infectious endocarditis.

HELPFUL TIP:

Paronychia, inflammation around the nail, may be acute or chronic. Acute paronychia is often due to bacterial infection and is treated with oral antibiotics, drainage, warm compresses, and soaks. Chronic paronychia is related to eczema and may have secondary *Candida* infection. Treatment is with topical steroids, topical antifungals, and oral antifungals.

QUICK QUIZ: DERM PHOTO

A 52-year-old white male presents to clinic with a nonhealing, asymptomatic “pimple” on the cheek. It has been present for 6 months and has recently started to bleed when he shaves. On examination, you note his fair skin, blue eyes, and ruddy complexion. You find the lesion in Figure 17-11.

Your preliminary diagnosis is:

- A) Sebaceous hyperplasia
- B) Squamous cell carcinoma

FIGURE 17-11. Basal Cell Carcinoma.

- C) Basal cell carcinoma
- D) Metastases from internal malignancy
- E) Merkel cell carcinoma

The correct answer is “C.” The photograph is a classic picture of a basal cell carcinoma with its rolled, pearly pink borders and telangiectasias. It is found commonly on sites that get a lot of sun exposure, especially the head and neck. People with fair skin and light hair and eyes are at particular risk. Sebaceous hyperplasia (“A”) can look similar but is ivory or yellow in appearance and has lobulated appearance with a central pore. Squamous cell carcinoma (“B”) is usually a hyperkeratotic or ulcerated papule or plaque. Metastases from solid organ malignancies (“D”) are subcutaneous, firm nodules, although they may ulcerate. Merkel cell carcinoma (“E”) is a rare tumor on the head and neck that usually appears as an ill-defined, violaceous nodule.

▶ CASE 17.6

While working in the emergency department, a 6-month-old healthy female infant is brought in by her grandmother. She is bleeding from her birthmark on her buttocks (see Fig. 17-12). Her grandmother watches her during the day while her mother is at work and has noticed the lesion getting larger recently. After holding pressure on the lesion for about 20 minutes, the bleeding stops. You educate the grandmother about the natural history of the “birthmark.”

Question 17.6.1 Which of the following is NOT a true statement about this type of birthmark?

- A) This is the most common type of soft-tissue tumor of infancy
- B) Most of these birthmarks undergo spontaneous involution
- C) Treatment is indicated in all lesions lest they become malignant
- D) β -Blockers are the most appropriate therapy for ulcerated lesions
- E) Many are not present at birth but develop shortly thereafter

FIGURE 17-12. Ulcerated Hemangioma of Infancy.

FIGURE 17-13. Pyogenic granuloma.

Answer 17.6.1 The correct (untrue) answer is “C.” The child has an ulcerated hemangioma of infancy. Infantile hemangiomas are benign proliferations of endothelial cell lineage that are usually present at birth or soon thereafter. They are characterized by rapid growth in the first several months of life with a plateau occurring around 1 year of age. They spontaneously involute over years. Treatment options should be individually tailored, depending on the size and location of the lesion. Lesions located on the central face or in the diaper area should be treated, as should ulcerated hemangiomas at any body site. Topical timolol or oral propranolol is the standard of care for infantile hemangiomas that require treatment. Larger, segmental hemangiomas should be further evaluated with imaging studies to rule out syndromes with other associated anomalies such as PHACES syndrome (posterior fossa malformation, hemangioma, arterial anomalies, cardiac defects, coarctation of the aorta, eye abnormalities, sternal defects/supraumbilical raphe) and LUMBAR syndrome (lower body hemangioma, urogenital anomalies, myelopathy, bony deformities, anorectal malformation/arterial anomalies, and renal anomalies).

The same patient returns, this time with mom, at age 5. The hemangioma has involuted. About 2 months ago, the mother noticed a spot on the patient’s left index finger, and now she is concerned that it is not resolving. The patient is not bothered by the lesion, except that it occasionally bleeds when she bumps it on something. On examination, you find a 3-mm dome-shaped, bright red nodule on the palmar aspect of the left index finger. It is nontender and smooth (see Fig. 17-13).

Question 17.6.2 The most likely diagnosis is:

- A) Basal cell carcinoma
- B) Squamous cell carcinoma
- C) Acne
- D) Pyogenic granuloma
- E) Nodular melanoma

Answer 17.6.2 The correct answer is “D.” This patient most likely has a pyogenic granuloma, which is essentially a nodular hemangioma arising at sites of trauma, especially the fingers

and toes. Although pyogenic granuloma is not cancerous, it can be confused with basal and squamous cell carcinomas as well as melanoma. For this reason, it is prudent to perform excision and histologic examination. After excision, the base of the lesion should be ablated (electrocautery or laser), or the pyogenic granuloma may return. Pyogenic granulomas are more common during pregnancy and have been associated with drugs such as oral retinoids, indinavir, methotrexate, sirolimus, and capecitabine. Acne (“C”) should not be a consideration, as sebaceous glands are not found on the palms. By the way, did you notice that this poor child has developed coarse, dark hair growth on her knuckles? As it turns out, she’s been playing with dad’s Rogaine.

► **Objectives: Did you learn to ...**

- Describe the natural history of infantile hemangiomas?
- Identify options for treating ulcerated hemangiomas?
- Describe the features and management of pyogenic granuloma?

► CASE 17.7

A 78-year-old female presents with a hive-like rash on her legs. It started 1 week ago and was preceded by itching of the legs without any visible changes. Red blotches rapidly developed that quickly became blisters. She denies pain or drainage. She also has some sores in her mouth. She reports overall good health and takes no medications. On examination, you find an afebrile, comfortable looking female. She has 1+ pitting edema at her ankles. You notice round, tense bullae erupting on erythematous patches on the abdomen and extremities. There are also scattered erosions present at the sites of previous bullae. The bullae contain clear fluid. There is no purulent material or blood (see Fig. 17-14).

Question 17.7.1 Which of the following is the most likely diagnosis?

- A) Pemphigus vulgaris
- B) Bullous pemphigoid
- C) Varicella zoster
- D) Dermatitis herpetiformis
- E) Stevens–Johnson syndrome (SJS)

Answer 17.7.1 The correct answer is “B.” Bullous pemphigoid is an autoimmune disorder and is primarily a disease of the elderly. Often patients will report pruritus or urticaria-like lesions, prior to the eruption of typical bullous lesions. When the bullae form, they are frequently asymptomatic but can be intensely pruritic and/or mildly tender. In contrast to pemphigus vulgaris (“A”) and SJS (“E”), systemic symptoms are not part of bullous pemphigoid. Additionally, pemphigus vulgaris lesions are painful, and classically the bullae are flaccid rather than tense. SJS generally occurs in response to medications, and this patient is taking none. Varicella zoster (“C”) should follow a unilateral dermatomal pattern rather than appear bilaterally; zoster is usually associated with pain and paresthesia.

FIGURE 17-14. Bullous Pemphigoid (Courtesy of Drs. Carolyn Wanat and Megan Noe.)

Dermatitis herpetiformis (“D”) presents with crops of vesicles and excoriations rather than bullae.

Although she feels well, the lesions are dramatic, and the patient is very concerned that she might have cancer. To confirm your diagnosis, you decide to biopsy the skin.

Question 17.7.2 The most appropriate way to perform a biopsy in this situation is:

- A) 4-mm punch biopsy of the margin of an intact bulla for light microscopy
- B) 4-mm punch biopsy of perilesional normal skin for light microscopy
- C) 4-mm punch biopsy of perilesional normal skin for direct immunofluorescence
- D) A and B
- E) A and C

Answer 17.7.2 The correct answer is “E.” Bullous pemphigoid is diagnosed definitively by demonstration of autoantibodies deposited along the basement membrane of **normal** skin. Direct immunofluorescence examination of normal-appearing skin (“C”) can demonstrate linear depositions of IgG and C3 along the dermal-epidermal junction. A biopsy of the edge of an intact bulla (“A”) will show the characteristic pathology of a subepidermal blister with eosinophils. For a definitive diagnosis, both “A” and “C” should be done.

You assure her that the lesions are not cancerous.

Question 17.7.3 What else can you tell her about the prognosis of bullous pemphigoid?

- A) The average course resolves spontaneously in 5 to 6 years
- B) It is associated with an increased risk of systemic malignancy
- C) It is associated with a high mortality rate
- D) It will likely spread to cover her entire body until she’s one big blister, and her hair will fall out, and her friends will shun her, a la Job in the Old Testament

Answer 17.7.3 The correct answer is “A.” Bullous pemphigoid may undergo complete resolution and never recur. Alternatively, the disease may have resolutions and exacerbations over time. It is not associated with an increased risk of cancer or a high mortality rate. Very extensive involvement may lead to skin infections and bacteremia, but diffuse disease is not common.

She seems miserable. You want to offer her the medication with the fastest onset of action.

Question 17.7.4 What is the most appropriate treatment option with a fast onset of action?

- A) Oral azathioprine
- B) Oral cephalexin
- C) Oral prednisone
- D) Topical antimicrobials

Answer 17.7.4 The correct answer is “C.” Bullous pemphigoid is an autoimmune disease, so anti-inflammatory medications and immunosuppressive agents are used to treat it. Oral steroids are the first-line treatment because of the quick onset of action; however because of concerns for long-term side effects, patients should be transitioned to “steroid-sparing” agents as necessary. Once the disease is under control, oral steroids should be tapered to the lowest effect dose in combination with a tetracycline antibiotic or other immunosuppressive agent such as azathioprine, methotrexate, or mycophenolate. For patients with limited disease, high-potency topical steroids can also be used. Topical antimicrobials are used when treating infected, open bullae but are not effective for the treatment of the disease itself.

► **Objectives: Did you learn to ...**

- Distinguish bullous diseases from one another?
- Diagnose and treat bullous pemphigoid?

QUICK QUIZ: PAPULAR ERUPTION

A 30-year-old female presents with a several month history of bumps on her chin and around her mouth. Although she has never had problems with acne, she thought that she was developing acne and tried benzoyl peroxide. A month ago, she stopped the benzoyl peroxide because it did not seem to

FIGURE 17-15. Perioral dermatitis.

work, and she switched to hydrocortisone cream, which has worsened the outbreak. The rash is neither itchy nor painful. She works in an office and cannot recall any contact irritants. On examination, you find erythematous papules with small pustules on the chin and laterally around her mouth (see Fig. 17-15). The neck and the remainder of the face are not involved.

Which of the following treatments do you recommend?

- A) Oral tetracycline
- B) Oral isotretinoin
- C) Topical high-potency steroids
- D) Topical triple antibiotic ointment
- E) Topical retinoic acid

The correct answer is “A.” This patient appears to have perioral dermatitis. Appropriate treatments for perioral dermatitis include topical metronidazole or topical erythromycin or oral tetracycline antibiotics (tetracycline, minocycline, or doxycycline). The etiology of perioral dermatitis is unknown. “B” and “E” are incorrect, since these are treatments of acne vulgaris. “C” is incorrect, since high-potency topical steroids can make the condition worse, with rebound erythema upon discontinuation. Topical triple antibiotic ointment (“D”) is not likely to be effective.

► CASE 17.8

A 15-year-old male presents to your office complaining of “zits” on his face and back. He has several scattered comedones on his face and several deep nodules on his back. He also has some papulopustular lesions on his chin. You diagnose him with acne vulgaris.

Question 17.8.1 Which of the following is NOT TRUE about acne?

- A) Non-comedonal acne is an inflammatory process
- B) It commonly presents first in adolescence
- C) It may first appear in adulthood
- D) It is more severe in females than in males
- E) The incidence is lower in Asians and Africans than in Caucasians

Answer 17.8.1 The correct (and untrue) answer is “D.” Acne is an inflammatory process that involves the pilosebaceous units of the face and trunk. It can be comedonal, papulopustular, or nodulocystic in presentation. It typically presents first in adolescence with girls developing it from age 10 to 17 years and boys from 14 to 19 years. However, it may not appear until early adulthood. It is more severe in males than in females (thus “D” is not true), and it is less prevalent among Asians and Africans.

HELPFUL TIP:

Open comedones (blackheads) and closed comedones (whiteheads) are considered non-inflammatory lesions, whereas papular and cystic lesions are considered inflammatory. And no matter how tempting, patients should not pick at them! Picking may exacerbate scarring.

Your patient has heard many things about acne and wonders if they are true.

Question 17.8.2 Regarding acne, all of the following are true EXCEPT:

- A) Acne is not caused by medications
- B) Acne can be caused by industrial exposures such as cutting oils, aromatic hydrocarbons, and petroleum-based products
- C) Infrequent facial cleansing does not cause acne
- D) Emotional stress affects the course of acne
- E) Acne can present at any age

Answer 17.8.2 The correct (and untrue) answer is “A.” Acne can be caused by many medications including oral steroids, EGFR inhibitors (chemotherapeutic agents), lithium, isoniazid (INH), and phenytoin. Medication-induced acne presents as monomorphic papules on the face, chest, and back. Exposure to industrial chemicals that occlude the follicle can also lead to an acneiform eruption. Neither infrequent washing nor chocolate (or any other foods) cause acne—no matter what your mother told you. However, stress (like that homecoming dance in high-school) can often flare acne.

There are different types of acne that can affect individuals at various stages of life. Neonatal acne presents shortly after birth and is transient. Infantile acne presents at 6 to 12 months of age and resolves within 1 to 2 years. The most common time to develop acne is around puberty; however, women in their

thirties and forties can also experience acne flares with hormonal fluctuations. As an aside, oral contraceptives (OCPs) go both ways with regard to acne: several OCPs are marketed to treat acne, but they have been reported to worsen acne in some patients. The result of OCPs may depend on the hormonal milieu of the specific patient (women with hyperandrogenism may benefit) and the type of progestin in the OCP. Acne is often improved in the summer months and worsen in the fall and winter. Many women also tend to flare up right before menses.

Question 17.8.3 For acne, which of the following treatment principles is correct?

- A) Treatment can often lead to initial worsening of lesions
- B) Therapeutic response often takes several months
- C) Mild acne can be treated with topical medications
- D) Often times, two or more therapeutic agents must be combined for effective treatment
- E) All of the above are correct

Answer 17.8.3 The correct answer is “E.” Topical retinoids, topical antibiotics, and benzoyl peroxide are the first-line agents and can be titrated as needed. Retinoids should be applied at bedtime. The main oral antibiotic agents are tetracyclines and should be used as **add-on therapy** to topical agents for moderate-to-severe inflammatory acne. OCPs with low androgenic progestones can also be helpful. Since acne lesions may take up to 2 months to resolve, one may not notice a therapeutic response for several months (once the current crop of lesions resolve).

HELPFUL TIP:

Topical retinoids such as tretinoin are most effective for comedonal acne. Other topical retinoids include adapalene and tazarotene.

After a few months of topical therapy with benzoyl peroxide wash, topical clindamycin cream, and topical tretinoin, your patient returns with persistent lesions, including mild scarring and cystic lesions. You are considering isotretinoin, which is indicated for severe, recalcitrant, nodular acne.

Question 17.8.4 Which of the following is FALSE regarding the use of isotretinoin?

- A) Two methods of contraception are required in all reproductive age women along with frequent pregnancy tests
- B) It should not be used with tetracycline
- C) Hypertriglyceridemia is a possible side effect
- D) Patient should be monitored closely for changes in mood
- E) A patient can only receive one course of isotretinoin

Answer 17.8.4 The correct (or rather False) answer is “E.” Isotretinoin is an oral retinoid and is pregnancy category X. Because of this, the FDA has developed a mandatory patient

registry called “iPLEDGE.” All patients must enroll in this registry before receiving the medication and prescribers also need to be registered. Female patients of reproductive age are required to use two contraceptive methods *and have monthly pregnancy tests*. As both tetracycline and isotretinoin can lead to pseudotumor cerebri, they should not be used together. Hypertriglyceridemia, dry eyes, dry lips, and dry skin are common side effects. Less common side effects include decreased night vision, joint pain, and headaches. Isotretinoin has been reported to cause premature closure of growth plates rarely. There have been reports in the popular press and the scientific literature of suicide in patients on isotretinoin, though population-based studies have failed to demonstrate a causal relationship. Patients with a history of mental health issues should be followed carefully for any changes in their mood or behavior. Approximately one-third of patients who receive isotretinoin will require additional courses during their lifetime.

HELPFUL TIP:

Oral retinoids (isotretinoin) are vitamin A derivatives, so vitamin A supplements should be avoided as the combination may lead to vitamin A toxicity.

HELPFUL TIP:

Women should continue contraception for 1 month after discontinuing treatment.

► **Objectives: Did you learn to ...**

- Diagnose and treat acne?
- Identify side effects of isotretinoin?

► **CASE 17.9**

A 26-year-old female patient presents to your office with painful, nonpruritic pink bumps that started last week on her shins. You find the firm lesions easier to palpate than to visualize (see Fig. 17-16).

Question 17.9.1 What is the most likely diagnosis in this patient?

- A) Erythema multiforme
- B) Urticaria
- C) Erythema nodosum
- D) Erythema migrans
- E) Lumpy shin disease (aka, “footballer’s disease” in England)

Answer 17.9.1 The correct answer is “C.” This is erythema nodosum. Typically, these firm nodules occur first on shins and are often more easily palpated than seen. They may then spread to the thighs, trunk, and extensor surfaces of the arms. Erythema multiforme (“A”) presents as erythematous, targetoid lesions usually affecting the distal extremities including palms

FIGURE 17-16. Erythema nodosum.

and soles. Urticaria (“B”) is not tender but would be intensely pruritic. Erythema migrans (“D”) is the quintessential lesion of Lyme disease: a nontender, nonpruritic red plaque with a central clearing. While “E” is technically correct in its description, we know of no such disease entity.

HELPFUL TIP:

Erythema migrans is often thought of as a single “bull’s eye” lesion in the area of the tick attachment. However, the “bull’s eye” is present in a minority of cases, and erythema migrans can have multiple widespread lesions in some patients with Lyme.

Question 17.9.2 Which of the following can cause erythema nodosum?

- A) OCPs
- B) Streptococcal pharyngitis
- C) Sarcoid
- D) Viral upper respiratory infection
- E) All of the above

Answer 17.9.2 The correct answer is “E.” All of these entities may cause erythema nodosum, but viral URI and streptococcal pharyngitis are most common. Multiple medications can also be responsible.

This patient does relate a history of URI symptoms about 1 week prior to the onset of her symptoms.

Question 17.9.3 What advice are you going to give this patient?

- A) The rash tends to be self-limiting and will resolve in 4 to 6 weeks
- B) The rash will heal with scarring
- C) The rash will likely spread to the face and upper extremities before it resolves
- D) This is a chronic disease and no treatment is available

Answer 17.9.3 The correct answer is “A.” In general, erythema nodosum heals spontaneously in 3 to 6 weeks without scarring. There are treatment options available if the patient is symptomatic. If erythema nodosum is caused by an infection, that infection should be treated appropriately. If it was caused by a medication, such as an oral contraceptive pill, it should be discontinued. Nonsteroidal anti-inflammatory agents can be used to help with the pain. For patients with severe painful disease, systemic steroids can be considered.

► **Objectives: Did you learn to ...**

- Recognize erythema nodosum?
- Describe some of the causes and natural history of erythema nodosum?

QUICK QUIZ: ERYTHEMA MULTIFORME

Which of the following cause erythema multiforme?

- A) Viral upper respiratory infection
- B) Cimetidine
- C) Herpes simplex outbreak
- D) Nifedipine
- E) All of the above

The correct answer is “E.” All of the above are causes of erythema multiforme as are many, many other medications. The most common precipitator of erythema multiforme is herpes simplex. Look for this association in your patients.

HELPFUL TIP:

Sunlight is a frequent precipitator of an outbreak of herpes labialis.

► **CASE 17.10**

A patient presents to your office with a 1-week history of a pruritic rash that comes and goes. No lesion is present for more than 24 hours. It involves his entire body except for his face. He cannot remember any new products with which he has been in contact (soaps, detergents, etc.). He is quite concerned. You correctly diagnose urticaria (Fig. 17-17).

FIGURE 17-17. Urticaria (Courtesy of Drs. Karolyn Wanat and Megan Noe.)

Question 17.10.1 Your next step is:

- A) Skin testing for various commercial products
- B) Viral titers for CMV, EBV, etc.
- C) RAST test for common allergens
- D) Recommend no further evaluation
- E) Prescribe an epinephrine injection for emergency use at home

Answer 17.10.1 The correct answer is “D.” No workup is needed at this time. Urticaria should be classified as “acute” (<6 weeks) or “chronic” (>6 weeks). Acute urticaria requires no further workup and should be treated symptomatically with antihistamines. Note that steroids do not add to antihistamines and should only be used in the case of angioedema (*Ann Emerg Med.* 2018;71(1):125–131.e1). In patients with chronic urticaria, a more detailed history should be taken looking for other symptoms or signs of infection, with laboratory testing as appropriate. In fact, beyond a good history, an extensive workup is pretty much futile. It is almost impossible to identify a cause of urticaria by laboratory testing. “E,” an epinephrine injector, is not indicated for the treatment of urticaria but would be appropriate if this patient has experienced an anaphylactic reaction.

Question 17.10.2 Urticaria is categorized as which of the following?

- A) Type I hypersensitivity reaction
- B) Type II hypersensitivity reaction
- C) Type III hypersensitivity reaction
- D) Type IV hypersensitivity reaction
- E) None of the above

Answer 17.10.2 The correct answer is “A.” Urticaria is a clinical feature of a type I reaction. Other clinical presentations of type I reactions include anaphylaxis and angioedema. See Chapter 4 for a detailed answer on hypersensitivity reactions.

Question 17.10.3 You decide to provide symptomatic care for this patient. Appropriate medications include which of the following?

- A) Ranitidine
- B) Doxepin
- C) Diphenhydramine
- D) Cetirizine
- E) All of the above

Answer 17.10.3 The correct answer is “E.” All of the above can be useful in the symptomatic treatment of urticaria. Patients should be started on sedating and nonsedating antihistamines to control their symptoms. Doses greater than the recommended daily dose are frequently required. H₂-blockers are effective in the 10% to 15% of patients who do not respond to H₁-blockers. Of note, H₂-blockers also are used in anaphylaxis treatment, but the evidence is weak. Finally, doxepin is a particularly effective H₁- and H₂-blocker that can be used as a sedating antihistamine.

The patient returns to see you 6 weeks later and is still having symptoms. You are wondering a bit more about potential causes of this unfortunate individual’s urticaria.

Question 17.10.4 Which of the following are causes of urticaria?

- A) Sweating
- B) Cold (OK, get over it. Move to Hawaii and quit whining!)
- C) Water (So that is why you never shower and only drink beer?)
- D) Pressure (OK, get over it. Use an antigravity unit and quit whining!)
- E) All of the above

Answer 17.10.4 The correct answer is “E.” All of the above can cause urticaria. In fact, these are not uncommon causes and can be identified by history. Patients may develop urticaria with exercise and sweating (cholinergic urticaria), cold (during the winter), and pressure (e.g., walking). Of particular note is water urticaria that occurs with water contact, including bathing and showering. See Table 17-2 for a more complete listing.

HELPFUL TIP:

Cold urticaria often starts with lesions appearing on exposed skin but may be worsened with rewarming.

You decide that this patient probably has cold urticaria (the fact that it is summer does not dissuade you as it may be related to all of that air conditioning!).

Question 17.10.5 The next drug you might want to try on this patient is:

- A) Cyproheptadine (Periactin)
- B) Prednisone
- C) Montelukast
- D) Nifedipine
- E) Aspirin

TABLE 17-2 CAUSES OF URTICARIA: A PARTIAL LIST

Physical Urticaria	Allergic	Systemic	Medications (Direct Mast Cell Degranulators)
<ul style="list-style-type: none"> • Pressure • Water • Vibration • Cold • Sunlight 	<ul style="list-style-type: none"> • Foods (nuts, fish) • Insect stings • Drugs (IgE mediated) 	<ul style="list-style-type: none"> • Malignancy • SLE • RA • Chronic Hep B and C • EBV 	<ul style="list-style-type: none"> • NSAIDs • Aspirin • Opiates • ACE Inhibitors • Contrast dye

Answer 17.10.5 The correct answer is “A.” The physical urticarias (cold and pressure especially) may respond better to cyproheptadine than other modalities. If this patient had a “typical” urticaria, you might want to try prednisone, one of the leukotriene inhibitors or nifedipine (which interferes with mast cell degranulation). Remember that leukotriene inhibitors, steroids, etc., are second line and should be used only when first-line drugs have failed or are not tolerated (cyproheptadine for physical urticaria; doxepin, antihistamines, etc., for “typical” urticaria). There are no good studies on the effectiveness of leukotriene inhibitors (anecdotal evidence only), but they might be worth trying when all else fails.

**HELPFUL TIP:**

Any number of drugs can cause urticaria. Look at the medication list! Medications that act as mast cell degranulators should be avoided in patients with chronic urticaria, including aspirin, opiates, polymyxin B, NSAIDs, and systemic lidocaine.

► **Objectives: Did you learn to ...**

- Recognize urticaria?
- Identify potential causes of urticaria?
- Develop a treatment strategy for patients with urticaria?

**QUICK QUIZ: PRECANCEROUS LESIONS**

Actinic keratoses (AKs) are precursors to what?

- A) Nothing
- B) Melanoma
- C) Basal cell carcinoma
- D) Squamous cell carcinoma
- E) Granuloma annulare

The correct answer is “D.” AKs are precursors to squamous cell carcinomas. As such, they should be treated. Options include cryotherapy, laser therapy, or 5-fluorouracil topically.

**HELPFUL TIP:**

Less than 1% of AKs progress to squamous cell carcinoma per year. Some spontaneously involute and some remain as AKs. However, in an individual, the risk of an AK developing into a squamous cell carcinoma increases with the number of AKs present.

**QUICK QUIZ: SKIN BARNACLES**

What is the appropriate treatment for an asymptomatic seborrheic keratosis?

- A) No treatment necessary
- B) Cryotherapy
- C) Surgical excision
- D) Topical steroids
- E) Topical antibiotic ointment

The correct answer is “A.” Seborrheic keratoses are benign lesions that do not develop into malignancies. They are the greasy-looking, stuck-on growths that occur with age. They can be treated, if symptomatic, with cryotherapy. They look ugly, patients hate them, but they are harmless.

► **CASE 17.11**

A 50-year-old female with type 2 diabetes controlled with insulin complains of a rash that has developed on her legs over the past year. It started as a small patch on her left leg and then “spread” to her right leg. It is neither painful nor pruritic. You are impressed by the rash she shows you (Fig. 17-18).

Question 17.11.1 The most appropriate next step in the management of these lesions is which of the following?

- A) A topical mid-potency steroid under occlusion or intralesional steroids
- B) Discontinue insulin
- C) Increase her insulin dose
- D) Liberal use of emollients (e.g., petrolatum)
- E) Leg elevation and application of compressive stockings

Answer 17.11.1 The correct answer is “A.” This patient has developed necrobiosis lipoidica, a benign condition of the skin affecting a small percentage of patients with diabetes. Look for brownish red patches or plaques with yellowish areas through the center. The center is often shiny with telangiectasias. The legs are most often involved and the lesions may be painful. The name describes the pathology: necrobiosis refers to the inflammation around destroyed collagen, and lipoidica refers to the yellowish color associated with lipid deposits. It *does*

FIGURE 17-18. Necrobiosis Lipodica (Wolff K, Johnson RA, Suurmond D. *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*. 5th ed. New York: McGraw-Hill; 2005, Fig. 5-1. Copyright © The McGraw-Hill Companies, Inc. All rights reserved.)

not seem to be caused by insulin or affected by glucose control, so “B” and “C” are not appropriate choices. These lesions can be confused with eczema, and in fact may respond to topical steroids (“A”); however, emollients are not useful. Finally, necrobiosis lipoidica might be confused with the skin changes associated with venous stasis and chronic edema, which would be treated as in “E.” Patients should know that necrobiosis lipoidica is often chronic and difficult to treat but benign. The diagnosis is clinical but can be confirmed by biopsy, and treatment is not always necessary.

Your patient also complains of thick, dark, velvety patches under her arms (Fig. 17-19). She’s unsure of the duration, but states, “They’ve been with me a while. I just wondered if my medication might cause these.” She gives you an accusing look, and you have to admit that she takes more than a few medicines related to her diabetes.

Question 17.11.2 Which medication provides a clue to the diagnosis?

- A) Aspirin
- B) Lisinopril
- C) Insulin
- D) Simvastatin

Answer 17.11.2 The correct answer is “C.” The lesions are typical of acanthosis nigricans, a hyperkeratotic, hyperpigmented condition affecting skin folds (neck, inguinal area, axilla, etc.). The common causes of acanthosis nigricans are obesity, insulin resistance, and diabetes. From medical school, we all remember acanthosis nigricans as a cutaneous manifestation of internal malignancy. But such a presentation is rare. Cancer is more likely in patients with extensive and quickly progressing lesions, and as you might expect, it’s not a good sign.

FIGURE 17-19. Acanthosis nigricans.

HELPFUL (ISH) TIP:

Another cutaneous manifestation of internal malignancy is the sign of Leser–Trelat: a large crop of seborrheic keratoses that erupt quickly. Note that seborrheic keratoses themselves are benign and that knowing about Leser–Trelat is mostly good for looking smart.

Your patient returns a year later and the lesions on her legs have essentially disappeared. Now she has a new concern. She reports a sore on the bottom of her great toe. She’s uncertain how it occurred and thinks it has only been present for a few days. You find a 1-cm circular ulcer at the plantar aspect of her great toe. Pulses are diminished.

Question 17.11.3 Which of the following should be the next step in treatment?

- A) Culture the wound
- B) Perform an MRI of the foot
- C) Perform monofilament testing to check sensation in the foot
- D) Debride the wound
- E) Obtain ankle–brachial indices

Answer 17.11.3 The correct answer is “E.” The described wound is most likely a diabetic foot ulcer, but the location and the patient’s history of diabetes do elicit concern for an ulcer related to vascular disease. In addition, good vascular supply to the foot is necessary for wound healing. Therefore, you need to know the status

of blood flow to the foot. This may be accomplished by physical examination. For patients at high risk for peripheral vascular disease or without strong pulses, ankle-brachial indices would be the next step. Culture of an open foot ulcer ("A") is pretty much worthless as it will likely return as polymicrobial. X-ray may be warranted as well as probing the lesion to see if it reaches the bone in order to evaluate for osteomyelitis, but starting with MRI ("B") is jumping the gun in this particular case. Knowledge of a patient's baseline monofilament sensation ("C") is important and good general foot care (shoes that fit, meticulous skin and nail care) can help in the prevention of future ulcers. Wound debridement ("D") will help to remove necrotic tissue and improve the speed of wound healing. The biofilm must be removed down to healthy tissue in order to maximize healing.

Ankle-brachial indices in both legs are normal. The rest of her skin is in good condition. Through her diligent care and control of her diabetes, the ulcer heals. She returns 3 months later with a new skin concern. On her anterior shin, she has developed a clear fluid-filled blister about 1 cm in diameter and irregular in shape. There is no erythema, no pruritus, and no pain. She denies trauma and new environmental contacts.

Question 17.11.4 Which of the following is the most likely diagnosis?

- A) Dyshidrotic eczema
- B) Contact dermatitis
- C) Staphylococcal scalded skin syndrome (SSSS)
- D) Bullosis diabeticorum
- E) Drug eruption

Answer 17.11.4 The correct answer is "D." Bullosis diabeticorum, or bullous disease of diabetes, occurs in less than 1% of diabetic patients. However, patients may be alarmed by it and seek treatment. The cause is unknown, but it typically follows a benign course and resolves spontaneously over a few weeks or months. Because it requires no intervention, it is useful to distinguish bullosis diabeticorum from dyshidrotic eczema and contact dermatitis, both of which may mimic the disease except for pruritus and inflammation.

► **Objectives: Did you learn to ...**

- Identify necrobiosis lipoidica, acanthosis nigricans, and bullosis diabeticorum?
- Treat these conditions (if necessary)?
- Evaluate a diabetic foot ulcer?

QUICK QUIZ: SKIN SO ITCHY

A 60-year-old male who underwent pacemaker placement 3 days ago comes in with the pruritic rash seen in Figure 17-20.

This rash is most likely:

- A) Grover disease
- B) Lichen planus
- C) Contact dermatitis

FIGURE 17-20. Contact dermatitis.

- D) Atopic dermatitis
- E) Pyoderma gangrenosum

The correct answer is "C." This is contact dermatitis, which may be acute, subacute, or chronic. It is an erythematous, pruritic eruption that usually blisters and leaves a crust. More chronic forms of contact dermatitis present with lichenification and scaling. The rash in Figure 17-20 does not look like any of the other choices. Grover disease (not related to the Sesame Street muppet but it would be cool if it were) ("A"), also known as transient acantholytic dermatosis, presents with small, sometimes pruritic, erythematous papules on the back and chest, which may blister. Lichen planus ("B") presents with pruritic, red-to-purple, flat-topped papules. Atopic dermatitis ("D") is discussed earlier in the chapter. Pyoderma gangrenosum ("E") presents with painful, red nodules and pustules that ulcerate. Again, since we cannot display pictures of all diseases mentioned, please look at one of the websites included at the beginning of this chapter.

HELPFUL TIP:

Pyoderma gangrenosum is a diagnosis of exclusion but may be differentiated from other ulcer types by the exquisite pain it causes and the pathergic phenomenon it displays, where the wound will worsen in response to surgical manipulation (e.g., biopsy, debridement). It can be associated with inflammatory bowel disease, inflammatory arthritis, solid organ neoplasm (23%!), hematologic neoplasm or other hematologic disorders. Look at some pictures online. This is not one to miss.

QUICK QUIZ: MR. SCRATCHER

A 76-year-old male comes to your clinic with a 1-year history of pruritic, eczematous rash on his chest and back. He has no atopic history or eczema as a child. He has no other active

medical issues. He has tried moisturizers and over-the-counter hydrocortisone cream, which have provided minimal relief.

Which of the following is the most appropriate next step in his management?

- A) Tacrolimus ointment
- B) Skin scraping for KOH preparation
- C) High-dose topical steroids
- D) Punch biopsy
- E) Oral antihistamines

The correct answer is “D.” The development of a new, eczematous rash in an adult patient can be associated with more serious condition. This may be indicative of an underlying lymphoproliferative malignancy such as cutaneous T-cell lymphoma. In addition, a drug hypersensitivity reaction can also be a consideration. The most appropriate next step in this patient’s management would be punch biopsy.

QUICK QUIZ: DARIER SIGN

A 4-year-old girl comes to clinic accompanied by her mother for her yearly checkup. Her mother requests that you examine her daughter’s skin because of a rash. Upon examination, you identify scattered reddish-brown macules on the back and chest. When stroked, the lesions urticate. There are no other complaints or abnormalities on physical examination.

What is the most likely diagnosis?

- A) Atopic dermatitis
- B) Contact dermatitis
- C) Congenital nevi
- D) Cutaneous lupus
- E) Urticaria pigmentosa

The correct answer is “E.” This child’s rash is most likely secondary to urticaria pigmentosa, which is a cutaneous form of mastocytosis. Clinical findings include reddish-brown macules or slightly raised papules, which represent cutaneous accumulations of mast cells. These occur most commonly on extensor surfaces, thorax, and abdomen. When stroked, these lesions can urticate (Darier sign). Urticaria pigmentosa is the most common skin manifestation of mastocytosis in children and adults. Eighty percent of cases appear during the first year of life. Lesions resolve in >50% of patients by adolescence. The diagnosis is confirmed by skin biopsy. In children, urticaria pigmentosa is rarely associated with systemic disease.

▶ CASE 17.12

A 44-year-old female presents for a scaly rash for the past 6 months. It started on her knees and elbows and has spread to involve her scalp, abdomen, and gluteal cleft (Fig. 17-21). She has also noticed the appearance of “little holes” in her finger nails. She has tried moisturizers without improvement. She

FIGURE 17-21. Herpes zoster.

also reports stiffness in her wrists and ankles that is worse in the morning. She denies smoking, but drinks three to four glasses of wine every night.

Question 17.12.1 What is the most likely diagnosis?

- A) Cutaneous T-Cell Lymphoma
- B) Psoriasis
- C) Tinea Corporis
- D) Contact Dermatitis
- E) Eczema

Answer 17.12.1 The correct answer is “B.” This clinical scenario is most suggestive of psoriasis. Psoriasis is a chronic inflammatory disease of the skin that affects about 3% of the population. Psoriasis is characterized by well-circumscribed plaques with silver scale. Common areas of involvement are the scalp, extensor surfaces, and gluteal cleft. Patients with psoriasis can also have nail involvement including pitting, oil spots and onycholysis (lifting of the nail plate from the nail bed), and subungual parakeratosis that can resemble onychomycosis. About 30% of patients with psoriasis also have psoriatic arthritis and any patient with joint symptoms should be referred to rheumatology for evaluation. Patients with psoriasis also are at higher risk of developing cardiovascular disease, diabetes, hypertension, and metabolic syndrome. Cutaneous T-cell lymphoma (“A”) more commonly occurs in areas covered by a “bathing suit” on the trunk and on the scalp and extensor surfaces as above. Tinea Corporis (“C”) can mimic psoriasis but is typically not as widespread. Adults with tinea corporis may also have concomitant tinea pedis. The rash associated with contact dermatitis (“D”) should be more geometric—from contact with the allergen—and is typically not symmetric, as above. Finally, in adults, eczema more commonly occurs on the hands, feet, and flexor, not extensor, surfaces. Also, eczema is not associated with nail pitting.

Based on the clinical appearance, you diagnose the patient with psoriasis and estimate the plaques to cover about 5% of her body surface area. You prescribe a medium-to-high

potency topical steroid. She returns in 3 months and notes her psoriasis has not improved with regular use of the topical steroid.

Question 17.12.2 Given the patient has not improved with topical steroids, what is an appropriate treatment option?

- A) More topical steroids
- B) Oral Steroids
- C) Oral Antifungal agent
- D) Phototherapy
- E) Methotrexate

Answer 17.12.2 The correct answer is “D.” Phototherapy is a well-established treatment option for patients with moderate-to-severe psoriasis. Most commonly, narrow band ultraviolet B (nbUVB) light (311 nm) is used. Other treatment options for severe psoriasis include: biologics—monoclonal antibodies that bind to inflammatory cytokines like tumor necrosis factor (adalimumab [Humira], certolizumab [Cimzia], etanercept [Enbrel], infliximab [Remicade]); IL-12/23 (ustekinumab [Stelara]); IL-17 (brodalumab [Siliq], ixekizumab [Taltz]; secukinumab [Cosentyx]) and IL-23 inhibitors (guselkuma [Tremfya], tildrakizumab [Ilumya]); and apremilast (Otezla), an oral phosphodiesterase-4 inhibitor. Methotrexate (“E”) is also a treatment for psoriasis and psoriatic arthritis, but this woman reports drinking three to four glasses of alcohol nightly, so she is not an appropriate candidate for methotrexate. While changing topical steroids can sometimes help to improve psoriasis (“A”), in patients with 5% BSA, who report good compliance, alternative therapies should be considered. While oral steroids (“B”) may improve the redness of psoriatic plaques, *they should not be used for the chronic management of psoriasis* because of concern for rebound or pustular psoriasis flare upon completion of therapy. While tinea corporis can mimic psoriasis, in patients without evidence of superficial dermatophyte infection, like a positive KOH scraping, oral antifungal agents (“C”) are unlikely to improve psoriasis.

► **Objectives: Did you learn to ...**

- Diagnose psoriasis?
- Identify the various treatment modalities utilized, often with assistance from a dermatologist, to treat psoriasis?

QUICK QUIZ: PATCHY HAIR LOSS

A 14-year-old female presents to your office with a circular, shiny bald patch on the parietal scalp. She did not know that it was there until her hairdresser first noticed it about a month ago. She is very anxious that she is going to lose all her hair. On exam, there are two circular alopetic patches on the left parietal and left occipital scalp with exclamation point hairs present around the border. Pitting is also present on several finger nails.

The most likely diagnosis is:

- A) Tinea capitis
- B) Alopecia areata
- C) Androgenic alopecia

- D) Trichotillomania
- E) Telogen effluvium

The correct answer is “B.” Alopecia areata is an immune-mediated disorder that causes non-scarring hair loss, typically presenting with circular, discrete patches on the scalp, but other hair-bearing sites can also be affected. The clinical course of alopecia areata is unpredictable. About 50% of patients achieve hair-regrowth within a year, but recurrence is common. Uncommonly the hair loss can progress to involve the entire scalp (alopecia totalis) and/or all body sites (alopecia universalis). Intralesional or topical steroids are first-line therapy for localized alopecia areata.

The other diagnoses listed above are all in the differential diagnosis of patchy or diffuse hair loss. Tinea capitis (“A”) is a superficial dermatophyte infection of the scalp, more common in children. While patients may present with circular patches or hair loss, there is typically an overlying crust or scale, which was not present in this case. Inflammation and cervical lymphadenopathy can also be present. Trichotillomania (“D”) is an impulse control disorder where patients repeatedly pull out their own hair. While trichotillomania may present with discrete patches of hair loss, short or broken-off hairs are typically seen throughout the patch or at the periphery.

Androgenetic alopecia (“C”) (male/female pattern hair loss) is a gradual loss of hair in adult men and women. Men typically develop gradual thinning of hair on the temporal and vertex scalp, often affecting the frontal hairline. Women most commonly report thinning of the hair on the frontal and vertex scalp, creating noticeable thinning around the part. Treatment in men includes finasteride (first line) and topical minoxidil. For women, treatment includes minoxidil with spironolactone (an antiandrogen) as second line. Telogen effluvium (“E”) is diffuse hair thinning caused by a rapid shift in the follicular hair cycling leading to premature shedding of hair. Common triggers for telogen effluvium include childbirth, major illness/surgery, drugs, malnutrition, and severe emotional stress (death of a friend/family member, moving, starting a new job). Discrete patches of hair loss are typically not seen in androgenic alopecia or telogen effluvium. Evaluation of telogen effluvium includes “the hair pull test.” Grasp 50 to 60 hairs and pull. The extraction of more than 6 to 10 hairs is abnormal. Treatment is to address the underlying cause.

► CASE 17.13

A 30-year-old stressed out medical student presents to your clinic with a worsening, painful rash on one side of her chest. She denies any prior spots like this and has no other medical problems. She is up-to-date on her vaccinations because of medical school and complains that this rash is interfering with studying for the upcoming final block of examinations (she wants to be a dermatologist, so she really has to “ace” her examinations). Physical examination demonstrates a linear group of vesicles with

FIGURE 17-22. (Courtesy of Drs. Karolyn Wanat and Megan Noe.)

erythema on her left chest following a dermatomal pattern. See Figure 17-22 (in which the young medical student has turned into an older man).

Question 17.13.1 Treatment should be initiated with which of the following therapies:

- A) Cephalexin
- B) Mupirocin
- C) Paroxetine
- D) Valacyclovir
- E) No treatment is necessary as this is self-limited

Answer 17.13.1 The correct answer is “D.” This is most likely herpes zoster, which is reactivation of the varicella zoster virus. Valacyclovir is an effective treatment. Even in immunocompetent patients, herpes zoster can be reactivated from the dorsal root ganglion during periods of stress. Although it can be self-limited, treatment with antiviral (valacyclovir or acyclovir) is recommended during the first 72 hours to decrease outbreak and risk of post-herpetic neuralgia. With the presentation of pain, agents such as gabapentin, amitriptyline, or pregabalin are also often prescribed. Post-herpetic neuralgia can also be treated with topical lidocaine patches; however, these should not be applied to open blisters/wounds on the skin. A live,

attenuated, vaccine to prevent zoster (Zostavax) is available. In 2017, a two-dose recombinant zoster vaccine (Shingrix) was FDA approved for healthy adults 50 years of age and older. It is more effective than Zostavax and is now considered preferable.

► **Objective: Did you learn to ...**

- Recognize and treat herpes zoster (Shingles)?

Clinical Pearls

- Be sure to look for abnormal looking skin lesions on the palms, soles of the feet, and near the nails, as these lesions may progress to more aggressive forms of melanoma before they are discovered.
- Confirm a toenail fungal infection prior to initiating systemic antifungal therapy.
- Do not perform a shave biopsy on a skin lesion if you are suspecting melanoma as depth of the lesion is used to stage melanoma and determine prognosis.
- Do not routinely recommend diuretics as general therapy to lessen the edema of venous stasis as they may make symptoms worse by decreasing circulating volume and increase renal retention of sodium. Instead, recommend weight loss, compression stockings, and leg elevation.
- Do not use systemic antibiotics for first-line treatment of acne. Instead, employ topical agents as first-line therapy.
- Do not use topical antifungal agents to treat fungal nail infections. They are relatively expensive, have marginal benefit, and a high recurrence rate.
- Recommend regular sun protection using sunscreen, light protective long-sleeved clothing, hat, and sunglasses.
- Recommend timely removal/biopsy of any suspicious looking nevi.
- Refer infants with larger, segmental hemangiomas to dermatology and obtain imaging studies to rule out syndromes with other associated anomalies.

BIBLIOGRAPHY

Neurology

Daniel M. Anderson, Qiang Zhang, and Teri Thomsen

► CASE 18.1

A 75-year-old right-handed man presents to the emergency department (ED) with dizziness that started 5 hours ago. His dizziness consists of a spinning sensation and he feels off balance as he walks. He reports coughing when trying to drink water earlier, but otherwise notes no other symptoms. He has an unremarkable past medical history and is taking no medications. On examination, he is found to have left-sided ptosis and left facial numbness to pinprick. Gag reflex is absent. Motor examination is otherwise unremarkable. Sensory examination revealed decreased pinprick sensation of the right arm and leg. He is unsteady while walking, tending to lean leftward.

Question 18.1.1 What is the most likely diagnosis in this patient?

- A) Acute vestibulitis/labyrinthitis
- B) Benign paroxysmal positional vertigo (BPPV)
- C) Cerebellar stroke
- D) Brain stem stroke
- E) Ménière attack

Answer 18.1.1 The correct answer is “D.” Although dizziness can be associated with all of the above disorders, a brain stem stroke is the most likely answer. The associated symptoms of ptosis (suggestive of Horner syndrome: miosis, ptosis, hypohydrosis—generally from disruption of the sympathetic innervation), absent gag reflex with patient report of possible dysphagia, and crossed sensory findings (decreased sensation of the left side face and the right arm and leg) are most consistent with brain stem localization. In peripheral etiologies of vertigo (“A,” “B,” and “E”), one would not expect these findings (sensory phenomena, ptosis, or swallowing difficulties). In BPPV (“B”), one would expect brief attacks, lasting seconds to minutes, and not a prolonged attack. In Ménière’s (“E”), there is often some history of tinnitus, ear fullness, and/or hearing loss (low frequency initially). Acute vestibulitis/labyrinthitis (“A”) are resultant of

inflammation of the inner ear and most commonly present following a viral respiratory tract infection. Onset is typically sudden, about 1 to 2 weeks after resolution of infection, and consist of vertigo and loss of hearing vs. tinnitus without sensory findings. A pure cerebellar stroke (“C”) would not be expected to have sensory findings.

HELPFUL TIP:

When a patient complains of dizziness, ask what the patient means by “dizziness.” The term “dizziness” means different things to different patients. “Dizziness” may represent vertigo, lightheadedness, pre-syncope, disequilibrium when walking (e.g., falling to one side), anxiety, etc. Also, know that there is controversy among experts as to whether this delineation of dizziness is more misleading than it is helpful.

In conferring with your colleague, she asks if you are going to give tissue plasminogen activator (tPA).

Question 18.1.2 Which one of the following is NOT a contraindication to intravenous (IV) tPA?

- A) Age >75
- B) INR >1.7
- C) Platelets <100,000
- D) Stroke within last 3 months
- E) Glucose <50
- F) Hemorrhage seen on head CT

Answer 18.1.2 The correct answer is “A.” Acute stroke treatment with thrombolytics **may** be of benefit if administered to carefully selected patients within **3 hours** of symptom onset, or **4.5 hours** of symptom onset if certain criteria are met (see Table 18-1). When administered properly, the number needed to treat for improvement at 3 months is **6**. However, there is no survival benefit. The risk of hemorrhage is 6%

TABLE 18-1 ELIGIBILITY AND CONTRAINDICATIONS FOR TPA FOR ACUTE ISCHEMIC STROKE, SYMPTOM ONSET 0–4.5 HOURS**Eligibility**

- Age \geq 18 years
- Clinical diagnosis of ischemic stroke causing measurable neurological deficit

Contraindications

- Intracranial hemorrhage on CT
- History of intracranial hemorrhage
- Clinical presentation suggesting subarachnoid hemorrhage
- Intracranial/intraspinal surgery within the past 3 months
- Stroke or serious head trauma within the past 3 months, or posttraumatic infarction
- Sustained blood pressure of SBP $>$ 185 or DBP $>$ 110 mm Hg
- Symptoms consistent with infective endocarditis
- Known or suspected aortic dissection
- Intra-axial intracranial neoplasm
- Active internal bleeding or known bleeding diathesis
- Recent GI bleeding within 21 days
- Platelet count $<$ 100,000
- PTT $>$ 40 or on anticoagulation with an INR of $>$ 1.7 or PT \geq 15
- Current use of low-molecular-weight heparin (LMWH), direct thrombin inhibitors, or direct factor Xa inhibitors

Relative contraindications

- Symptoms minor or rapidly improving
- CT showing multilobar infarction ($>$ 1/3 middle cerebral artery distribution)
- Seizure at onset of acute stroke
- Glucose $<$ 50 mg/dL or $>$ 400 mg/dL
- Known arteriovenous malformation or aneurysm
- Major surgery or serious trauma, excluding head trauma, in the past 14 days
- History of GI (over 21 days ago) or genitourinary tract hemorrhage
- Recent arterial puncture at a non-compressible site in the preceding 7 days
- Recent lumbar puncture in the preceding 7 days
- Myocardial infarction in the past 3 months, pericarditis
- Preexisting disability or dementia
- Pregnancy or within 14 days after delivery
- Ophthalmic hemorrhagic conditions including diabetic hemorrhagic retinopathy

Additional relative contraindications for patients presenting in the window of 3–4.5 hours from symptom onset

- Age $>$ 80 years
- History of prior stroke and diabetes
- Any active anticoagulant use, even with INR \leq 1.7
- NIH stroke score $>$ 25

AHA/ASA 2018 guideline.

**HELPFUL TIP:**

Make sure you are compulsive about inclusion and exclusion criteria! Thrombolytics **do not** seem to confer an advantage in those with a “mild, non-disabling stroke” (NIH stroke scale 0–5 and a deficit that *would not* preclude the patient from employment) (*JAMA*. 2018 Jul 10; 320(2):156–166). When in doubt, call the nearest stroke-accredited hospital to speak to the on-call neurologist.

The patient is outside of the 4.5-hour window for thrombolysis and has a blood pressure of 200/100 mm Hg.

Question 18.1.3 The best next step in treatment at this point is to:

- Administer IV labetalol with a blood pressure goal of 140/90 mm Hg
- Administer IV labetalol with a blood pressure goal of 130/85 mm Hg
- Administer IV nitroglycerin with a blood pressure goal of 150/90 mm Hg
- Administer sublingual nifedipine with a blood pressure goal of 160/95 mm Hg
- Monitor the patient's blood pressure and avoid antihypertensives

Answer 18.1.3 The correct answer is “E.” Do not treat this patient's blood pressure unless the blood pressure is $>$ 220 mm Hg systolic or $>$ 120 mm Hg diastolic; and even then the goal would be to reduce blood pressure by 15% over 24 hours. Treating blood pressure during the acute phase of ischemic stroke reduces central nervous system (CNS) perfusion and puts ischemic brain at risk. Obviously, this does not apply if the patient has a hypertensive urgency or hypertensive crisis (e.g., heart failure or other end-organ dysfunction). **Note that this is for ischemic stroke and not hemorrhagic stroke. Lowering the blood pressure to a systolic of around or below 160 mm Hg is indicated in hemorrhagic stroke.** In this scenario, if you use an antihypertensive, labetalol or nicardipine is preferred. You can also use hydralazine if the heart rate is low. Why not nitrates? Nitrates cause intracranial vasodilatation increasing intracranial pressure.

Question 18.1.4 After admission to a monitored bed, which of the following diagnostic evaluations is LEAST likely to be of further benefit in this patient?

- Fasting lipid profile
- Magnetic resonance angiography (MRA) of the head and neck
- Fasting glucose
- Hypercoagulable testing
- Transesophageal echocardiogram

Answer 18.1.4 The correct answer is “D.” Hypercoagulable states are an uncommon cause of stroke. If you are unable to determine the origin of a clot in a thromboembolic stroke and

(1 in 16). Of those with symptomatic hemorrhagic transformation, 60% are fatal. There is no upper age cutoff for administration of tPA. Strong contraindications include intracranial hemorrhage, minor or improving symptoms, as well as those listed in Table 18-1. The field of acute stroke care is highly dynamic and lots of progress has been made recently. In addition to tPA, thrombectomy has become standard of care for acute ischemic strokes with large vessel occlusion. When in doubt, please do not hesitate to contact your neurology colleagues.

the patient is otherwise low-risk (let's say a healthy 25-year-old male who runs marathons), then you can consider a workup for a hypercoagulable state. Such an evaluation is not useful in most stroke patients—like your typical 80-year-old hypertensive female, even if her carotid Doppler's and echocardiogram are negative. In addition to monitoring the patient for signs of neurologic decline or complications, evaluation of potential risk factors for recurrent stroke is an integral part of stroke care. Hypertension, hyperlipidemia, cardiac arrhythmia or structural defects, illicit drug use (IV drugs and stimulants), smoking, and diabetes mellitus are risk factors for recurrent stroke and should be evaluated. MRA allows noninvasive evaluation of intracranial and cervical blood vessels in both the anterior and posterior circulation. Echocardiography is also an important part in the evaluation of stroke, and **transesophageal** echocardiography is more sensitive for identifying thrombotic sources for stroke when compared with transthoracic echocardiogram.

The patient is found to have a lateral medullary stroke on MRI and has heavy atherosclerotic burden in his vertebral arteries. Echocardiogram and telemetry are normal.

Question 18.1.5 What would be the optimal antithrombotic medication in this patient for prevention of recurrent stroke?

- A) Coumadin (warfarin)
- B) Aspirin
- C) Plavix (clopidogrel)
- D) Aggrenox (aspirin/dipyridamole)
- E) Pletal (cilostazol)

Answer 18.1.5 The correct answer is "B." In patients with a noncardiogenic source for their stroke, there is no data to support the use of anticoagulation (warfarin) for stroke prevention. Similarly, there is no prospective data to support a role for cilostazol or pentoxifylline in the prevention of stroke.

With regard to antiplatelet agents, low-dose aspirin is the first-line choice. **There has been little benefit shown in increasing the dose of aspirin to more than 81 mg every day, although this may change.** Newer data suggests higher doses of aspirin are needed (325 mg) for those over 70 kg (*Lancet*. 2018 Jul 12;392(10145):361–362). If a patient fails aspirin (recurrent stroke of same mechanism), either **change** to clopidogrel or Aggrenox (combination aspirin/dipyridamole); both are equally effective in stroke prevention.

Dual antiplatelet therapy is gaining favor in TIAs and minor ischemic strokes (NIH stroke scale ≤ 3 or ABCD2 score of 4 or more if patient had a TIA) (NOT major ischemic strokes). You may see aspirin and clopidogrel used together for the first 21 days after a minor ischemic stroke or TIA (*BMJ*. 2018;363:k5130). CHANCE study showed the use of aspirin and clopidogrel within the first 24 hours after symptom onset was effective and superior to aspirin alone for decreasing risk of stroke within the first 90 days without increase in hemorrhage

(*N Engl J Med*. 2013;369:11–19). A more recent study showed that dual antiplatelet for 90 days conferred an overall lower risk of major ischemic events (5% vs. 6.5%) but a higher risk of major hemorrhage (0.9% vs. 0.4%) (*N Engl J Med*. 2018;379:215–225). Stay tuned to see how this all plays out for the standard of stroke care moving forward.

HELPFUL TIP:

Patients with a cryptogenic stroke may have a patent foramen ovale. Current data suggests that repairing this can reduce stroke recurrence especially in those <60 years of age (*BMJ*. 2018;362:k2515); you still need to continue aspirin or another antiplatelet agent.

Your next patient is a 59-year-old male who appears to have had a simple TIA with left-sided focal weakness. The TIA lasted <10 minutes and the patient has a normal blood pressure and is nondiabetic.

Question 18.1.6 His risk of having a stroke in the 48 hours after a simple TIA is:

- A) 1%
- B) 5%
- C) 10%
- D) 20%
- E) 30%

Answer 18.1.6 The correct answer is "A." The overall risk of stroke ranges from 4% to 20% in the 90 days after a TIA. This is a pretty wide range. To narrow down the range a bit, the ABCD² (Table 18-2) has been developed and takes into account age, duration of symptoms, blood pressure, and diabetes. This can be used to predict the 48-hour risk of stroke.

Rapid evaluation of the at-risk patient is warranted, as some of these patients may need anticoagulation or carotid endarterectomy for stroke prevention.

TABLE 18-2 ABCD² CRITERIA

Age: 1 point for age ≥ 60 years
 Blood pressure: 1 point for systolic >140 or diastolic >90 mm Hg
 Clinical features: Focal weakness (2 points) or only speech difficulty (1 point)
 Duration of symptoms: >60 minutes (2 points), ≤ 59 minutes (1 point)
 Diabetes: 1 point

ABCD ² Score	Risk of Stroke in Next 48 Hours (%)
0–3 points	1
4–5 points	4.1
6–7 points	8.1

**HELPFUL (AND UNFORTUNATE) TIP:**

The initial MRI is falsely negative 13% of the time at 4.5 hours in nonposterior circulation regions (*Stroke*. 2013;44(6):1647–1651). It is even worse in the posterior circulation. The initial MRI picked up only 50% of strokes in the posterior circulation that were <1 cm in size and 92% of those >1 cm in size (*Neurology*. 2014;83(2):169–173). What does this mean for you? If you think a patient has had a stroke but the MRI is negative, the patient may still have had a stroke.

► **Objectives: Did you learn to ...**

- Identify signs/symptoms suggestive of acute ischemic stroke (cerebral infarction)?
- Initiate a diagnostic evaluation for a patient with a possible stroke?
- Describe the role of intravenous tPA in the treatment of acute ischemic stroke?
- Evaluate options for secondary prevention of stroke?
- Assess stroke risk after TIA?

**QUICK QUIZ: CAROTID ARTERY DISEASE: WHEN TO CUT?****Which of the following referrals for carotid endarterectomy is most likely to result in a benefit to the patient?**

- A) A symptomatic woman with 70% or greater stenosis to a surgeon who has a 5% complication rate
- B) An asymptomatic man with 60% stenosis to a surgeon who has a 7% complication rate
- C) A symptomatic woman with a 50% to 69% stenosis and a life expectancy of >5 years to a surgeon who has a 5% complication rate
- D) None of the above
- E) All of the above

The correct answer is "A." All sources agree that a symptomatic patient who has 70% stenosis of the carotid will benefit from surgery, provided that the surgeon's complication rate is sufficiently low. Men, but not women, seem to have a benefit with **symptomatic** stenosis of 50% to 69% if the life expectancy is >5 years **and** the surgeon's complication rate is <6% (NNT 22). In **asymptomatic** patients, those with >60% stenosis will benefit from carotid endarterectomy, but NNT is 33 and the benefit is less than those with symptomatic disease. Stenting is another option. It seems as though long-term outcomes with stenting and endarterectomy are about the same although more data is needed (*N Engl J Med*. 2016;374(11):1021–1031). Stenting seems to be worse than endarterectomy in patients over 70, however (*Lancet*. 2016;387(10025):1305–1311), and there are more periprocedural complications in all ages.

**QUICK QUIZ: A PAIN IN THE NECK**

A 35-year-old female presents for worsening right-sided posterior neck pain that radiates to her right occiput. The pain has been dull and intermittent for about a week and associated with some right posterior scalp tenderness. She became alarmed today because she felt dizzy after her workout. She describes several minutes of vertigo that resolved a few hours ago. Now, sitting in your examination room, she denies vision changes, muscle weakness, numbness, paresthesia, swallowing problems, and speech deficits. Since she's training for a "Viking's Valor Race," she has intensified her workouts in the past few weeks, lifting heavier weights. She is relatively healthy but does take lisinopril for hypertension due to fibromuscular dysplasia. Her vitals are normal. Her neurological examination is normal.

The most appropriate next step in the care of this patient is:

- A) Reassurance, rest from exercise, ibuprofen
- B) Referral to a neurologist
- C) Initiation of aspirin 81 mg daily
- D) Urgent head CT
- E) Urgent MRI/MRA of the head and neck

The correct answer is "E." This patient is presenting with symptoms concerning for vertebral artery dissection. Extracranial arterial dissections of the head and neck are a relatively more common cause of stroke in young adults compared with older adults. Fortunately, many patients experience symptoms of dissection (typically head and/or neck pain, although a Horner syndrome can develop in patients with carotid artery dissection) prior to having a stroke and can be identified early if the physician is attentive and orders the appropriate test. In this case, "D" is not the right test. Head CT would be unlikely to show anything since she does not currently have neurologic signs or symptoms. Even with a CT angiogram of the brain, the extracranial neck arteries (where the problem exists) would not be visualized. Thus, the imaging must include the head and neck and must provide views of the arteries. If "E" is not available, CTA of the **head and neck** is a reasonable alternative. Classically, an angiogram was used to make the diagnosis, but it is more common now to use MRA or CTA. Of note, patients with fibromuscular dysplasia are more likely to have vertebral and carotid artery dissections, but the vast majority of patients with vertebral or carotid dissection do **not** have any known connective tissue disorder. Case series of dissections often describe a minor trauma (e.g., weight lifting, amusement park rides, various sports, "fender bender" accidents, chiropractic neck manipulation, etc.) prior to the onset of symptoms. Stroke often occurs 7 to 9 days after the dissection. Traditionally, anticoagulation has been used for carotid or vertebrobasilar dissection. However, this practice has been called into question (*Lancet Neurol*. 2015;14(4):361–367).

QUICK QUIZ: DRIP AND SHIP

A 65-year-old female presents to the emergency room with sudden onset left-sided weakness that started 3 hours ago. She has a past medical history of atrial fibrillation, but her warfarin was held for the past 6 days due to a planned colonoscopy. On exam, she has moderate-to-severe dysarthria but is oriented to person, time, and place with intact language. She has a forced right gaze deviation and a left homonymous hemianopsia. She has profound weakness on the left arm and leg, and a left facial droop. She has decreased sensation on the left face, arm, and leg. Head CT shows no acute pathology, and INR is 1.1. You started IV tPA, and you do have the option to fly your patient to the university hospital with a 30-minute trip. When deciding on the need to contact the neurology/neurointervention team at the university hospital, which of the following neurological deficit is most specific for a large vessel occlusion that would potentially require emergent thrombectomy?

- A) Left-sided limb weakness
- B) Left facial weakness
- C) Left-sided sensation loss
- D) Right gaze deviation
- E) Dysarthria

The correct answer is “D.” While all of the findings are consistent with MCA stroke, right gaze deviation is consistent with a cortical lesion in the right frontal lobe. One of the major functions of the frontal eye field is to drive contralateral gaze; therefore, a lesion will cause gaze deviation to the ipsilateral side. When a patient presents with right MCA syndrome with gaze deviation, the patient needs to be evaluated for large vessel occlusion. Major clinical trials have shown that endovascular thrombectomy resulted in significantly better functional outcomes for patients with large vessel occlusion (proximal MCA or internal carotid artery). Initial trials indicated that thrombectomy is effective in patient within 6 hours of symptom onset. Recent trials have extended that time window to 24 hours in selected group of patients. The bottom line is that you should contact your neurology colleagues when you are concerned that your patient has a large vessel occlusion, as these patients usually do not respond well to IV tPA alone. “B,” left limb and facial weakness may happen with right proximal middle cerebral artery (MCA) occlusion, but it can also happen with internal capsule stroke which is actually very common with small vessel disease. “C,” left-sided sensation loss is part of the right MCA syndrome, but it can also happen with thalamic stroke which is also very common in small vessel disease. Dysarthria (“E”) can occur with right proximal MCA occlusion but is not very helpful with localizing the lesion.

HELPFUL TIP (A BRIDGE TO NOWHERE):

According to the 2017 American College of Cardiology Expert Consensus, for a patient with nonvalvular atrial fibrillation and a low thrombotic risk, it is reasonable to

hold anticoagulation without bridging before a procedure. For patients with moderate thrombotic risk (prior history of ischemic stroke, TIA, or systemic embolism more than 3 months ago), you should determine the bleeding risk (HAS-BLED score). If there is increased risk of bleeding, holding anticoagulation without bridging is recommended. If there is no significant bleeding risk, consider bridging. For patients with high thrombotic risk (CHA2-DS2-VADSc score 7 to 9, or if the patient had a stroke, TIA, or systemic embolism within the past 3 months), bridging should always be considered.

► CASE 18.2

A 24-year-old right-handed woman presents to you in the ED after her second episode of loss of consciousness. The first spell occurred 6 months ago and was associated with a 60-second loss of consciousness and jerking movements of her arms and legs. Following the spell, she was confused for about 15 minutes. At that time, her initial ED evaluation was unremarkable. She presents today following a spell that occurred about 45 minutes ago. Her friends observed her to have language difficulties with inability to communicate before falling to the ground with shaking of her arms and legs for about 2 minutes. They could not get her to respond during this time. Afterward, she was confused, and they brought her to the ED. Upon arrival in the ED, she is mildly drowsy but otherwise oriented. She has no memory of the earlier events. Her general medical and neurological examinations are unremarkable.

Question 18.2.1 Which of these tests would be LEAST helpful in determining the etiology of this spell?

- A) Urine toxicology screen
- B) Electrolytes
- C) Neuroimaging (head CT or MRI)
- D) Electrocardiogram (ECG)
- E) Electroencephalogram (EEG)

Answer 18.2.1 The correct answer is “D.” In this case, ECG would be the lowest yield, as this spell is most suggestive of a seizure. The major clue is the focal neurological deficit consisting of language difficulties preceding the bilateral tonic-clonic phase. This suggests a focal onset epilepsy. Syncopal episodes, which are often of primary cardiac etiology or other cause that reduces global circulation (orthostasis, for example), are generally of shorter duration without postictal confusion. It is common for syncope to be accompanied by movements that can look like seizure-like activity. This can include anything from myoclonus (brief single muscular contractions), tonic activity or tonic-clonic activity even with head turning (*Cardiol Clin.* 2015;33(3):377–385). However, this does not make it a primary seizure disorder.

All of the other tests would be useful. Evaluation of a first-time seizure should include assessment for alcohol or other drug withdrawal (especially benzodiazepines) as well as drug intoxication (cocaine, synthetic marijuana AKA “Spice” and

“K2,” and methamphetamine) (“A”). Infection, including meningitis and encephalitis, can provoke a seizure. Hyponatremia, hypernatremia, hypocalcemia, hypoglycemia, hyperglycemia, hypomagnesemia, hypophosphatemia, and uremia are all associated with seizures (“B”). To rule out structural lesions (e.g., tumor and vascular malformation) and stroke, neuroimaging (“C”) should be performed. Although MRI has greater sensitivity, it is often not available in a timely manner, and thus, CT is the modality of choice emergently, but this will not exclude acute ischemic stroke. EEG (“E”) would be able to assess for any ongoing seizure activity or help classify the type of epilepsy to guide antiepileptic medication selection.

HELPFUL TIP:

All patients with **syncope**, including children, deserve at least one ECG in order to rule out prolonged QT interval, Brugada syndrome, etc. If the spell is not clearly a seizure and could be syncope, get an ECG. **Patients with simple syncope, no head trauma, and a normal neurologic examination do not need a CT scan (see www.choosingwisely.org).**

HELPFUL TIP:

The most common cause of status epilepticus in a patient with a known seizure disorder is noncompliance! One of the most common causes of breakthrough seizures in those with a known seizure disorder is sleep deprivation.

Evaluation in the ED, including electrolytes, CBC, brain CT scan, and urine toxicology, is unremarkable. An electroencephalogram (EEG) is obtained in the ED and read as normal. The patient is feeling well and does not wish to remain in the hospital. Her friends assure you that they will be with her over the next 24 hours.

Question 18.2.2 After reviewing her test results with her, what do you recommend for further management?

- A) Continued follow-up with no further workup or treatment
- B) Video/EEG monitoring
- C) Initiate treatment with antiepileptic drug(s)
- D) Tilt table testing
- E) PET CT of the brain

Answer 18.2.2 The correct answer is “C.” This is this patient’s second presumed seizure. In adults with a first seizure, only 30% to 60% will go on to have a second seizure. In patients who have a second seizure, the likelihood of going on to have a third is 80% to 90%; therefore, after a second unprovoked seizure, treatment is recommended. Video/EEG monitoring (“B”) is appropriate for classifying spells of unclear etiology. In order for video/EEG to be an effective tool, the patient should have spells frequently enough to capture them during a reasonable inpatient stay

(3 days average). Tilt table testing (“D”) would not be of value, as syncope is unlikely to be the cause of these spells, and PET CT (“E”) is reserved for patients undergoing workup for epilepsy surgery. This patient is a female of childbearing age; therefore, choosing a medication that is relatively safe during pregnancy and discussion of teratogenic side effects should occur prior to starting the medication.

You discuss her case with the neurologist, Dr. Lotta Branes, who agrees that she should start an antiepileptic drug (AED) since this is her second unprovoked seizure.

What is the sensitivity of a single interictal EEG for a seizure focus?

- A) 20%
- B) 30%
- C) 50%
- D) 60%
- E) 90%.

The correct answer is “D.” A single interictal (between seizures) EEG has only a 60% sensitivity for picking up a seizure focus. The sensitivity goes up to 90% after three interictal EEGs. However, this still means that an EEG will be negative in 10% of those with epilepsy even after three EEGs.

Question 18.2.3 Which of the following does not increase the sensitivity of EEG for epilepsy?

- A) Multiple interictal EEGs on different days
- B) 24-hour EEG monitoring
- C) A period of sleep during the EEG
- D) A large area of cerebral abnormality
- E) A lesion deep in the temporal lobe

Answer 18.2.3 The correct answer is “E.” Both prolonged EEG monitoring and a patient that falls asleep during the EEG increase the chances of finding an epileptic discharge. The size of the epileptic focus needs to be large enough and close enough to the scalp for extracranial electrodes to pick up the abnormality. Therefore, deep lesions such as mesial temporal lesions may have normal EEGs and may even have a normal EEG during a seizure if there is minimal seizure spread to adjacent regions.

She has multiple questions about AEDs ... and so do you!

Question 18.2.4 Which of the following AEDs is **NOT** typically associated with weight gain?

- A) Valproic acid (Depakote)
- B) Lamotrigine (Lamictal)
- C) Carbamazepine (Tegretol)
- D) Gabapentin (Neurontin)

Answer 18.2.4 The correct answer is “B.” Valproic acid (“A”), carbamazepine (“C”), and gabapentin (“D”) are all associated

with weight gain. Lamictal (“B”) is typically weight neutral; Zonisamide and topiramate are associated with weight loss.

Question 18.2.5 Which of the following adverse effects is NOT typically associated with phenytoin (Dilantin)?

- A) Cerebellar atrophy
- B) Gingival hyperplasia
- C) Stevens–Johnson syndrome
- D) Hypertension
- E) Bone demineralization

Answer 18.2.5 The correct answer (one that is not typically seen) is “D.” Phenytoin (Dilantin) is associated with a number of idiosyncratic effects including cerebellar atrophy (“A”), hirsutism, Stevens–Johnson syndrome (“C”), and gingival hyperplasia (“B”). Diplopia and nystagmus can be prominent side effects, particularly with supratherapeutic doses. Dizziness, drowsiness, fatigue, headache, nausea, vomiting, weight loss, and urine discoloration (pink, red, or reddish-brown) are among some of the side effects seen with phenytoin. Many AEDs cause increased metabolism of vitamin D via the liver. Long-term use of AEDs may lead to osteoporosis (“E”), so vitamin D supplementation with calcium is routine. Phenytoin is associated with hypotension (NOT hypertension) and cardiac dysrhythmia (particularly with IV administration) and can cause “purple glove syndrome” if the peripheral IV infiltrates. This is due to the solution/carrier for the drug. Fosphenytoin (Cerebyx) does not have risk of “purple glove syndrome” and has much lower incidences of hypotension and arrhythmias, so is the formulation of choice when giving phenytoin IV.

Question 18.2.6 When starting antiepileptic drugs, which of the following needs to be titrated slowly to avoid a life-threatening dermatologic reaction?

- A) Levetiracetam (Keppra)
- B) Topiramate (Topamax)
- C) Carbamazepine (Tegretol)
- D) Lamotrigine (Lamictal)
- E) Lacosamide (Vimpat)

Answer 18.2.6 The correct answer is “D.” Although phenytoin, carbamazepine, and lamotrigine are all associated with Stevens–Johnson syndrome, lamotrigine should be titrated up slowly over several months. One of the most universally reported side effects with any antiepileptic medication is fatigue or drowsiness. Levetiracetam has been associated with mood irritability. Topiramate should be avoided in any patient with prior nephrolithiasis and has been associated with tingling of fingers/toes, weight loss, and changes the taste of carbonated beverages. Fast up-titration of topiramate can also cause confusion and speech issues. Carbamazepine at high levels will cause diplopia, nystagmus, and ataxia, which is also common with other drugs at supratherapeutic doses and is reversible when medication is adjusted. Carbamazepine can also cause hyponatremia. *Again, many AEDs cause increased metabolism of vitamin D via the liver. Long-term use of AEDs may lead to osteoporosis, so vitamin D supplementation with calcium is routine.*

Question 18.2.7 Which of the following AEDs is NOT Class D for pregnancy?

- A) Valproic acid (Depakote)
- B) Phenytoin (Dilantin)
- C) Lamotrigine (Lamictal)
- D) Phenobarbital
- E) Primidone

Answer 18.2.7 The correct answer is “C.” The newer AEDs including: gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, and zonisamide are currently Class C in pregnancy. Valproic acid, phenytoin, phenobarbital, primidone, and carbamazepine are all Class D drugs in pregnancy. Topiramate has been associated with birth defects and should be avoided. In particular, valproic acid has a known association with neural tube defects. As a result, it is recommended that **ALL women of childbearing age be on folate and a prenatal vitamin while on AEDs.** It is NOT recommended that women discontinue AEDs when pregnant, rather simplifying to monotherapy is recommended if possible. Antiepileptic drug levels need to be monitored during pregnancy as the blood level of medications like lamotrigine and levetiracetam can fall to subtherapeutic levels as pregnancy progresses. Adjusting dosing may be necessary to keep the patient close to their pre-pregnancy drug levels.

HELPFUL TIP:

In the third trimester, vitamin K 10 mg PO daily is recommended by some experts due to depression of clotting factor levels with many antiepileptics. This lowering of clotting factors has been associated with neonatal bleeding.

Question 18.2.8 Which of the following drugs does NOT have potential interactions with oral contraceptives?

- A) Valproic acid (Depakote)
- B) Carbamazepine (Tegretol)
- C) Oxcarbazepine (Trileptal)
- D) Phenytoin (Dilantin)
- E) Topiramate (Topamax)

Answer 18.2.8 The correct answer is “A.” Interactions with oral contraceptives, decreasing the efficacy of the OCP **not** the anti-convulsant, have been reported with oxcarbazepine (Trileptal), phenobarbital, phenytoin (Dilantin), lamotrigine (Lamictal), and topiramate (Topamax).

Zonisamide (zonegran), valproic acid (Depakote), tiagabine (Gabitril), levetiracetam (Keppra), gabapentin (Neurontin), and felbamate (Felbatol) do not interfere with oral contraceptives. A barrier method of contraception, in addition to oral contraceptives, is recommended in women on AEDs, particularly those with known interactions with oral contraceptives.

Question 18.2.9 Which of the following is NOT part of routine counseling with epilepsy and the initiation of therapy with an antiepileptic drug?

- A) Work safety
- B) Calcium and vitamin D supplementation
- C) Driving
- D) Alcohol consumption
- E) Epilepsy surgery

Answer 18.2.9 The correct answer is “E.” Epilepsy surgery is reserved for patients who are intractable to medical management and have failed at least two AEDs at doses used in clinical trials. Exceptions would include patients with focal pathology (e.g., malignancy or vascular malformation). “B,” calcium and vitamin D supplementation, should be initiated in patients on AEDs due to increased risk of osteoporosis (*get the hint that this is important yet?*). “A” and “C,” work and driving safety issues, should be discussed. Most states have specific laws regarding driving and seizures and the time before resumption of driving privileges varies greatly; check the laws in your state(s) of practice. Epileptic patients should be warned of potentially dangerous activities at work and home (e.g., working on ladders, with heavy equipment, bathing, and swimming). Patients should also be warned of potential factors that could lower their seizure threshold, including alcohol consumption (“D”), herbal ephedra supplements, sleep deprivation, infection, and medication noncompliance.

► **Objectives: Did you learn to ...**

- Evaluate a patient with a potential new diagnosis of epilepsy?
- Identify some areas of specific concern regarding women's issues in epilepsy?
- Recognize commonly encountered or serious side effects with antiepileptic drugs?
- Counsel patients with epilepsy for daily activities and regarding medication management?

QUICK QUIZ: SEIZURE DISORDERS

All of the following are indicated in the treatment of absence seizures (aka generalized nonconvulsive epilepsy) EXCEPT:

- A) Ethosuximide (Zarontin)
- B) Acetazolamide (Diamox)
- C) Valproic acid (Depakene)
- D) Clonazepam (Klonopin)
- E) Phenytoin (Dilantin)

The correct answer is “E.” Phenytoin is not indicated in the treatment of absence seizures. The other options are indicated. Other drugs known to be useful in absence seizures include lamotrigine (Lamictal), phenobarbital, and topiramate (Topamax).

HELPFUL TIP:

Primary generalized epilepsy (epilepsy that tends to start in childhood/juveniles and is likely of genetic origin) typically responds to different medications than focal onset epilepsy (temporal lobe epilepsy, for example). Broad spectrum antiepileptics that are used for *generalized epilepsy* include: valproic acid (Depakene), topiramate (Topamax), levetiracetam (Keppra), and lamotrigine (Lamictal). Medications that are typically used for *focal onset epilepsy* include levetiracetam (Keppra), carbamazepine (Tegretol), oxcarbazepine (Trileptal), lacosamide (Vimpat), and lamotrigine (Lamictal).

► **CASE 18.3**

A 60-year-old left-handed man comes in with a complaint of numbness and tingling in his lower extremities for about 10 months. He notes no weakness. He has had type 2 diabetes mellitus for 6 years and has a 30 pack-year smoking history. Examination reveals decreased sensation to light touch, pin-prick, and vibratory sensation in the feet extending to 7 cm below the knees symmetrically. You also notice lack of hair on his leg to the same level. Chest, abdomen, and upper extremities have normal sensation. His reflexes are 1+ in the upper extremities and quadriceps with absent Achilles bilaterally. The remainder of his neurological and general medical examination is unremarkable. He says his diet is good but he always brings you a dozen doughnuts when he visits ... with one or two missing.

Question 18.3.1 This history is most consistent with:

- A) Stroke
- B) Early mononeuritis multiplex
- C) Guillain-Barré syndrome (GBS)
- D) Brown-Sequard syndrome
- E) Peripheral neuropathy

Answer 18.3.1 The correct answer is “E.” This is the quintessential presentation of a patient with diabetic peripheral neuropathy. “A” is incorrect because of the distribution. Bilateral distal lower extremity sensory changes are not likely from a stroke. “B,” mononeuritis multiplex, is—at least initially—not in a stocking-glove distribution. Patients with mononeuritis multiplex will notice a stepwise loss of sensation and motor ability in discrete peripheral nerve distributions. Eventually, these may become confluent and resemble a stocking-glove neuropathy. However, this is found late in the disease. Additionally, there is usually motor involvement. “C” is unlikely because GBS has a relatively rapid onset and is associated with motor findings. “D,” Brown-Sequard syndrome, is the result of a lesion in one side of the spinal cord. Patients have diminished proprioception, vibration sense, and strength on the side of the lesion, and decreased sharp sensation and loss of temperature sense on the other side. Since

our patient's findings are symmetrical in both distribution and manifestation, it is not Brown–Sequard syndrome. The finding of decreased reflexes also localizes to the peripheral nerve, which supports peripheral neuropathy.

Question 18.3.2 Which of the following laboratory tests would NOT be useful in helping to determine a particular cause of this patient's neuropathy?

- A) Serum immunofluorescence electrophoresis
- B) TSH/free T4
- C) Hemoglobin A_{1C}
- D) Electrolytes (Na, K, Cl, CO₂)
- E) Vitamin B12

Answer 18.3.2 The correct answer is “D.” Electrolytes are not likely to give us a diagnosis in this patient. The initial evaluation of a patient with “stocking-glove” sensory loss should focus on finding potentially modifiable causes of neuropathy. These would include hypothyroidism (“B”), diabetes (“C”), and vitamin B12 deficiency (“E”). In addition, serum immunofluorescence electrophoresis (“A”) can help to identify monoclonal gammopathy, which is associated with neuropathy. Heavy metal testing may also be of use, although it is in the second round of testing.

HELPFUL TIP:

A history of alcohol use is important, as chronic alcohol abuse is commonly associated with polyneuropathy, even in the absence of vitamin B12 or other nutritional deficiencies.

Your patient is on a number of medications.

Question 18.3.3 Which of the following medications is known to cause a peripheral neuropathy?

- A) Metronidazole
- B) HMG-CoA reductase inhibitors
- C) Amiodarone
- D) Disulfiram
- E) All of the above

Answer 18.3.3 The correct answer is “E.” All of the above can cause a peripheral neuropathy. Some of the other drugs that can cause neuropathy include **fluoroquinolones**, phenytoin, isoniazid, several chemotherapeutic agents, nitrofurantoin, ddC, and D4T. See Table 18-3 for more causes of peripheral neuropathy.

Question 18.3.4 Electrophysiological testing (electromyography and nerve conduction studies or EMG/NCV) can be helpful for all of the following EXCEPT:

- A) Localizing a compressive neuropathy
- B) Identifying subclinical motor deficits
- C) Identifying a specific etiology of the neuropathy (e.g., diabetic vs. B12 deficiency vs. syphilis)

TABLE 18-3 CAUSES OF PERIPHERAL SENSORY NEUROPATHY

Infectious

Syphilis
Lyme disease
Mycoplasma
West Nile virus
Leprosy

Nutritional

Vitamin B12 deficiency
Thiamine (vitamin B1) deficiency
Folic acid deficiency
Vitamin B6 toxicity
Celiac disease

Drugs

Metronidazole
Fluoroquinolones
Nitrofurantoin
Dapsone
Isoniazid
Phenytoin
Thalidomide
Disulfiram
Amiodarone
Vincristine/Vinblastine
Cisplatin
Hydroxychloroquine/Chloroquine
Statins
Entanercept
Infliximab
HIV therapies (didanosine, stavudine, zalcitabine)

Metabolic

Diabetes
Hypothyroidism

Toxic

Alcohol
Mercury
Thallium
Other heavy metals

Miscellaneous

Amyloid
Paraneoplastic syndromes
Mitochondrial disease
Chronic inflammatory demyelinating polyneuropathy (CIDP)
Monoclonal gammopathy

- D) Determining axonal damage versus demyelination as the primary pathologic process
- E) Differentiating between primarily myopathic and neuro-pathic processes

Answer 18.3.4 The correct answer is “C.” EMG and NCS are not capable of yielding results specific to the etiology of neuropathy (e.g., identifying diabetic neuropathy vs. B₁₂ vs. syphilis); however, they can yield a pattern suggestive of a particular etiology. For example, increasing motor reaction to repeated stimulation is classic Eaton–Lambert syndrome (a paraneoplastic syndrome), while a decreasing motor response with repeated stimulation is

suggestive of myasthenia gravis. EMG can be helpful in confirming the presence of a radiculopathy in the proper clinical setting. They can also determine whether the process is primarily axonal (damage directly to the axons/reduction in the number of axons) versus demyelinating (damage to the myelin sheath). NCS can help localize a compressive lesion such as carpal tunnel syndrome or ulnar neuropathy at the elbow versus a brachial plexus injury or radiculopathy. EMG and NCS can be used to differentiate between myopathic and neuropathic processes.

HELPFUL TIP:

If electrophysiological testing shows an acquired primary demyelinating neuropathy, a neurologic consult is recommended. The differential diagnosis of demyelinating neuropathies is small and they may respond to immunotherapy in the right clinical setting.

After being followed in clinic for several years, the patient begins to complain of a painful, burning sensation developing in his feet and ankles. This pain developed gradually over the past few years in the areas that previously were numb. He has a friend who was started on gabapentin (Neurontin) for a similar problem and is wondering if this would be a good drug for him.

Question 18.3.5 Which of the following is NOT an adverse reaction or contraindication to gabapentin?

- A) Dizziness
- B) Peripheral edema
- C) Fatigue and drowsiness
- D) Hepatic disease
- E) Paresthesias

Answer 18.3.5 The correct answer is “D.” Gabapentin (Neurontin) is renally—rather than hepatically—cleared. In the setting of renal dysfunction, reduced dosing is necessary. Although gabapentin is generally well-tolerated, numerous side effects have been reported. Among the most prominent complaints are those of dizziness, vertigo, and ataxia. Fatigue and drowsiness are also relatively common adverse effects; paresthesias, myalgias, and weakness have also been reported. Peripheral edema (particularly lower extremities) and facial edema are also seen as a result of therapy with gabapentin. Titrating slowly to the target dose over several weeks can improve tolerance.

Your patient is concerned about swelling in his legs, as he has had problems with this in the past and does not want to try gabapentin at this time.

Question 18.3.6 All of the following medications would be a reasonable FIRST choice for treatment of painful neuropathy EXCEPT:

- A) Amitriptyline
- B) Topical lidocaine ointment

- C) Oxycodone
- D) Topical capsaicin cream
- E) Pregabalin (Lyrica)

Answer 18.3.6 The correct answer is “C.” Opiates are not the treatment of choice for peripheral neuropathy and tend not to be effective in this setting. Tricyclic antidepressants (TCAs) are commonly used in the setting of neuropathic pain, and along with gabapentin and pregabalin, they are recommended by the American Academy of Neurology. The evidence for TCAs suggests they are superior to other classes of drugs. If pain is confined to a small area, a topical treatment such as capsaicin cream or topical lidocaine may be effective. Lidoderm patches prescribed outside the setting of postherpetic neuralgia represent an off-label use.

HELPFUL TIP:

Other treatments for neuropathic pain include anticonvulsant drugs such as gabapentin, pregabalin, valproic acid, and carbamazepine. SNRIs such as duloxetine have also found to be reasonable treatments. **You want a number needed to treat? For a 50% pain reduction, the NNTs are as follows: TCAs: 3.6, strong opiates: 4.3, Duloxetine/SNRIs: 6.4, Gabapentin: 7.2–8.3, Pregabalin: 7.7** (*Lancet Neurol.* 2015;14(2):162–173). These drugs have different mechanisms of action and one type may work better for some patients than others. What does this mean for your patient? Basically, most of these drugs will not work for most patients. Don't expect success ... as you well know from experience. Or maybe all your chronic neuropathy pain patients are all happy, smiley, and sunny!! Finally, gabapentin has become a drug of abuse which enhances the high of opiates and has been found as a co-intoxicant in cases of opiate overdose death. Several states list it as a controlled substance.

Question 18.3.7 What is the most common infectious cause of peripheral neuropathy in the world (not just in the United States)?

- A) HIV
- B) Lyme
- C) Leprosy
- D) Hepatitis C
- E) Tuberculosis

Answer 18.3.7 The correct answer is “C.” The most common infectious cause of peripheral neuropathy in the world is leprosy. Leprosy (Hansen disease) is caused by *Mycobacterium leprae*, an acid-fast bacillus. It usually presents with a hypopigmented anesthetic patch. The sensory deficits start with loss of temperature sensation followed by loss of pain and then tactile sensations. Modalities carried by the posterior columns (proprioception and vibration) are spared. Sensation in the palms, soles, mid-chest, and mid-back is preserved until late in the disease. “A,”

HIV, can cause peripheral neuropathy, most commonly being a symmetric, distal polyneuropathy. Autonomic dysfunction and mild weakness accompany distal paresthesias and burning sensations with sensory loss. Keep in mind that many of the medications used in HIV therapy are also associated with peripheral neuropathies. Early neurologic manifestations of Lyme disease (“B”) include lymphocytic meningitis, cranial neuropathy (a Bell palsy–like picture), or painful radiculoneuritis. Guillain–Barré syndrome (GBS), and mononeuritis multiplex can be seen early in the course of Lyme disease. Advanced (late) neurologic complications of Lyme disease include peripheral neuropathy and encephalomyelitis. “D,” hepatitis C (and hepatitis B) can cause peripheral nerve manifestations. Hepatitis B has been associated with GBS (demyelinating) and mononeuritis multiplex. Hepatitis C is also associated with multiple mononeuropathies. Tuberculosis has rarely been associated with neuropathy, but isoniazid is well-known to cause peripheral neuropathy (that’s why we prescribe pyridoxine (B6) with it).

HELPFUL TIP:

In the United States, diabetes and alcohol use disorders are the most common causes of peripheral neuropathy.

► Objectives: Did you learn to ...

- Recognize common etiologies of peripheral neuropathy?
- Identify appropriate uses of electrophysiological testing?
- Identify types of neuropathy that are potentially treatable?
- Prescribe medical therapy for painful peripheral neuropathy?

QUICK QUIZ: WRIST DROP

Which of the following is most likely to cause an isolated wrist drop?

- A) C3 disk lesion
- B) Ulnar nerve compression
- C) Radial nerve compression
- D) C4 disk lesion
- E) Median nerve compression

The correct answer is “C.” Compression of the radial nerve (such as sleeping with someone’s head on your arm) can cause an isolated wrist drop, the so-called “Saturday Night Palsy.” Suspect alcohol or other drug abuse in patients with this lesion. It is pretty hard to get this type of compressive lesion if you are not passed out or very sedated. “B,” ulnar nerve compression (cubital tunnel syndrome), presents with pain and numbness in the elbow and fourth and fifth fingers and weakness of the intraosseous muscles (weakness with spreading fingers). “E,” median nerve compression (including carpal tunnel syndrome), leads to numbness on the palmar surface of the thumb and fingers two, three, and the radial half of four. There is weakness and perhaps atrophy of the thenar muscles (unable to maintain opposition of thumb to fifth finger against resistance).

► CASE 18.4

A 25-year-old woman presents to your clinic complaining of a bifrontal headache that started this morning. She describes the pain as throbbing and 8/10 in severity. She is complaining of photophobia and nausea. She has had similar headaches in the past, lasting a few hours to all day. She is unable to work during these headaches and prefers a dark, quiet room (as do we all). The physical examination, including neurological examination, is unremarkable.

Question 18.4.1 Which of the following statements is most accurate?

- A) She likely does not have migraine headaches because her headache is bilateral
- B) She likely does not have migraine headaches because they most commonly present in the fourth to fifth decade of life
- C) She likely does not have migraine headaches because they rarely occur in the morning
- D) She likely has migraine headaches

Answer 18.4.1 The correct answer is “D.” She likely has migraine headaches. Migraine headaches may vary considerably in severity, time of day, and characteristics. The International Headache Society (IHS) has a useful classification system with criteria for the diagnosis of migraine headaches (Table 18-4). “B” is incorrect because migraine headaches typically present in the first three decades of life. Attacks typically last less than 1 day, although they may occasionally last longer. Migraine headaches are typically moderate to severe in intensity, may occur at any time during the day, and occur with or without aura. Most, but not all, migraine headaches are unilateral, and accompanied by nausea and vomiting. They are more prevalent among women, with a 1-year prevalence rate of approximately 18% in women, 6% in men, and 4% in children. Family history is important, as 80% of patients with migraine headache have a first-degree relative with migraines.

Migraine headaches are classified as migraine with aura and migraine without aura. Typical auras develop over several minutes and last for less than 60 minutes. Auras may involve visual, language, sensory, or motor deficits. The visual auras are by far the most common and may appear as photopsias (flashes of

TABLE 18-4 IHS CRITERIA FOR THE DIAGNOSIS OF MIGRAINE WITHOUT AURA

At least five attacks fulfilling the following criteria:

- Headache lasting 4–72 hours (untreated or unsuccessfully treated)
- Headache has at least two of the following characteristics:
 1. Unilateral location
 2. Pulsating quality
 3. Moderate or severe pain intensity
 4. Aggravation by or causing avoidance of routine physical activity
- During headache at least one of the following:
 1. Nausea and/or vomiting
 2. Photophobia and phonophobia
- No evidence of organic disease

light), scotomas (blind spots), or complex shapes that build or move across the visual field. The IHS criteria for migraine with aura are listed in Table 18-5.

HELPFUL TIP:

Remember that the IHS criteria are research tools. Patients may have a migraine and not meet all of the criteria noted by the IHS. While patients with a certain type of migraine headache will ideally meet all criteria, it is not necessary to meet all criteria to make a clinical diagnosis of migraine headache.

You have decided to treat this woman's migraine headache.

Question 18.4.2 Which medication would be LEAST appropriate for acute management of her headache?

- A) Oral ibuprofen
- B) Intranasal sumatriptan
- C) IV meperidine (Demerol)
- D) Intranasal DHE

Answer 18.4.2 The correct answer is "C." The least appropriate treatment from the above list would be Demerol (meperidine). The long-term use of opiates for rescue therapy has not been found to improve the quality of life in patients with migraines. Oral NSAIDs ("A"), including aspirin and combination analgesics containing caffeine, are a first-line choice for mild-to-moderate migraine attacks or severe attacks that have been NSAID responsive in the past. "B," the "migraine-specific" treatments, commonly called the "triptans" (e.g., sumatriptan, zolmitriptan, naratriptan, rizatriptan, almotriptan, eletriptan, and

frovatriptan—wow, talk about "me too" drugs ...), are effective and relatively safe for the acute treatment of migraine headaches. Triptans are an appropriate initial treatment choice in patients with moderate-to-severe migraines who have no contraindications to their use (see below). Alternative vasoconstrictive agents, including DHE nasal spray (dihydroergotamine, "D"), can provide a safe and effective treatment of acute migraine attacks. DHE can be administered IV as well. Vasoconstrictive side effects, including the risk of coronary artery spasm, should specifically be discussed with patients prior to initiation of therapy.

HELPFUL TIP:

Adding oral metoclopramide to aspirin or NSAIDs will improve their rate of success. Part of the nausea and vomiting from migraines (and the reason that oral medications often do not work) is from gastroparesis. Metoclopramide overcomes this problem and treats nausea as well. Our favorite drug to treat headaches is prochlorperazine, 10 mg IV or 25 mg PR. This works for both migraine and tension-type headaches. See Table 18-6 for a list of abortive treatments for migraine headaches.

Question 18.4.3 Which of the following statements is correct?

- A) If a patient does not respond to sumatriptan, there is no point in trying another triptan because the patient will not respond
- B) DHE and sumatriptan may be safely used within the same 24-hour time period
- C) Sumatriptan use is contraindicated in patients with known coronary artery disease, regardless of age
- D) Flushing, sweating, and paresthesias after a dose of sumatriptan is an indication of a severe reaction and continued use of this medication is contraindicated

Answer 18.4.3 The correct answer is "C." The triptans should not be used in patients with known coronary disease. Patients who do not respond to one triptan may respond to other triptans, and a trial of other triptans is appropriate. Also, a patient may respond initially to a triptan but not respond on other occasions. Each triptan has a maximum recommended dose, and a good rule of thumb is that the initial dose may be repeated once in a 24-hour period of time. However, avoid the use of DHE within 24 hours after a triptan has been given due to increased vasoconstriction and the possibility of vasospasm.

Question 18.4.4 Contraindications to the use of "triptans" include all of the following EXCEPT:

- A) Lung cancer
- B) Uncontrolled hypertension
- C) Use of an MAO inhibitor within the last 2 weeks
- D) Use of an ergot preparation within the last 24 hours

TABLE 18-5 IHS CRITERIA FOR THE DIAGNOSIS OF MIGRAINE WITH AURA

At least two attacks fulfilling criteria A and B:

A. One or more of the following *fully reversible* aura symptoms:

1. Visual
2. Sensory
3. Speech and/or language
4. Motor
5. Brainstem
6. Retinal

B. At least three of the following six characteristics:

1. At least one aura symptom spreads gradually over ≥ 5 minutes
2. Two or more aura symptoms occur in succession
3. Each individual aura symptom lasts 5–60 minutes
4. At least one aura symptom is unilateral
5. At least one aura symptom is positive
6. The aura is accompanied, or followed within 60 minutes, by headache

History, physical, and appropriate diagnostic tests exclude a secondary cause

Answer 18.4.4 The correct answer is “A.” Lung cancer is not a contraindication to the use of triptans. In addition to “B” to “D,” caution should be used in patients with history of stroke, known cardiac risk factors, and impaired liver function.

HELPFUL TIP:

Common reactions to triptans include jaw tightness, flushing, anxiety, dizziness, and sweating. These are uncomfortable but not dangerous. Serious reactions to triptans include coronary vasospasm, anaphylaxis, or hypertensive crisis in patients with known CAD, hypersensitivity to triptans, or uncontrolled hypertension.

HELPFUL TIP:

Consider dexamethasone as an adjunct therapy in severe headache. A single dose of dexamethasone 10 mg PO, IV, or IM after abortive therapy in the ED may prevent headache recurrence in patients who have had a headache for more than 24 hours (NNT 9).

TABLE 18-6 AMERICAN HEADACHE SOCIETY GUIDELINES FOR ACUTE TREATMENT OF MIGRAINE

Level A: Established as effective (supported by at least two Class I studies)	<ul style="list-style-type: none"> • Acetaminophen (non-incapacitating) • Aspirin • Diclofenac • Ibuprofen • Naproxen • Sumatriptan PO/SC/IN • Almotriptan • Eletriptan • Frovatriptan • Naratriptan • Rizatriptan • Zolmitriptan • DHE (IN/Pulmonary inhaler) • Butorphanol IN
Level B: Probably effective (supported by one Class I study or two Class II studies)	<ul style="list-style-type: none"> • Prochlorperazine IV/IM/PR • Metoclopramide IV • Chlorpromazine IV • DHE (IV/IM/SC) • Ketorolac IV/IM • Magnesium Sulfate IV
Level C: Possibly effective (supported by one Class II study or two Class III studies)	<ul style="list-style-type: none"> • Valproate IV • Ergotamine • Codeine PO • Butorphanol IM • Tramadol IV • Dexamethasone IV

Headache 2015; 55:3–20 (Update since the American Academy of Neurology 2000 guideline).

Your patient has decided to take ibuprofen for her headaches. This medication seemed to be effective at first, but she notes that for the past several weeks she has been taking two to three doses of ibuprofen per day without significant headache relief. She has had a dull bilateral headache that is moderate in severity for the last 2 weeks. The medication dulls the headache but it comes right back. She has no personal or family history of coronary artery disease.

Question 18.4.5 Which of the following statements is correct?

- A) She likely has a tension headache and should increase her frequency of ibuprofen and continue to take it on a daily basis
- B) She likely has a medication-overuse headache in addition to chronic migraine headache (status migrainosus) and should taper and then discontinue ibuprofen
- C) A medication such as sumatriptan used on a daily basis does not increase the risk of rebound headache
- D) She likely does not have medication-overuse headache because opiates are the only medications that increase the risk of these headaches

Answer 18.4.5 The correct answer is “B.” See below for a detailed explanation.

Question 18.4.6 Which of the following medications taken on a frequent basis is LEAST likely to cause medication-overuse or rebound headache?

- A) Sumatriptan
- B) Morphine
- C) Ibuprofen
- D) Amitriptyline
- E) All of the above are equally likely to cause rebound headache

Answer 18.4.6 The correct answer is “D.” Frequent use of opiates, acetaminophen, NSAIDs, ergotamine, triptans, and any other analgesics may put a patient at risk for medication-overuse or rebound headache. Although analgesic rebound headache characteristics can vary significantly, the patient typically reports a pattern of headache that decreases modestly in severity with the use of their analgesic of choice, and then in 2 to 4 hours (depending on the medication), the headache returns to its previous severity or worsens further. Failure to repeat analgesic use results in a withdrawal headache (similar to the caffeine withdrawal headaches physicians often experience when they miss their morning coffee). In the case of triptans, the headache may not worsen for many hours or even until the next day, but a cycle of regular use of the medication is still established. At this time, no clear consensus on the duration of therapy necessary to produce analgesic rebound is reported. As a general rule, it is best to limit the use of analgesic medications to no more than two- to three-headache days per week. In addition, limit the patient’s analgesic use to no more than 2 to 3 weeks per month. Patient education is the most important part of therapy in treating analgesic rebound or medication-overuse headaches.

**HELPFUL TIP:**

Treatment of rebound headaches consists of discontinuing the medication. Several approaches have been tried to reduce headaches after the analgesic has been withdrawn. These include IV or oral steroids, long-acting NSAIDs (naproxen), and elective admission, and therapy with IV DHE (dihydroergotamine) or Thorazine (chlorpromazine). These should be combined with a prophylactic medication such as amitriptyline (or other tricyclic) used on a daily basis. Patients can also take hydroxyzine and prochlorperazine when they have a breakthrough headache at home; these medications do not cause rebound headaches.

Question 18.4.7 Which of the following medications would be the LEAST appropriate for the preventative treatment of your patient's migraine headaches?

- A) Verapamil
- B) Propranolol
- C) Amitriptyline
- D) Clonazepam

Answer 18.4.7 The correct answer is "D." Clonazepam is not used as a preventive treatment for migraine headaches. Keep in mind the common side effects of these medications and the appropriateness in your specific patient. For example, valproate would be a bad choice for many patients secondary to weight gain or teratogenicity. Propranolol ("B") and verapamil ("A") may cause hypotension. Amitriptyline ("C") may cause cardiac arrhythmia in certain patients, while constipation and urinary retention are relatively common in elderly patients. Topiramate (Topamax) may actually cause weight loss, as well as kidney stones and impaired cognition.

**HELPFUL TIP:**

A number of medications are useful in the **prevention** of migraine headaches. The American Academy of Neurology evidence-based guideline classified these medications into different groups:

- Medications with established efficacy (with two or more class I trials) include: divalproex sodium (Depakote), propranolol/timolol/metoprolol, and topiramate (Topamax).
- Medications that are probably effective (with one class I or two class II studies) include: amitriptyline, venlafaxine (Effexor), and atenolol/nadolol.
- Medications that are possibly effective (with one class II study) include: cyproheptadine (Periactin), lisinopril, candesartan, clonidine, guanfacine, carbamazepine (Tegretol), and nebivolol/pindolol.
- Other medications such as nortriptyline, verapamil, fluoxetine (Prozac), gabapentin (Neurontin), magnesium, and vitamin B₂ have also been used in migraine prevention, but clinical studies were inadequate to establish efficacy or with conflicting data. Of note,

for some older medications, class I clinical studies are lacking mostly because they are not patentable or do not promise a financial return.

- More expensive approaches (not included in the AAN guideline) such as botulinum toxin injection and the newly approved Erenumab (Aimovig, an anti-CGRP receptor monoclonal antibody (*anti-calcitonin gene-related peptide*)) should be considered for patients with refractory migraine headaches. Erenumab (Aimovig) provides 2.5 additional headache free days/month at a cost of >\$5,000/year. There are more drugs in this class on the near horizon.

**HELPFUL TIP:**

Combination products such as butalbital/caffeine/acetaminophen/codeine (e.g., Fiorinal with codeine) have no role in the treatment of migraine or other headaches. Addiction, abuse, and diversion and withdrawal are potential issues with these drugs.

Question 18.4.8 Which one of the following medications is rated Class B or better in pregnancy?

- A) Phenergan (promethazine)
- B) Imitrex (sumatriptan)
- C) Codeine
- D) Amitriptyline
- E) None of the above

Answer 18.4.8 The correct answer is "E." Headache treatment in pregnancy remains a difficult problem. Although numerous medications are available for headache treatment, their safety in pregnancy has not been established. Amitriptyline, nortriptyline, venlafaxine, promethazine, prochlorperazine, codeine, hydrocodone, and meperidine are all Class C. The triptan class of medications, including sumatriptan, remains Class C, though pregnancy registries, retrospective, and observational studies suggest that sumatriptan is safe. Valproic acid is a class D in pregnancy. Ergotamine (DHE 45) is Class X.

Question 18.4.9 In which of the following patients is neuroimaging LEAST likely to be useful?

- A) A 30-year-old woman with a headache typical of a migraine
- B) A 23-year-old woman with a history of migraine headaches that is very concerned because her current headache of 1-week duration is more severe than her typical migraine headaches. She has been unable to sleep or concentrate at work because of her "headache anxiety"
- C) A 60-year-old man with new headache, worse in the morning and of 6 weeks duration
- D) A 40-year-old man with a headache and right-arm weakness

Answer 18.4.9 The correct answer is "A." According to the American Academy of Neurology, neuroimaging is not typically recommended in **migraine** patients with a normal neurologic

examination. Imaging may be considered in patients who are disabled by their fear of serious pathology or if the provider is suspicious about underlying pathology. Factors that may lead one to consider neuroimaging include a new onset, atypical headache, or unexplained abnormal neurologic examination.

HELPFUL TIP:

Not all unilateral headaches are migraines. Think of occipital neuralgia, temporal arteritis, jolts and jabs (ice-pick) headache, temporalis muscle overuse/TMJ syndrome, chronic paroxysmal hemicrania, short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) syndrome, and cluster headaches, among others. We can't cover all of these in our limited space. We are trying our hardest, captain.

► Objectives: Did you learn to ...

- Recognize and diagnose migraine headaches?
- Initiate appropriate acute therapy for migraine headaches?
- Identify contraindications and adverse reactions of the triptan medications?
- Recognize and treat analgesic-related headaches?
- Identify appropriate preventive therapy for chronic headaches?

► CASE 18.5

A 30-year-old woman presents to your office with a 2-day history of progressive, unilateral arm (proximal and distal) numbness without weakness. She has been diagnosed with fibromyalgia in the past. She is taking fluoxetine for depression and has a history of previous hospitalizations for depression.

Question 18.5.1 Which of the following is the most appropriate next step?

- Monitor her symptoms and reassure that her numbness is likely related to her fibromyalgia
- Order nerve conduction velocity (NCV) studies
- Order a head CT
- Get additional history; ask about previous similar episodes or other neurological concerns
- Order a chest radiograph (CXR) and complete blood cell count (CBC)

Answer 18.5.1 The correct answer is “D.” Of course, the answer is “more history.” With a progressive neurological deficit, the first step in the workup is to further explore the history. Frequently, patients will not mention previous neurological symptoms because they—the symptoms, not the patients—are vague (although, to be fair, some patients are vague).

When you ask about previous spells, she notes that she had an episode of left leg numbness that lasted about 1-week several years ago, but she thought nothing of it, as it was mild. Six

months ago, she had a 3-day visual disturbance in her right eye, during which she found it difficult to read and focus on objects; no blind spot was noticed. However, she had pain in the eye, especially when moving it.

Question 18.5.2 What is the most likely diagnosis based on the history given?

- Multiple sclerosis (MS)
- Fibromyalgia
- Conversion disorder
- Atypical migraine
- Ischemic strokes

Answer 18.5.2 The correct answer is “A.” MS would be the most likely diagnosis based on the history related above. MS most commonly presents in women 20 to 35 years old and in men 35 to 45 years old. It is almost five times more prevalent among women than men and is more common in the Caucasian population. MS is a CNS demyelinating disease that is thought to occur by an immune-mediated process. The demyelinating lesions of MS can occur anywhere in the CNS including the brain, brain stem, spinal cord, and optic nerves. The presenting symptoms of MS vary, but common symptoms are visual complaints, weakness, urinary retention, and sensory deficits. Although migraine (“D”) can be associated with neurologic symptoms, one would expect more stereotypic events and a history of previous headaches. Fibromyalgia (“B”) is associated with numerous somatic complaints, but is not typically associated with sensory deficits or visual problems. Conversion disorder (“C”) can produce all of the symptoms described earlier but is a diagnosis of exclusion in the setting of a physical exam that doesn't follow anatomic localization. Ischemic strokes (“E”) would present with sudden onset of symptoms that improve slowly over weeks to months. In contrast, MS lesions have a slower onset with symptoms building over a day or two and then improve over weeks to months.

HELPFUL TIP:

MS has a geographic predilection. The incidence of MS increases with increasing distance from the equator. (Alaskans are screwed.) Various theories have suggested an association with sunlight exposure, vitamin D, virus exposure, or ethnicity.

Question 18.5.3 If your patient indeed does have MS, which type is most likely?

- Neuromyelitis Optica
- Relapsing–remitting
- Primary progressive
- All of the above are equally likely

Answer 18.5.3 The correct answer is “B.” The two common forms of MS are primary progressive and relapsing–remitting. The diagnosis of relapsing–remitting MS is based on clinical grounds and laboratory data. Clinically, symptoms of CNS dysfunction develop over hours to days, stabilize, and then

improve. It is important to identify clinical events disseminated in space and time. In this case, your patient had a prior history of optic neuritis and lower extremity numbness and now has arm numbness. “A,” neuromyelitis optica, is a CNS demyelinating disease that can have a similar presentation to MS but typically has long spinal cord lesions (greater than three vertebral segments) and tends to spare the subcortical white matter, which is a classic lesion location in MS. Neuromyelitis optica is treated slightly differently than MS and tends to be more aggressive, so a correct diagnosis is important.

Question 18.5.4 Which of the following tests would NOT be helpful in further diagnosing MS?

- A) MRI brain with contrast
- B) Lumbar puncture
- C) Nerve conduction studies
- D) Visual-evoked potentials
- E) MRI cervical and thoracic spine with contrast

Answer 18.5.4 The correct answer is “C.” MS is a central demyelinating process and does not produce abnormalities that would be seen on nerve conduction studies. “A” and “E,” MRI of the brain, cervical and thoracic spine, would be helpful. Brain MRI is 85% to 97% sensitive in detecting MS plaques. Multiple areas of increased signal in the periventricular area are suggestive of, but not specific for, MS. Gadolinium-enhancing lesions suggest active disease. “B,” lumbar puncture, can also be useful. Cerebrospinal fluid (CSF) abnormalities suggestive of MS include oligoclonal bands and increased synthesis of IgG and mild lymphocytic pleocytosis. A spinal fluid examination may be considered if the clinical diagnosis of MS is suspected but is not definite. However, the positive and negative predictive value of CSF oligoclonal bands is inadequate to do more than support the clinical diagnosis. Finally, “D,” visual-evoked potentials, may be helpful if the etiology of prior vision loss is unclear. Evoked potentials may be used to aid in the diagnosis of MS by indicating prior demyelination of the optic tract (optic neuritis) if the clinical history is vague (e.g., eye pain without vision loss or no recollection of symptoms). This will aid in proving the occurrence of different events separated by space and time.

Question 18.5.5 Which of the following is not a recognized therapy for MS?

- A) Corticosteroids
- B) Interferon- β
- C) Glatiramer acetate (Copaxone)
- D) Sulfasalazine
- E) Dimethyl fumarate (Tecfidera)

Answer 18.5.5 The correct answer is “D.” Sulfasalazine is not useful in the treatment of MS. Immune-modulating therapy reduces the number of exacerbations and active lesions on MRI. These include interferon- β -1a (Avonex and Rebif) and interferon- β -1b (Betaseron), as well as glatiramer acetate (Copaxone). These medications are more efficacious if started early in the course of the disease. Common adverse effects of interferon include fatigue, depression, and myalgias.

Corticosteroids (“A”) have a role in treating severe acute exacerbations (e.g., optic neuritis, severe neurological impairments limiting activities of daily living) in the form of a short burst and taper (typically methylprednisolone, 1 g/day often followed by an oral prednisone taper). Steroid use does not appear to offer long-term functional benefit, excluding the possible exception of IV pulsed steroid dosing. There have been oral and infusion immunosuppressant medications FDA approved for relapsing-remitting MS. The first FDA-approved treatment for primary progressive MS occurred in 2017, ocrelizumab (Ocrevus), an anti-CD20 monoclonal antibody.

Question 18.5.6 Which of the following treatments have NOT been associated with progressive multifocal leukoencephalopathy?

- A) Natalizumab (Tysabri)
- B) Ocrelizumab (Ocrevus)
- C) Glatiramer acetate (Copaxone)
- D) Dimethyl fumarate (Tecfidera)

Answer 18.5.6 The correct answer is “C.” Progressive multifocal leukoencephalopathy is a serious brain infection by the JC virus that has a high mortality rate. The JC virus attacks immunocompromised hosts. (Yes, it is a polyomavirus virus and not the prion disease Creutzfeldt-Jakob. JC is not an abbreviation, it is the name of the virus). Dimethyl fumarate, ocrelizumab, and natalizumab are all immune-suppressing medications that carry a risk of PML. Ocrelizumab is new to the market but a few cases have emerged. In general, any medication that is immunosuppressive carries some risk of PML. Interferon and glatiramer are not associated with PML.

The patient is wondering what she can do to prevent exacerbations.

Question 18.5.7 Which of the following is associated with exacerbation of MS symptoms?

- A) Cold temperatures (you could recommend she move to Florida)
- B) Urinary tract infection
- C) Influenza vaccination
- D) Trauma

Answer 18.5.7 The correct answer is “B.” Urinary tract infections can exacerbate MS. Unfortunately, urinary tract infections are particularly common in those with MS because of the frequent occurrence of neurogenic bladder and possible need for frequent intermittent self-catheterization. Systemic infection has also been reported to provoke MS exacerbations. “A” is of special note. Cold is not associated with exacerbations, but heat is notorious, and this phenomenon actually has a name—Uhthoff phenomenon. Patients with MS should be instructed to avoid hot tubs, saunas, steam rooms, etc. “C,” vaccinations, including influenza vaccine, had been posited as a cause of exacerbations. However, a review of multiple clinical trials showed no increased risk of exacerbations in patients with MS receiving the influenza, hepatitis B, or tetanus

vaccinations. **Note that we do not have experience with nasal influenza vaccine and MS. Since the nasal vaccine contains live virus, it should probably be avoided in patients with MS.** “D,” trauma, has been suggested as a possible exacerbation trigger, but the American Academy of Neurology clinical practice guidelines state that the majority of class II evidence available on this issue supports no connection.

HELPFUL TIP (A WORD ON OTHER DRUGS FOR MS):

Ampyra (dalfampridine) is supposed to increase walking distance. Nuedexta (dextromethorphan + quinine) is designed to reduce pseudobulbar symptoms (emotional lability with spontaneous laughing, crying). Both are of marginal benefit.

There are many more “newer” therapies for relapsing–remitting MS (e.g., dimethyl fumarate [Tecfidera], mitoxantrone [Novantrone], natalizumab [Tysabri], teriflunomide [Aubagio], ocrelizumab [Ocrevus], and others), most of which require neurologic specialty care and carry high risk of adverse events.

► Objectives: Did you learn to ...

- Identify epidemiologic characteristics of MS?
- Identify appropriate workup for patients with possible MS?
- Diagnose MS?
- Discuss potential treatment options available for long-term disease modification as well as acute exacerbations?
- Recognize factors that might result in exacerbations of MS?

► CASE 18.6

A 43-year-old woman with a history of myasthenia gravis presents to the ED while on vacation. She reports she is feeling tired and rundown and endorses flu-like symptoms in addition to some worsening of her proximal lower extremity weakness. On examination, she is afebrile with a respiratory rate of 18. She has mild diplopia with lateral gaze. Her strength is 4/5 proximally and 4+/5 distally bilaterally. Her sensory examination is normal. Plantar responses are down-going bilaterally.

Question 18.6.1 In determining this patient’s further disposition, what is the most important test?

- Arterial blood gas
- CXR
- Head CT
- Spirometry (forced vital capacity [FVC] and negative inspiratory force [NIF])
- CBC

Answer 18.6.1 The correct answer is “D.” This patient is experiencing an exacerbation of myasthenia gravis. This could be occurring for any number of reasons including concurrent illness or possibly noncompliance with her regimen. The greatest morbidity and mortality for this patient lies in the potential for respiratory failure and arrest. In primary neuromuscular respiratory

failure (e.g., myasthenia gravis, acute inflammatory demyelinating polyradiculoneuropathy, Guillain–Barré syndrome), the arterial blood gas (“A”) may remain normal despite impending respiratory collapse. The best way to evaluate respiratory status is with the FVC and NIF. If the FVC is less than 15 mL/kg or NIF less than -20 cm H₂O, elective intubation should be considered, although some centers will choose to monitor these patients closely in an intensive care setting. Once a patient with myasthenia gravis has been intubated, you should stop their pyridostigmine as it will increase respiratory secretions and GI motility leading to diarrhea. Neither of these is desirable in an intubated ICU patient (the nurses will love you for this one) and the pyridostigmine will not liberate them from the ventilator. Monitoring the FVC/NIF should be done regularly throughout the hospital course until the patient is clinically improved and stable.

You decide to give this patient a dose of edrophonium trying to reverse her symptoms. When you do this, she becomes increasingly weak, requiring intubation.

Question 18.6.2 The BEST explanation of this is:

- Since she has missed multiple doses of her pyridostigmine, she has become desensitized and will have an overwhelming response to small doses of IV edrophonium
- Influenza has made her particularly susceptible to edrophonium
- The patient has taken too much pyridostigmine by accident
- The alcohol that she has had on vacation has changed her pyridostigmine requirement

Answer 18.6.2 The correct answer is “C.” Myasthenic crisis can be due to two causes. First, the patient may have not taken enough medication or may have missed doses. In this case, edrophonium will improve symptoms. The second cause is **too much** pyridostigmine. This will also cause weakness. In this case, the edrophonium will worsen the patient’s symptoms. Here’s how it works. Pyridostigmine and edrophonium are both cholinesterase inhibitors similar to organophosphates. They act by binding to acetylcholinesterase and preventing the breakdown of acetylcholine in the neuromuscular junction. Too much of either drug (or a combination of the drugs) will cause weakness and an organophosphate toxicity-like syndrome (salivation, lacrimation, defecation, urination, weakness, etc.).

Question 18.6.3 Which of the following IS NOT likely to contribute to the diagnosis of myasthenia gravis?

- Tensilon (edrophonium) test
- Nerve conduction studies
- Anti-thymocyte antibodies
- Anti-acetylcholine receptor antibodies

Answer 18.6.3 The correct answer is “C.” Anti-thymocyte antibodies are used to treat renal rejection and have also been used in aplastic anemia, red cell aplasia, and other disorders. They have no relationship at all to myasthenia gravis ... sorry. All of the others can be used in the diagnosis of myasthenia gravis. The

edrophonium test (“A”) is a functional test. One must be ready to intubate the patient when performing an edrophonium test, as weakness may get worse. Nerve conduction studies (“B”) show a reduction in the amplitude of the response to repeated stimulation (thus, patients get weaker with repeated muscle use). Antiacetylcholine receptor antibodies (“D”) are found in the majority (80–90%) of patients with myasthenia gravis. Children or adolescents presenting with myasthenia-like symptoms may be antibody negative, in that case congenital myasthenic syndromes should be considered as these are genetic diseases affecting the neuromuscular junction and will not get better with immune suppression. However, congenital myasthenic syndrome may either improve or worsen with pyridostigmine based on the genetic defect and may have other treatment options.

HELPFUL TIP:

Myasthenia gravis can be systemic or limited to the ocular muscles. It is often associated with a thymoma (or thymus hyperplasia), and patients with myasthenia gravis should have a chest CT scan to rule out thymoma or thymus hyperplasia. If present, removal of the thymoma will often “cure” the patient’s disease.

Question 18.6.4 Which of the following is LEAST likely to be confused with myasthenia gravis on the basis of its neurologic symptoms?

- A) Eaton–Lambert syndrome
- B) Guillain–Barré syndrome (GBS)
- C) Amyotrophic lateral sclerosis (ALS)
- D) Botulism toxicity
- E) Penicillamine-induced myasthenia gravis

Answer 18.6.4 The correct answer is “B.” Remember that myasthenia gravis has no sensory findings. GBS includes sensory findings of pain, paresthesias, numbness, etc. that are generally absent in the other syndromes. “A,” Eaton–Lambert syndrome, is a paraneoplastic process, which consists of weakness **that gets better with repetitive movement**. This is the exact opposite of what is seen with myasthenia gravis where repetitive tasks lead to increased weakness. Thus, Eaton–Lambert syndrome is often worse in the morning and better toward the afternoon—the reverse of what is seen with myasthenia gravis. Patients with amyotrophic lateral sclerosis (“C”), botulism (“D”), and penicillamine-induced myasthenia gravis (“E”) do not have sensory symptoms. Thus, these can be confused with myasthenia gravis.

HELPFUL TIP:

ALS results in upper and lower motor neuron death. With upper motor neuron disease, reflexes remain intact and often times are brisk. Reflexes are generally lost in Guillain–Barré and other causes of lower motor neuron disease such as diabetes, Charcot–Marie–Tooth disease, polio and other causes of acute, flaccid paralysis (i.e., West Nile Virus, others).

The patient and her husband have some questions about myasthenia gravis and are wondering if there are any medications that might exacerbate this patient’s weakness.

Question 18.6.5 Which of the following can worsen myasthenia gravis?

- A) Fluoroquinolones
- B) Verapamil
- C) β -Blockers
- D) Oral contraceptives
- E) All of the above

Answer 18.6.5 The correct answer is “E.” All of the above can worsen myasthenia gravis. Other drugs of note include: aminoglycosides, anesthetic and paralytic agents, diuretics, tetracyclines, and magnesium, among many others.

You decide to add to the treatment of this patient.

Question 18.6.6 Which of the following is considered a standard therapy for myasthenia gravis?

- A) Plasmaphoresis for an acute myasthenic crisis
- B) IVIG
- C) Prednisone
- D) Azathioprine
- E) All of the above are used for myasthenia gravis

Answer 18.6.6 The correct answer is “E.” Do you see a pattern here? All of the treatments are immunomodulators. The combination of high-dose prednisone with either IVIG or plasma exchange is used to treat acute myasthenia crises. The choice of IVIG or plasma exchange is based on the patient’s comorbidities, tolerability, prior success, and hospital resources. Caution is advised when initiating prednisone acutely as some patients will have temporary worsening of symptoms before improving. Other options are cyclosporine and mycophenolate. The idea here is to reduce anti-endplate antibodies (although nobody is quite sure how IVIG works). Pyridostigmine is used only for mild symptomatic relief. Remember thymectomy as this may be a cure if a thymoma is present.

► Objectives: Did you learn to ...

- Manage a patient with an exacerbation of myasthenia gravis?
- Understand the use of diagnostic tests in myasthenia gravis?
- Recognize diagnoses that can be confused with myasthenia gravis?

► CASE 18.7

A 29-year-old woman presents to the ED with sudden onset of a severe headache involving bilateral occipital pain associated with nausea. She has a history of migraine headaches consisting of right-sided throbbing pain that typically respond to sumatriptan but occasionally require IV ketorolac

and metoclopramide. The headache has not responded to her sumatriptan (Imitrex) injection. She appears to be in moderate pain but otherwise has a normal general and neurological examination. This is the “worst headache of her life.”

Question 18.7.1 What is the next step in the management of this patient?

- A) Ketorolac (Toradol) and metoclopramide IV
- B) Hot tea and soft pillow
- C) Dihydroergotamine (DHE) IV
- D) Head CT
- E) Lumbar puncture

Answer 18.7.1 The correct answer is “D.” Although this patient has a history of migraines, she is reporting a sudden onset headache that is markedly changed from her typical pattern of headache. In this setting—especially with the “worst headache of her life”—the diagnosis of subarachnoid hemorrhage (SAH) must be ruled out. None of the other answers are correct. While pain management can be given before CT (e.g., IV morphine or fentanyl), ketorolac (“A”), aspirin, and DHE (“C”) are inappropriate if there is a question of SAH. Ketorolac and aspirin have antiplatelet effects, which can increase bleeding. DHE can cause vasospasm and worsen brain ischemia. Finally, if you recall, this patient tried her sumatriptan. One should not use DHE within 24 hours of a triptan. The need for a lumbar puncture is discussed below.

The patient’s head CT is negative.

Question 18.7.2 What next?

- A) Lumbar puncture
- B) IV hydroxyzine and meperidine and discharge when she is comfortable
- C) IV hydroxyzine and promethazine (Phenergan) and discharge when she is comfortable
- D) Discharge home with prescription for acetaminophen and oxycodone (Percocet)
- E) Discharge home with prescription for rizatriptan (Maxalt)

Answer 18.7.2 The correct answer is “A.” In the setting of a “worst headache of life,” a CT scan to rule out SAH is required. The sensitivity of CT scan of the brain for hemorrhage in the setting of SAH is 90% to 95% within 24 hours of the event (decreases to 80% at 72 hours). CT only picks up 50% of warning leaks. As a result, a **negative head CT does not adequately rule out SAH** and should be followed with a lumbar puncture. The CSF from the lumbar puncture must be spun down immediately to examine for xanthochromia. Xanthochromia is a yellow discoloration of the normally clear CSF resulting from degradation of hemoglobin. In addition to xanthochromia, markedly elevated RBC counts are indicative of SAH. If either the CT or LP is positive for SAH, MR angiogram or CT angiogram should be performed, and you should also contact your neurosurgery colleagues as some patients may need surgical intervention such as ventriculostomy.

HELPFUL TIP:

Thirty-nine percent of patients with an SAH have no neurologic signs or symptoms. Only 10% of patients with SAH have an initially focal examination. Patients with SAH may have a fever and leukocytosis. While looking at the patient’s fundi is important, the *absence of papilledema does not rule out SAH*. SAH can present as back pain. Since each bleed carries a 50% mortality, this is one diagnosis you do not want to miss. Use LP liberally in appropriate patients.

HELPFUL TIP:

You may hear about a couple of studies that have shown that a CT scan done within 6 hours of headache onset is sensitive enough to rule out SAH without the need for an LP. This has definitely not yet become the standard of care.

You complete the LP, and it is normal. Apparently, this was just the worst migraine of her life. After loading her up on some good drugs, her pain subsides. Problem solved!

► Objective: Did you learn to ...

- Identify a patient presenting with SAH symptoms and perform an appropriate workup

► CASE 18.8

A 40-year-old man presents with a complaint of low-back pain that is dull in nature, which started 2 days ago. This morning he woke up with a feeling of numbness and tingling in his feet, which gradually seemed to worsen. By noon, he noted difficulty walking and decided to come to the ED. He denies bowel or bladder incontinence. On examination, he is in no acute distress and has a respiratory rate of 12. He has strength of 5/5 in his upper extremities, and in his lower extremities, strength is 4/5 proximally and 3/5 distally. Sensory examination reveals a mild decrease in pinprick and light touch in a stocking distribution to the mid-calf. Reflexes in the upper extremities are 2+ and in the lower extremities are trace at the knees and absent at the Achilles. Plantar response is down-going bilaterally.

Question 18.8.1 What is the most likely diagnosis?

- A) Diabetic polyneuropathy
- B) Guillain-Barré syndrome (GBS)
- C) Diabetic amyotrophy
- D) Stroke
- E) Conversion reaction

Answer 18.8.1 The correct answer is “B.” Of the choices given above, the most likely diagnosis is Guillain-Barré syndrome (GBS), an acute immune-mediated polyneuropathy. With an acute onset of bilateral lower extremity weakness and sensory deficits,

the diagnosis of an acute cord-compressing lesion (e.g., tumor and epidural abscess) should also be considered and ruled out, especially when back pain is also present. The time course described previously is not consistent with diabetic polyneuropathy (“A”) nor would one expect to see weakness as a prominent symptom. Diabetic amyotrophy (“C”) is characterized by painful **proximal** muscle weakness with minor sensory loss. The onset of diabetic amyotrophy can be subacute or acute. The time course described above of gradually progressing deficits is not consistent with stroke (“D”). Additionally, the findings of a stroke should not be bilateral. Conversion reaction (“E”) is a diagnosis only of exclusion.

Question 18.8.2 Which of the following is/are associated with GBS?

- A) *Campylobacter jejuni* infection
- B) Lyme disease
- C) Epstein–Barr virus
- D) CMV virus
- E) All of the above

Answer 18.8.2 The correct answer is “E.” All of these infectious agents are associated with GBS, especially *Campylobacter*. Other associations include viral URIs, HIV, immunizations (rare), mycoplasma, epidural anesthesia, sarcoid, lupus, etc. Add to this the Zika virus and the West Nile virus. The point here is that one should look for an underlying illness in patients with GBS.

HELPFUL (AND INTERESTING) TIP:

Antibodies to *Campylobacter* have been shown to cross-react with nerve tissue, thus the association of *Campylobacter* with GBS.

Question 18.8.3 Which of the following actions would NOT be appropriate for additional diagnosis and/or management of this patient with progressive weakness?

- A) Cardiac monitoring
- B) Forced vital capacity (FVC)
- C) Discharge to home on steroids with a follow-up in the morning
- D) EMG/NCV

Answer 18.8.3 The correct answer is “C.” This patient should **not be sent home**. Did you even consider it? Discharge is a particularly bad idea because his disease has worsened rapidly over the last 12 hours. As with other potential causes of neuromuscular respiratory failure, an FVC and NIF are necessary to determine adequate respiratory reserve. The FVC and NIF should be monitored closely during the acute illness. GBS can have a rapid and catastrophic worsening that necessitates monitoring during the acute phase of illness. Typically, patients reach the peak of severity about 2 weeks into the illness. Autonomic dysfunction is associated with GBS, and close cardiovascular monitoring is important. EMG/NCV can be of value in diagnosing GBS—although early on in the course of the disease, these tests may be normal.

A diagnosis of GBS is made.

Question 18.8.4 Which of the following is NOT an appropriate treatment modality?

- A) IVIG
- B) Plasma exchange
- C) Elective intubation if FVC is <15 mL/kg
- D) Corticosteroids

Answer 18.8.4 The correct answer is “D.” Corticosteroids are not used in the treatment of GBS. Multiple studies have shown no benefit to corticosteroids in this disease. Treatment options for GBS include careful monitoring of disease and supportive therapy with no intervention for mild cases but when patients develop motor deficits or respiratory failure, IVIG or plasma exchange are the two treatments that improve outcomes. If a patient requires ventilatory support or has weakness that precludes ambulation, treatment should be started immediately. Elective intubation is appropriate if the FVC is less than 15 mL/kg or the NIF is –20 cm H₂O. As discussed in regard to neuromuscular respiratory failure with myasthenia gravis, arterial blood gases are not reliable markers of impending failure, and the FVC must be closely monitored.

The family would like to know what the outcome in this patient with GBS will be, so you pull out your crystal ball.

Question 18.8.5 Well, instead of sarcasm, you actually opt for compassion and tell them that FULL RECOVERY can be expected in _____ percent of patients.

- A) 15%
- B) 50%
- C) 80%
- D) Greater than 95%

Answer 18.8.5 The correct answer is “A.” Fifteen percent of all patients with GBS will have **complete** resolution of their symptoms. Sixty-five percent will be left with minor deficits, and about 10% will become disabled. Patients with GBS should survive the illness unless there are comorbidities present that make weaning ventilator support difficult, such as severe COPD or autonomic crisis leading to cardiovascular collapse.

HELPFUL TIP:

West Nile virus infection can present as either a GBS (symmetrical neurological symptoms with loss of reflexes) or a poliomyelitis-like syndrome (generally asymmetrical weakness with worse weakness proximally, loss of reflexes, fasciculations).

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of GBS?
- Identify underlying illnesses that are associated with GBS?
- Manage a patient with GBS?

► CASE 18.9

A 38-year-old woman is brought to the ED by her husband who expresses concerns over changes in her mental status over the past 2 days. She has become confused, forgetting the names of persons well-known to her, and forgetting what she is doing. Her conversations have become increasingly more difficult to follow, and over the past 12 hours, she has gradually become sleepier. On examination, she has a temperature of 38.5°C. She is drowsy but can be aroused. She has no meningismus. She is oriented only to person. She responds to questions slowly and incorrectly and follows only simple commands (“stick out your tongue”). The remainder of her neurological examination is essentially normal, given her limited ability to cooperate. CBC, coagulation studies, and electrolytes (including calcium, magnesium, and phosphorous) are normal.

Question 18.9.1 What is the best next step in evaluating this patient?

- A) Lumbar puncture
- B) Head CT
- C) Electroencephalogram (EEG)
- D) Chest x-ray (CXR)

Answer 18.9.1 The correct answer is “B.” Although performing all of the above tests will be helpful in evaluating this patient, the most important test to do at this time is a head CT to rule out any mass lesion or hemorrhage. You could argue that “A,” an LP, could be done first, and some experts would agree with that decision. However, the standard in the United States is to do the CT scan first if there is any possibility of a mass lesion. Once a mass lesion or hemorrhage has been ruled out, an infectious encephalitis or meningitis needs to be empirically treated with a goal of treatment within 30 minutes from the time of arrival in the ED. There is a possibility that nonconvulsive status epilepticus is causing these mental status changes. However, even if the EEG (“C”) showed nonconvulsive status epilepticus, a head CT and lumbar puncture would remain necessary. Although pneumonia could cause confusion, a CXR (“D”) is unlikely to be of high yield in this setting.

Her head CT is normal. You perform a lumbar puncture, which reveals 18 WBCs (all lymphocytes), 12 RBCs, CSF protein 67 mg/dL (elevated), and CSF glucose 70 mg/dL (normal). An EEG is normal.

Question 18.9.2 What is the next step in managing this patient?

- A) Admit for viral encephalitis with close monitoring
- B) Admit for viral encephalitis and start acyclovir and antibiotics
- C) Admit for bacterial meningitis and start antibiotics
- D) Discharge to home with close follow-up tomorrow at 8 am

Answer 18.9.2 The correct answer is “B.” The probable diagnosis in this setting is herpes simplex encephalitis. Her CSF results are consistent with a viral process and are not consistent

with bacterial meningitis (due to the normal glucose and only lymphocytes in the differential). Given the mortality of herpes simplex encephalitis (30–70%), all patients in whom the diagnosis is suspected should be started on acyclovir 10 mg/kg every 8 hours IV empirically (with appropriate dosage adjustments for renal failure), while further confirmatory testing is pending (CSF PCR for the herpes simplex virus). There can be false-negative tests so if there is high clinical suspicion for HSV encephalitis then treatment should continue. Treatment should be for a minimum of 10 days. It is important to recognize that the EEG and CT may be normal in herpes simplex encephalitis, particularly early in the disease. However, on CT, one may see evidence of temporal lobe hemorrhage and/or hypodensity in the temporal lobes. EEG can show either periodic lateralized epileptiform discharges or focal slowing in the temporal lobes. Temporal lobe changes may be even more prominently visualized on MRI, and this may be of benefit in cases in which the diagnosis remains unclear. Even with prompt, appropriate treatment, only 38% of patients returned to normal or near-normal neurologic functioning at 2 years. “B” includes antibiotics because most clinicians would cover for bacterial meningitis until the CSF cultures come back negative.

► Objectives: Did you learn to ...

- Recognize the clinical presentation of and the laboratory findings in viral encephalitis?
- Initiate appropriate treatment in a patient with a presumptive diagnosis of herpes encephalitis?

► CASE 18.10

A 70-year-old male presents to your office as a new patient. He is with his wife, who assists in providing the history. His appetite is reduced, and he has lost 10 lb in the past 6 months. His only medication is aspirin, and he has no significant past medical history. On examination, his vital signs are normal, and he is in no acute distress. His gait is slow, and he takes eight steps to turn. He has retropulsion (takes two steps backward when you pull him from behind). There is a resting tremor in both hands but more prominently in the right. You find cogwheel rigidity in both arms as well, but again more prominently displayed on the right. His cognitive screening tests are normal.

Question 18.10.1 The most likely diagnosis is:

- A) Essential tremor
- B) Parkinson disease
- C) Normal pressure hydrocephalus (NPH)
- D) Progressive supranuclear palsy
- E) Stroke

Answer 18.10.1 The correct answer is “B.” This patient most likely has Parkinson disease. “A” is incorrect because essential tremor is typically worsened by activity and is not associated with the other neurologic findings seen in this patient. “C” is incorrect. The classic triad of NPH includes urinary

incontinence, gait ataxia, and dementia. “D” might be a consideration, but there is no specific finding of progressive supranuclear palsy here (e.g., aggressive course, more severe axial rigidity, dysarthria, dysphagia, and downward gaze paresis). Stroke is quite unlikely to present in this insidious fashion with generalized findings.

Question 18.10.2 Which of the following is NOT a common feature of idiopathic Parkinson disease?

- A) Rigidity
- B) Extraocular movement paresis
- C) Bradykinesia
- D) Postural instability
- E) Asymmetric resting tremor

Answer 18.10.2 The correct answer is “B.” There are four cardinal features of Parkinson disease: tremor, bradykinesia, rigidity, and postural instability. Two or more of these features should be present to make the diagnosis. The tremor of Parkinsonism is classically a resting tremor (as opposed to the postural, intention, or action tremor) and is most common in the hands, typically with one side affected more than another. Rigidity (“A”) is described as increased resistance to passive movement. Cogwheel rigidity is a ratchet-like sensation noted when testing a limb with concurrent tremor. Extraocular movement paresis (“B”) is more commonly seen in progressive supranuclear palsy (PSP). Bradykinesia (“C”) may be observed by monitoring the speed and amplitude of movements. Gait disturbance (“D”) with reduced stride length and stooped posture is a common finding, but generally occurs later in the course of the disease. Postural stability and ability to rise from a chair are also impaired. Postural stability may be tested by retropulsion.

You are fairly certain that your patient has Parkinson disease.

Question 18.10.3 Which of the following is not common in idiopathic Parkinson disease?

- A) Micrographia
- B) Hypomimia
- C) Hypophonia
- D) REM sleep behavioral disorder
- E) Alien limb phenomenon

Answer 18.10.3 The correct answer is “E.” Alien limb phenomenon can be present in addition to parkinsonism in cortical basal syndrome, but it is not common in idiopathic Parkinson disease. Micrographia (“A”), writing in small letters, is associated with Parkinson disease. Decreased facial expression (hypomimia (“B”)) with decreased rate of eye blink and diminished vocal volume (hypophonia (“C”)) are also common with Parkinson disease. Other conditions that occur in patients with Parkinson disease include depression, cognitive impairment, and REM sleep behavioral disorder (“D”) (e.g., kicking and screaming during REM sleep in response to vivid, disturbing dreams).

HELPFUL TIP:

There are “Parkinson plus” syndromes, so-called because they present with parkinsonian features with additional characteristics. Look for these syndromes in those that you believe may have Parkinson disease:

- (1) **Progressive supranuclear palsy:** associated with supranuclear gaze palsy, dysarthria, dysphagia, postural instability, and axial rigidity.
- (2) **Multiple system atrophy (formerly known as Shy-Drager syndrome):** notable for early autonomic dysfunction, including marked orthostatic hypotension.
- (3) **Corticobasal syndrome:** associated with apraxia, cortical sensory dysfunction, and the **“alien limb phenomenon”** (ICD-10 code R41.4 if you are interested). Alien limb phenomenon occurs when the patient’s arm moves by itself (e.g., will reach up to touch the patient’s face). Sometimes the patient is not aware of what the alien limb is doing until the movement draws his or her attention. The patient may not believe that the limb belongs to them. Spontaneous limb movements also occur when the patient is startled or the limb is touched (anyone see Dr. Strangelove?).

Question 18.10.4 The diagnosis of Parkinson disease is most appropriately made:

- A) With a brain MRI
- B) By CSF analysis
- C) Clinically
- D) By a neurologist
- E) At autopsy

Answer 18.10.4 The correct answer is “C.” The diagnosis is based on a history and physical examination that are consistent with Parkinson disease. Additionally, a response to dopaminergic agents is *virtually diagnostic* of Parkinson disease. If the patient does not have some response to a dopaminergic agent, reconsider your diagnosis. “A” is incorrect because there are no findings on brain MRI that are specific for the diagnosis of Parkinson disease. Likewise, “B” is wrong because CSF analysis cannot provide the diagnosis. “D” is clearly wrong—do you really need a neurologist for this? The “gold standard” for diagnosis is neuropathologic examination, but you would rather not wait for the autopsy to diagnose Parkinson disease.

HELPFUL TIP:

Up to 10% of patients with Parkinson disease will have some degree of intention tremor in addition to their resting tremor. A DAT (123I-FP-CIT single-photon emission tomography) scan may be helpful in differentiating Parkinson spectrum disorders from essential tremor and drug-induced parkinsonism. It is positive for nigrostriatal dopaminergic denervation in Parkinson spectrum disorders and negative in essential tremor and drug-induced parkinsonism.

Your patient takes only aspirin, which you know does not cause parkinsonism.

Question 18.10.5 Which of the following medications is frequently associated with a Parkinson-like syndrome in the elderly?

- A) ACE inhibitors
- B) HMG-CoA reductase inhibitors
- C) Calcium channel blockers
- D) Metoclopramide
- E) All of the above

Answer 18.10.5 The correct answer is “D.” Metoclopramide is a frequent cause of the misdiagnosis of Parkinson disease in the elderly. Additional medications, such as SSRIs, antipsychotics, and others, can mimic Parkinson disease. Importantly, *drug-induced parkinsonism may last for up to 6 months after discontinuation of the offending agent.*

You think it is best to initiate treatment in this patient.

Question 18.10.6 Possible treatments of Parkinson disease include all of the following EXCEPT:

- A) Levodopa
- B) Deep brain stimulation
- C) Pramipexole
- D) Donepezil
- E) Selegiline

Answer 18.10.6 The correct answer is “D.” Donepezil is used to treat Alzheimer disease. The initial symptoms of Parkinson disease typically respond well to levodopa and the dopamine agonists. Selegiline is a monoamine oxidase B inhibitor and yields modest symptomatic benefits. Dopamine receptor agonists, such as pramipexole (Mirapex) and ropinirole (Requip), may be used in the initial treatment of Parkinson disease.

HELPFUL TIP:

Surgical options for advanced Parkinson disease include deep brain stimulation and pallidotomy. Subthalamic nucleus and globus pallidus internus are commonly used targets of deep brain stimulation in Parkinson disease treatment. Both reduce tremor and bradykinesia. Pallidotomy is rarely used these days, given the effective and reversible nature of deep brain stimulation.

Question 18.10.7 Which of the following is *NOT* a common side effect of levodopa?

- A) Nausea
- B) Paresthesias
- C) Dyskinesia/dystonia
- D) Hallucinations

Answer 18.10.7 The correct answer is “B.” Paresthesias are not associated with the use of carbidopa/levodopa. Carbidopa inhibits peripheral metabolism of levodopa and therefore allows a higher proportion of levodopa to cross the blood–brain barrier for CNS

effect. Carbidopa helps to prevent levodopa-induced nausea (“A”). Dystonia and dyskinesia (“C”) are common with therapy lasting more than 2 years or at peak dose responses and may necessitate lowering the doses. Psychiatric problems (“D”), including hallucinations and psychosis, can be seen with dopaminergic agonists and levodopa. Other common side effects of levodopa include hypotension, confusion, and other psychiatric disturbances.

HELPFUL TIP:

Levodopa is a dopamine precursor, and carbidopa is a peripheral dopadecarboxylase inhibitor that does not cross the blood–brain barrier. The symptoms of tremor, rigidity, and bradykinesia are initially relieved by levodopa. However, with time, larger doses and more frequent doses are required to maintain control of symptoms. Deep brain stimulation may be helpful in patients with advanced Parkinson disease to reduce doses of dopaminergic medications.

You decide to start levodopa/carbidopa (Sinemet) three times daily. At the follow-up visit, the patient is doing relatively well on this combination. However, he notices that in the mornings and prior to the next dose of medication, he tends to be stiff and has difficulty ambulating.

Question 18.10.8 The most appropriate next step is to:

- A) Initiate a “drug holiday” to restore the patient’s sensitivity to the drug
- B) Add another dopaminergic agent such as ropinirole (Requip)
- C) Add a catechol-O-methyl-transferase (COMT) inhibitor such as entacapone (Comtan)
- D) Add an anticholinergic agent such as benztropine (Cogentin)

Answer 18.10.8 The correct answer is “C.” The patient is experiencing the “wearing-off” phenomenon. There are several ways to address this. One option is to add a COMT inhibitor (like entacapone [Comtan]) in order to slow down the metabolism of levodopa. COMT inhibitors have no effect on their own and should only be used with levodopa. Another option is to switch the patient from immediate-release carbidopa/levodopa to a sustained-release product (e.g., Sinemet CR). Another common approach to the “wearing-off” phenomenon is altering the dosing of carbidopa/levodopa—either increasing the dose or shortening the interval between doses. Istradefylline (Nourianz), an adenosine receptor agonist, has recently been approved for wearing off phenomenon. There is also now inhaled levodopa (Inbriza) that can be used 5 times per day, though you have to question your management if your patient needs Inbriza 5 times per day.

HELPFUL TIP:

Tolcapone (Tasmar) is associated with fatal hepatic necrosis and requires monitoring of liver function tests (LFTs). Thus, entacapone (Comtan) is the preferred drug (though a benign side effect is urine discoloration). Alcapone is associated with tax evasion and “hits.” This Capone should be avoided as well (get it? Al Capone??).

When you counsel your patient regarding medication use, you urge him not to stop taking his medication all at once.

Question 18.10.9 Which of the following is NOT a potential adverse effect of abrupt discontinuation of dopaminergic agonists and/or levodopa?

- A) Neuroleptic malignant syndrome (NMS)
- B) Severe rigidity
- C) Confusional state
- D) Severe dyskinesias

Answer 18.10.9 The correct answer (not a potential adverse effect) is “D.” Levodopa and dopamine agonists should be tapered. Abrupt discontinuation of these medications may precipitate NMS (“A”). In addition, abrupt withdrawal is also associated with an acute confusional state (“C”) separate from the mental status changes seen in NMS. Severe worsening of the patient’s parkinsonism is expected, which can result in prominent rigidity (“B”). Dyskinesias are frequently seen with dopaminergic agonist/levodopa **therapy**, but are not exacerbated or triggered by **withdrawal** of these agents.

HELPFUL TIP:

Diagnostic criteria for definite NMS include hyperthermia, muscle rigidity, and five of the following: mental status changes, tremor, tachycardia, incontinence, labile blood pressure, metabolic acidosis, tachypnea/hypoxia, elevation of creatine kinase, diaphoresis/sialorrhea, and leukocytosis. Treatment includes supportive care as well as the use of benzodiazepines (lorazepam or diazepam... first line), dantrolene, bromocriptine, and amantadine, although there is limited data to support the use of any of these medications.

A year later your patient returns and seems to be doing well. You ask him about symptoms of Parkinson disease, if he is having any adverse effects of medications, and if he is experiencing any of the Parkinson-associated diseases.

Question 18.10.10 Which of the following is NOT associated with Parkinson disease?

- A) Depression
- B) Dementia
- C) REM sleep disorder
- D) Narcolepsy
- E) Hallucinations

Answer 18.10.10 The correct answer is “D.” Narcolepsy has not been associated with Parkinson disease. However, excess daytime sleepiness has been associated. This is likely due to a combination of factors, such as sleep disturbance, depression, dopaminergic drugs, and Parkinson disease itself. Depression is commonly seen in Parkinson disease and is reported to occur in up to 41% of patients. Dementia, typically with Lewy bodies

present on pathological analysis, is seen and can affect the decision to proceed with surgical treatment of Parkinson disease, as patients with advanced dementia get less benefit from surgery. Also, REM sleep behavior disorders are seen in Parkinson disease and can be a source of stress for families and caretakers. REM sleep behavior disorder is characterized by acting out of dreams that can consist of vocalizations as well as active and even violent movements. Typically, REM sleep behavior disorder responds to melatonin and clonazepam. Finally, hallucinations can be caused by Parkinson disease as well as by levodopa and dopamine agonists. Decreased visual contrast sensitivity and other visual changes as well can occur with Parkinson disease.

HELPFUL TIP:

The dopamine agonists (pramipexole, ropinirole, etc.) have been associated with compulsive behavior (sexual compulsion, compulsive gambling, etc.). This may explain why our elderly patients like to go to Las Vegas and Atlantic City ...

► **Objectives: Did you learn to ...**

- Identify common features of Parkinson disease?
- Diagnose Parkinson disease?
- Manage a patient with Parkinson disease?
- Understand pharmacotherapy available for Parkinson disease and some of the potential adverse effects of drug therapy?

► **CASE 18.11**

A 45-year-old left-handed woman who is a busy executive for a Fortune 500 company presents with excessive daytime sleepiness. She is otherwise healthy and takes no medications.

Question 18.11.1 How do you approach this problem?

- A) Reassure her that it is normal for people to be drowsy under stressful work conditions
- B) Begin zolpidem at night for sleep
- C) Schedule the patient for polysomnography
- D) Discuss the patient’s sleep hygiene
- E) Administer modafinil (Provigil) prior to important board meetings

Answer 18.11.1 The correct answer is “D.” It is essential that all patients with complaints of either insomnia or excessive daytime sleepiness have a thorough sleep history taken. Polysomnography may be necessary, but this test—like all diagnostic tests—should be driven by a hypothesis. A history is necessary to develop a hypothesis and determine a test’s utility. Starting hypnotic agents (“B”) or stimulants (“E”)—or both—without thoroughly investigating the underlying problem may cover up a significant, treatable problem and is considered bad form.

Question 18.11.2 Which of the following is NOT an important aspect of a sleep history?

- A) Sleeping and waking times
- B) Use of stimulants and alcohol
- C) Sleep interruptions (children, cell phones, pagers, etc.)
- D) Snoring
- E) Listening to “soft rock” (“easy listening” or “adult contemporary”) and traumatic brain injury.

Answer 18.11.2 The correct answer is “E.” Okay, maybe this one was too easy, but we hate “easy listening” music. The Geneva Convention prohibits its use on prisoners of war ... we’ve been told. All ranting aside, this tidbit of her history has no bearing on her sleep. Important parts of the sleep history include the sleeping environment (alone, with spouse or other individual, in the daylight hours, etc.), nap history, family history of sleep problems, and symptoms of specific sleep disorders (snoring, hypnagogic hallucinations, etc.). A medication history is important as well as a history of watching TV in bed, eating in bed, playing with a cell phone in bed, working on a computer prior to bed (such as many of us commonly do) etc., which indicate poor sleep hygiene. Traumatic brain injury is not associated with sleep disorders.

Question 18.11.3 Which of the following is NOT part of a typical sleep study?

- A) Monitoring of EEG
- B) Monitoring respirations and oxygen desaturations
- C) Evaluating the sleep latency in response to sleep aids, such as zolpidem and trazodone, to maximize effective pharmacologic therapy
- D) Monitoring EMG
- E) Video monitoring of sleep

Answer 18.11.3 The correct answer is “C.” Sleep studies are generally done in the naive state without the use of medications. All of the rest are true. “D” and “E” deserve more attention. “D,” monitoring EMG, allows informing the physician about muscle activity during sleep (e.g., restless limbs). “E,” video monitoring and taping, allows the physician to look for problems, such as awakening, evidence of restless leg syndrome, and sleep apnea. Of note, in home sleep studies are becoming more commonly employed for evaluation of sleep disorders.

Question 18.11.4 In considering a diagnosis of narcolepsy, which of the following is NOT part of the diagnosis?

- A) Cataplexy
- B) Sleep paralysis
- C) Hypnagogic hallucinations
- D) Sleep myoclonus
- E) Excessive daytime sleepiness

Answer 18.11.4 The correct answer is “D.” Sleep myoclonus (hypnagogic jerks) is commonly seen in normal people as they begin to fall asleep (witness colleagues at grand rounds with sudden tossing of the head) and is not a part of narcolepsy. Narcolepsy is a disorder characterized by four cardinal traits,

although not all need be present to make the diagnosis: cataplexy, excessive daytime sleepiness, sleep paralysis, and hypnagogic hallucinations. “A,” cataplexy, is a sudden loss of voluntary muscle control during which the patient may appear to be asleep; however, cataplexy does not have to be accompanied by sleep attacks, and the patient may be aware throughout the attack. “B,” sleep paralysis, can occur either at the onset of sleep or upon awakening and can be quite frightening to the patient. “C,” hypnagogic hallucinations, are vivid and typically fearful dreams that occur at the onset of sleep but can also occur upon awakening (hypnopompic hallucinations). “E,” excessive daytime sleepiness, is a hallmark of narcolepsy and can include sleep attacks as well as persistent drowsiness and “micro sleep” (brief intrusions of sleep during a waking state). The complete tetrad of symptoms is seen in only 10% of patients with narcolepsy.

Question 18.11.5 Which of the following is NOT a treatment for narcolepsy?

- A) Amitriptyline (Elavil)
- B) Clonazepam (Klonopin)
- C) Fluoxetine (Prozac)
- D) Modafinil (Provigil)
- E) Atomoxetine (Strattera)

Answer 18.11.5 The correct answer is “B.” Clonazepam is not a treatment for narcolepsy. The treatment of narcolepsy has two primary goals. The first goal is to address daytime sleepiness, which is primarily done with stimulants such as modafinil or methylphenidate. The second goal is to reduce the symptoms of cataplexy. This can be accomplished with agents such as tricyclic antidepressants, and to a lesser extent, SSRIs. Sodium oxybate (Xyrem) (sodium salt of gamma hydroxybutyrate acid, the “date rape drug”) can be used for treatment of cataplexy as well as excessive daytime sleepiness, although a risk evaluation and mitigation strategy should be exercised due to its abuse potential (including date rape); it should not be prescribed to those with a history of drug abuse, etc. Atomoxetine (Strattera) is a norepinephrine reuptake inhibitor, and has no addiction liability or recreational effects.

.....
After a thorough history, you find nothing to suggest narcolepsy besides daytime sleepiness. Of course, you are considering other diagnoses simultaneously—unless you are experiencing a sleep attack yourself (easy to do when studying for the boards).

Question 18.11.6 Which of the following would NOT suggest a possible diagnosis of obstructive sleep apnea?

- A) Difficulty falling asleep
- B) Frequent nighttime arousals
- C) Obesity
- D) Paroxysmal nocturnal dyspnea
- E) Snoring

Answer 18.11.6 The correct answer is “A.” Difficulty falling asleep is not one of the components of obstructive sleep apnea. Snoring, obesity, excessive daytime sleepiness, and paroxysmal

nocturnal dyspnea are all associated with obstructive sleep apnea. Some patients will note frequent arousals from sleep with or without accompanied shortness of breath.

HELPFUL TIP:

It is important to note that not all patients with sleep apnea are overweight, and this diagnosis must be considered in all patients with excessive daytime sleepiness or other suggestive symptoms. Small oropharyngeal airway (especially in **thin** women) and gastroesophageal reflux are associated with sleep apnea.

Question 18.11.7 What treatment options would NOT be appropriate to consider in your patient if she has obstructive sleep apnea?

- A) Bilevel positive airway pressure (BiPAP)
- B) Continuous positive airway pressure (CPAP)
- C) Positional therapy
- D) Uvulopalatopharyngoplasty (UPPP)
- E) Zolpidem

Answer 18.11.7 The correct answer is “E.” Sleep aids, including benzodiazepines, do not have a role in the treatment of obstructive sleep apnea and *may actually worsen symptoms*. CPAP and BiPAP are both potential treatments. Polysomnography (sleep testing) with titration of CPAP or BiPAP should determine which modality to use and the pressure settings. These should not be arbitrarily set to the “normal settings” for a patient. Of note, auto-pap (APAP) therapies are becoming more popular and have been shown to have similar treatment effects and to improve patient adherence (Syst Rev. 2012;1:20). Positional therapy (“C”), avoiding sleeping on one’s back, may be effective in some patients. Some techniques for achieving this goal include sewing an object on the back of the pajama shirt that will irritate the patient when they roll onto it (i.e., tennis balls in a sock). Weight loss, although not mentioned above, can provide improvement in symptoms as well. Surgical therapies including UPPP (“D”) can also be considered based on the patient’s symptoms and preferences. Guidelines suggest that not everyone needs a polysomnogram. Measuring the number of oxygen desaturations (home sleep apnea testing... HSAT) can be appropriate in patients without coexisting illness (COPD, CHF, cor pulmonale, etc.). HSAT is less sensitive than a formal polysomnogram. See *J Clin Sleep Med*. 2017;13(10):1205–1207 for more details.

HELPFUL TIP:

Just as Cookie Monster has learned that cookies are a “sometimes food,” hypnotic medications should generally be considered a “sometimes medicine.” Patients develop tolerance to all commonly used hypnotics with the possible exception of melatonin. Additionally, some hypnotics cause amnesia and others (like the orexin inhibitor class [e.g., suvorexant (Belsomra)]) cause prolonged daytime somnolence the next day. Suvorexant can also cause extremity weakness and some people carry out complex behaviors (such as driving) while unaware. Hypnotics only

add about 15 to 30 minutes to a patient’s total sleep time. For many patients, the risk–benefit ratio does not favor hypnotics. Start with sleep hygiene and CBT-I (Cognitive behavioral therapy for insomnia).

Further history leads you to suspect that she has restless legs syndrome, and you confirm the diagnosis with a sleep study.

Question 18.11.8 Which would be a *first-line* agent for treatment of restless legs syndrome?

- A) Clonazepam
- B) Codeine
- C) Methadone
- D) Pramipexole
- E) Tramadol

Answer 18.11.8 The correct answer is “D.” Restless legs syndrome is characterized by an urge to move the lower extremities due most often to an uncomfortable sensation. This sensation usually occurs during rest and is typically relieved by moving the legs. Dopamine agonists, such as ropinirole (Requip) and pramipexole (Mirapex), are the first-line treatments for restless legs syndrome. Gabapentin, gabapentin enacarbil (Horizant, a prodrug to gabapentin), and pregabalin can also be considered for RLS treatment. Levodopa (e.g., Sinemet) may be effective but the evidence is weak. A variety of other medications are used for restless leg syndrome but do not carry an FDA indication for it. Benzodiazepines (“A”) and narcotic medications (“B” and “C”) as well as tramadol have all been used as alternative therapies, though their effectiveness is unknown.

Question 18.11.9 What other workup would you suggest for this patient once the diagnosis of restless legs syndrome is made?

- A) No further workup is indicated, initiate treatment as above
- B) Serum calcium
- C) Serum iron studies, including ferritin
- D) Serum vitamin B12
- E) Serum vitamin B6

Answer 18.11.9 The correct answer is “C.” Studies have shown a link between low iron stores and restless legs syndrome. All patients with restless legs syndrome should have an iron profile performed, and low iron or ferritin levels merit iron supplementation (and workup for underlying cause, of course). Other associations are diabetes, pregnancy, end-stage renal disease, Parkinson disease, venous insufficiency, folate deficiency, and caffeine intake (dump that fourth cup of coffee ...)

► Objectives: Did you learn to ...

- Take an appropriate sleep history?
- Generate a differential diagnosis for daytime sleepiness?
- Gain familiarity with the diagnostic testing used in a sleep laboratory?
- Identify the presentations of and treatments for common sleep disorders, including narcolepsy, obstructive sleep apnea, and restless legs syndrome?

**HELPFUL TIP:**

One of the favorite parasomnias of the editors is “exploding head syndrome” (this is actually real, not a joke). Patients have the feeling of popping or explosions occurring in their head as they fall asleep.

▶ CASE 18.12

A 60-year-old right-handed gentleman presents with the complaint of head pain.

Question 18.12.1 Which of the following historical descriptions is of the LEAST VALUE in identifying a specific diagnostic classification for head/face pain?

- A) Right-sided, electric, stabbing pain involving primarily the cheek, occurring for seconds to minutes repeatedly throughout the day
- B) Right-sided, electric, stabbing pain involving primarily the throat, tongue, and right ear
- C) Right-sided severe headache involving the orbit and associated with lacrimation and rhinorrhea typically occurring at the same time each day for a given period of time
- D) “Sinus pressure” with a history of sinus headaches responsive to antibiotics in the past
- E) Pattern of severe right-sided “stabbing and boring” headaches around the age of 30 that went away with scheduled indomethacin

Answer 18.12.1 The correct answer is “D.” Sinus headaches are typically a diagnosis of exclusion. Acute sinusitis can cause severe head-and-face discomfort, but **sinusitis remains a relatively uncommon (and way overdiagnosed) etiology for recurrent head-and-face pain.** The specific headache syndromes described in “A,” “B,” “C,” and “E” are described in more detail in the following questions.

Question 18.12.2 Let’s say this patient gives you the history of right-sided severe headache involving the orbit associated with lacrimation and rhinorrhea typically occurring at the same time each day for a couple of weeks. Which of the following would you use for initial acute treatment of this headache syndrome?

- A) Naproxen
- B) Oxygen
- C) Tylenol
- D) Verapamil

Answer 18.12.2 The correct answer is “B.” The type of headache syndrome described is most consistent with cluster headaches. These are most commonly seen in men and are characterized by exquisite pain, typically centered at the orbit. Conjunctival injection, rhinorrhea, and lacrimation frequently accompany the headache. Pain is often disabling. As the name suggests, the patient tends to have headaches in groups (or clusters). These headaches are more common at night, and REM sleep is thought to be a triggering factor. For acute treatment, conventional

headache medications such as DHE and the triptans can be effective. Treatment with high-flow oxygen has also shown significant efficacy as an abortive treatment: typical protocol would be 8 L oxygen on nonrebreather for 15 minutes, with reports of 70% of patients achieving headache relief. Verapamil can be effective for prophylaxis but is not effective as an abortive. Other, more typical migraine prophylactic agents (propranolol, topiramate, indomethacin, valproic acid) have been tried, but no systematic studies have been done to evaluate their efficacy in cluster headaches.

Question 18.12.3 Let’s say your patient describes a history of severe right-sided “stabbing and boring” headaches around the age of 30 that went away with scheduled indomethacin. This description would be most consistent with which of the following headache syndromes?

- A) Tension headache
- B) Paroxysmal hemicrania
- C) Migraine without aura
- D) Chronic daily headache
- E) Analgesic rebound headache

Answer 18.12.3 The correct answer is “B.” Paroxysmal hemicrania is classically described as a unilateral headache with a stabbing/boring character. Although age of onset can vary greatly, it classically occurs in women in their thirties (although it can be seen in men as well). Patients will have between 2 and 40 episodes during a given day, although they do not occur at the same time as is typical with cluster headaches. Although autonomic symptoms (rhinorrhea, lacrimation, conjunctival injection, and ptosis) can be seen in a majority of patients, these headaches can be differentiated from clusters by the pattern of recurrence (sporadic throughout the day versus a predictable time of day for a certain period of time); significant overlap between the two headache syndromes does exist and differentiation can be difficult. Paroxysmal hemicrania is typically exquisitely sensitive to indomethacin, and response to indomethacin is highly correlated with this diagnosis. Migraine headaches (“C”) typically do not occur multiple times in one day and are usually described as a throbbing pain. Chronic daily headaches (“D”) as well as analgesic rebound headaches (“E”) are generally continuous in nature with limited, if any, periods of time without some degree of headache. Chronic daily headache in the setting of prolonged analgesic use is highly suggestive of analgesic rebound headache. The duration of analgesic therapy necessary to trigger and propagate these headaches remains uncertain. However, it can be as little as three times per week.

With further history, your patient describes right-sided, electric, stabbing pain involving primarily the cheek and occurring for seconds to minutes repeatedly throughout the day.

Question 18.12.4 What would be the first-line choice for therapy of this entity?

- A) Carbamazepine
- B) Amitriptyline
- C) Ibuprofen
- D) Morphine
- E) Microvascular decompression (Jannetta procedure)

Answer 18.12.4 The correct answer is “A.” This description is typical of trigeminal neuralgia. Carbamazepine has been shown to be effective in treating trigeminal neuralgia and was used for treatment of this disorder prior to being used for seizures. Tricyclic antidepressants, opioids, and nonsteroidal anti-inflammatory agents are not first-line agents for treatment. Typically, NSAIDs are of limited, if any, benefit in this setting. Other agents that have been used for treatment include gabapentin, pregabalin, oxcarbazepine, clonazepam, baclofen, phenytoin, lamotrigine, and topiramate. Microvascular decompression (the Jannetta procedure) can be effective in alleviating pain from trigeminal neuralgia. However, medical therapy remains the first-line treatment.

HELPFUL TIP:

A unilateral electric, stabbing pain occurring in the tongue, oropharynx, and occasionally extending to the ipsilateral ear has been described; this is known as **glossopharyngeal neuralgia**. Treatment of glossopharyngeal neuralgia is similar to the pharmacologic treatment of trigeminal neuralgia described above. If the patient complains of stabbing eye or temporal headaches lasting seconds, consider the diagnosis of primary stabbing “jolts and jabs” headaches (aka “ice pick” headache). They can occur 40 to 50 times a day or more and are likely a migraine variant.

► Objectives: Did you learn to ...

- Describe the features of various headache syndromes?
- Initiate treatment for cluster headaches, paroxysmal hemicrania, and trigeminal neuralgia?

► CASE 18.13

A 55-year-old male with a history of diabetes and *prostate carcinoma* presents to your office complaining of back pain, groin numbness, and an inability to initiate voiding. This has been worsening over the past 1 week.

Question 18.13.1 The most likely explanation for these symptoms is:

- A) Cauda equina syndrome
- B) Urinary outlet obstruction secondary to prostate carcinoma
- C) Hydroureter and hydronephrosis secondary to urolithiasis
- D) Neurogenic bladder from long-standing diabetes
- E) All of the above are equally likely

Answer 18.13.1 The correct answer is “A.” This is a presentation of cauda equina syndrome. Cauda equina syndrome is caused by compression of the cauda equina at the level of L4 or L5 by a protruding disk, tumor, etc. Symptoms include progressive fecal or urinary incontinence (secondary to inability to initiate voiding and loss of anal sphincter tone), impotence, distal motor weakness, and sensory loss in a saddle distribution. This patient’s symptoms are not likely to be due to urinary outlet obstruction (“B”). Urinary outlet obstruction should not

be associated with sensory changes in a saddle distribution. The same is true of “C.” “D,” neurogenic bladder from diabetes, could be a possibility. However, this should not include back pain or perineal numbness.

Question 18.13.2 On examination of this patient, you would expect to find:

- A) Increased rectal tone
- B) Decreased rectal tone
- C) Normal rectal tone
- D) No rectum

Answer 18.13.2 The correct answer is “B.” Patients with cauda equina syndrome should have decreased rectal tone. If you chose “D” ... well, there are a lot of things we could say but won’t.

Question 18.13.3 The initial treatment of this patient with cauda equina syndrome should include which of the following?

- A) Pain management with narcotics
- B) Dexamethasone administered IV
- C) Placement of a Foley catheter
- D) Urgent neurosurgical consultation
- E) All of the above

Answer 18.13.3 The correct answer is “E.” Pain management (“A”) is critical in any patient. Dexamethasone (“B”) may reduce tumor-related edema leading to a reduction in cord compression—although high-dose steroids are no more effective than usual doses. A Foley catheter (“C”) is indicated to treat the patient’s urinary retention. Since this is a neurosurgical emergency, urgent neurosurgical (“D”) or orthopedic consultation should be obtained. Local radiation may also be used acutely depending on your surgeon, oncologist, etc.

HELPFUL TIP:

The diagnosis of cauda equina syndrome is often delayed for months since many patients initially have incomplete syndromes, including only pain and mild neurologic symptoms. This is unfortunate since outcome depends on the degree of neurologic dysfunction at the time of diagnosis.

► Objectives: Did you learn to ...

- Recognize the clinical presentation of cauda equina syndrome?
- Identify causes of cauda equina syndrome?
- Initiate treatment of a patient with cauda equina syndrome?

QUICK QUIZ: SEIZURE DISORDERS

Absence seizures are characterized by all of the following EXCEPT:

- A) Loss of consciousness
- B) Feeling of déjà vu

- C) Rhythmic lip smacking or eye blinking
- D) Staring spells
- E) Occurrence up to hundreds of times per day

The correct answer is “B.” Feelings of déjà vu and other “psychic” phenomenon such as hallucinations are associated with temporal lobe (aka simple partial) seizures.

▶ CASE 18.14

A 2-year-old female presents to the ED after having a seizure. The parents note that the patient was fine this morning, spiked a temperature to 39.9°C, and then had a 5-minute bilateral tonic-clonic seizure that resolved spontaneously. This is her second such episode in 18 months. On arrival, the patient is febrile, lethargic, and looks postictal.

Question 18.14.1 Your next step is to:

- A) Reassure the parents that this is a simple febrile seizure
- B) Obtain blood cultures and start ceftriaxone
- C) Perform an LP if the CBC shows leukocytosis and elevated bands
- D) Administer acetaminophen and wait for 2 hours to see if the patient returns to baseline before deciding on further treatment
- E) Arrange for an outpatient EEG

Answer 18.14.1 The correct answer is “B.” This patient **must** be assumed to have meningitis until proven otherwise. Treatment should be started immediately. “A” is incorrect. This is not a simple febrile seizure by history. The child is postictal and looks ill. While it may end up being a simple febrile seizure, you cannot make that conclusion at this point. If the child did not look lethargic and was up and running around, no further evaluation or treatment would be needed at this time. “C” is incorrect. First, the CBC may be relatively normal even with meningitis. Second, you do not want to delay antibiotics until the CBC and LP are done. “D” is incorrect for the same reason. **The standard of care in meningitis is antibiotics within 30 minutes of hitting the door.** Waiting to see the patient’s response to acetaminophen for 2 hours will clearly put you out of this time window.

You do the right thing and treat the patient with ceftriaxone. The patient does look better in an hour or so, has returned to baseline and lumbar puncture was negative for infection. She is alert, attentive, and playing with toys. The parents are concerned about whether or not this patient has a seizure disorder. They would like a further evaluation.

Question 18.14.2 Which of the following is indicated at this point for a general patient with a first-time seizure (and not for this patient since she had a febrile seizure)?

- A) EEG done on the same day
- B) Admission to the hospital and EEG the next day

- C) Serum electrolytes and glucose
- D) Trial of antiepileptic drug
- E) None of the above

Answer 18.14.2 The correct answer is “C.” The workup of a seizure includes serum electrolytes, calcium, magnesium phosphate, glucose, etc. Note that these need not be done for someone with a known seizure disorder who has his or her typical seizure and returns to baseline. In these cases, only a drug level of their antiepileptic drug need be done unless there is some change in the seizure type, mental status, etc. “A” and “B” are incorrect. The EEG will be positive because of the recent seizure and may not reflect the underlying condition. Thus, waiting a couple of weeks after the seizure will give a better picture of what the brain’s innate electrical activity looks like. Of course, an EEG or other workup is not necessary for a febrile seizure. “D” is incorrect because we have not yet proven this child has a seizure disorder. Prescribing antiepileptic drugs would be premature.

HELPFUL TIP:

A “stat” EEG can be helpful if you are not sure if a patient is having an active seizure versus a nonepileptic spell (formerly called a “pseudoseizure” now called a “psychogenic nonepileptic seizure,” PNES). However, even a “stat” EEG will take several hours to be hooked up and read by a neurologist. A delay in therapy for hours would be unacceptable for a patient in status epilepticus and would lead to permanent brain damage or death. A “stat” EEG may also be helpful in a patient with mental status changes who you believe may be having nonconvulsive status epilepticus. Again, if there is clinical suspicion then waiting for the EEG should not delay therapy.

The parents are wondering what to do about treating this patient to prevent further febrile seizures.

Question 18.14.3 Your recommendation to prevent further seizures is:

- A) Acetaminophen at the onset of fever
- B) Ibuprofen at the onset of fever
- C) Phenytoin until the child reaches the age of 5
- D) Buccal midazolam at the onset of any fever
- E) None of the above

Answer 18.14.3 The correct answer is “E.” None of these choices are optimal in the management of this patient. “A” and “B” seem like a good idea but do nothing to reduce the occurrence of febrile seizures. Neither “C” nor “D” is effective. One study suggests that rectal diazepam at the onset of a fever will reduce the occurrence of febrile seizures. However, it is associated with some morbidity (e.g., sleepiness) and should be reserved for those with frequent febrile seizures.

**HELPFUL TIP:**

Daily phenobarbital **can** prevent febrile seizures but is associated with behavior and learning problems and is generally not recommended. Daily valproate may be effective as well. Neither of these is recommended because of side effects.

The parents have another child at home who has had one febrile seizure. He is now 12 months old. The parents want to know what his likelihood of having a seizure disorder is.

Question 18.14.4 You can let them know that he has approximately:

- A) 1% to 5% chance of developing a seizure disorder
- B) 10% to 15% chance of developing a seizure disorder
- C) 40% to 50% chance of developing a seizure disorder
- D) 80% to 90% chance of developing a seizure disorder

Answer 18.14.4 The correct answer is “A.” Patients who have a single febrile seizure have approximately 1% to 5% chance of developing a seizure disorder. This is essentially the same risk as the general population.

**HELPFUL TIP:**

About 50% of patients who have their first febrile seizure under age 15 months will have a recurrent febrile seizure. This drops to 30% if the first seizure is after 15 months of age. Family history is also involved; 45% of those who have a first-degree relative with febrile seizures will have a second seizure.

► **Objective: Did you learn to ...**

- Diagnose and manage febrile seizures in children?

► **CASE 18.15**

A 64-year-old man presents to the emergency department (ED) with confusion and hallucinations for the past 2 weeks. He has a history of end-stage liver disease due to NASH (non-alcoholic steatohepatitis) cirrhosis. He often sees rats running around and sometimes even feels the rats crawling on his body. He tries to get them off. General exam is significant for diffuse jaundice, asterixis, and prominent ascites. He is afebrile and does not have nuchal rigidity. O₂ saturation, heart rate, and blood pressure are normal. He is oriented to time, place, and person, although he is easily distractible and he is unable to spell “world” backward. Neurological exam is unremarkable otherwise. You start initial workup, and he has elevated plasma ammonia at 82 (elevated). He also has elevated bilirubin, AST, ALT, INR (1.8), and decreased albumin, all stable compared to 2 months ago. CBC and BMP are within normal limits. Urine analysis and paracentesis are not suggestive of infection. Cultures of urine, ascites, and blood pending.

Question 18.15.1 In addition to treating hyperammonemia, the **best** next step is?

- A) Lumbar puncture
- B) Electroencephalography (EEG)
- C) Check thiamine level
- D) Brain CT
- E) Brain MRI

Answer 18.15.1 The correct answer is “D.” Hyperammonemia may cause brain edema which can be life threatening and require neurosurgery consultation and intracranial pressure monitoring. Brain CT is also very sensitive for acute intracranial hemorrhage which may also cause mental status changes. Patients with chronic liver disease can develop subdural hematomas with minor trauma due to decreased level of coagulation factors. Brain MRI is a better test when there is clinical suspicion of acute ischemic stroke or intracranial malignancy. However, patients with delirium frequently have trouble tolerating the MRI procedure while sedation can potentially worsen delirium. Lumbar puncture is indicated if there is concern of CNS infection. For patients with elevated INR, empiric antibiotic coverage can be started for suspected CNS infection if LP cannot be completed safely. In this case, patient’s delirium is most consistent with hepatic encephalopathy. However, if a clear etiology of delirium is not identified, brain MRI, EEG, and lumbar puncture should be considered. The patient does not have a history of alcoholism, but poor nutrition status can also cause thiamine deficiency. It usually takes days for the thiamine level to come back; therefore, if there is any suspicion of thiamine deficiency, go ahead and give the thiamine.

**HELPFUL TIP: HOURS TO DAYS**

Delirium has five key features as defined in the American Psychiatric Association’s *Diagnostic and Statistical Manual*, 5th edition (DSM-V):

1. Disturbance in attention
2. The disturbance develops over a short period of time (usually hours to days), represents a change from baseline, and tends to fluctuate during the course of the day
3. An additional disturbance in cognition
4. The disturbances are not better explained by another preexisting, evolving, or established neurocognitive disorder
5. There is evidence that the disturbance is caused by a medical condition, substance intoxication or withdrawal, or medication side effect

The bottom line is, if patient develops an acute or sub-acute change in cognition, you need to identify the underlying etiology, as the disease process is frequently reversible.

Brain CT is normal. The patient is admitted and his plasma ammonia level improves but remains elevated the next day. However, he continues to experience hallucinations. He is on

the waiting list for a liver transplant. He is evaluated by the liver transplant team. During the interview, the liver team learns that patient might have been having occasional hallucinations for the prior 6 months, although he never had any psychiatric issues before. It is also noted that patient has a long history of “acting out” dreams. He fell off the bed during sleep a couple times in the past 6 months. Patient scores 12/30 on a MOCA test (a test for cognitive impairment; it takes 10-15 minutes to administer, has a better sensitivity than does the Mini Mental Status and it is available for free at www.mocatest.org).

Liver team raises the concern of dementia with Lewy bodies.

Question 18.15.2 All of the following are core clinical features of *early* dementia with Lewy bodies EXCEPT:

- A) Fluctuating cognition with pronounced variations in attention and alertness
- B) Recurrent visual hallucinations that are typically well formed and detailed
- C) Cardinal features of parkinsonism: bradykinesia, resting tremor or rigidity
- D) REM sleep behavior disorder
- E) Profound memory loss

Answer 18.15.2 The correct answer is “E.” Profound memory loss is a hallmark feature of Alzheimer’s dementia. Patients with dementia with Lewy bodies usually have preserved memory *early on*. Dementia with Lewy bodies is the second leading cause of dementia but largely underdiagnosed clinically. The new diagnostic criteria from American Academy of Neurology in 2017 added REM sleep behavior disorder (RBD) as a core clinical feature, because studies have shown that up to 90% of patients with RBD will eventually develop synucleinopathies (including Parkinson disease, dementia with Lewy bodies, and multiple system atrophy [previously Shy-Drager]). RBD is a parasomnia and occurs when there is loss of atonia and patients “act out” their dreams including thrashing, kicking, and punching. Multiple system atrophy includes loss/attenuation of autonomic function, parkinsonism, cerebellar ataxia, pyramidal signs (increased lower extremity muscle tone, hyper-reflexia, positive Babinski, loss of fine motor skills), and urogenital dysfunctioning (though not all need be present... autonomic dysfunction is generally present, though). Fluctuating cognition, visual hallucination, and parkinsonism are all core clinical features of dementia with Lewy bodies. Neuroleptic sensitivity is no longer considered a core clinical feature of dementia with Lewy bodies.

HELPFUL TIP: SLEEP AND PSYCH

Dementia is a disorder that is characterized by a decline in cognition involving one or more cognitive domains (learning and memory, language, executive function, complex attention, perceptual-motor, social cognition). The deficits must represent a decline from previous

level of function and be severe enough to interfere with daily function and independence (DSM-5). Dementia patients are more vulnerable to delirium. Therefore, it is not uncommon to see patients with delirium superimposed on underlying dementia. Cognitive evaluations from a quick MOCA to a full neuropsychological test battery are important, but the results are unreliable during acute delirium. Another major part of dementia evaluation is to rule out reversible conditions like B12 deficiency, liver disease, syphilis (in high-risk patients only ... syphilis is making a comeback), or hypothyroidism. Don’t forget obstructive sleep apnea and depression as both can mimic dementia and worsen cognitive symptoms in dementia.

Given that dementia with Lewy bodies is a neurodegenerative disorder with no effective disease-modifying therapy, the liver transplant team is wondering whether they should keep your patient on the liver transplant list. You contact the neurology team for further evaluation.

Question 18.15.3 All of the following tests are helpful with further evaluation for Lewy body dementia EXCEPT:

- A) Brain MRI
- B) DaTscan
- C) Polysomnography
- D) Electromyography (EMG)

Answer 18.15.3 The correct answer is “D.” An EMG is not particularly helpful in the evaluation of dementia. Brain MRI (“A”) is important in the evaluation of dementia as it can show a pattern of atrophy that could guide your diagnosis. DaTscanning (“B”) is useful when evaluating nigrostriatal dopaminergic denervation such as is seen in Parkinson’s disease (see earlier section on Parkinson’s disease). A sleep study (“C”) should be done (evaluating RBD). The diagnostic criteria for dementia with Lewy Bodies were updated in 2017. Please see Table 18-7 for current diagnostic criteria.

A behavioral neurology specialist evaluates your patient. More history from family members indicates a steady decline of his performance in activities of daily living over the past year. Neurology suggests that the patient’s presentation is most consistent with hepatic encephalopathy. Neurology also indicates that underlying dementia with Lewy bodies is a possibility, but the diagnosis cannot be made given patient’s ongoing delirium.

► **Objectives: Did you learn to ...**

- Identify signs/symptoms suggestive of delirium?
- Initiate a diagnostic evaluation for etiology of delirium?
- Tell the difference between delirium and dementia?
- Initiate a dementia evaluation?
- Diagnose dementia with Lewy bodies?

TABLE 18-7 2017 DIAGNOSTIC CRITERIA FOR DEMENTIA WITH LEWY BODIES

Essential for a diagnosis of DLB is dementia, defined as a progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational functions, or with usual daily activities. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent and occur early.

Core clinical features (*The first three typically occur early and may persist throughout the course*)

Fluctuating cognition with pronounced variations in attention and alertness.

Recurrent visual hallucinations that are typically well formed and detailed.

REM sleep behavior disorder, *which may precede cognitive decline*.

One or more spontaneous cardinal features of parkinsonism: these are bradykinesia (defined as slowness or movement and decrement in amplitude or speed), rest tremor, or rigidity.

Supportive clinical features

Severe sensitivity to antipsychotic agents; postural instability; repeated falls; syncope or other transient episodes of unresponsiveness; severe autonomic dysfunction, e.g., constipation, orthostatic hypotension, urinary incontinence; hypersomnia; hyposmia; hallucinations in other modalities; systematized delusions; apathy, anxiety, and depression.

Indicative biomarkers

Reduced dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET.

Abnormal (low uptake) ¹²³Iodine-MIBG myocardial scintigraphy.

Polysomnographic confirmation of REM sleep without atonia.

Supportive biomarkers

Relative preservation of medial temporal lobe structures on CT/MRI scan.

Generalized low uptake on SPECT/PET perfusion/metabolism scan with reduced occipital activity ± the cingulate island sign on FDG-PET imaging.

Prominent posterior slow-wave activity on EEG with periodic fluctuations in the pre-alpha/theta range.

Probable DLB can be diagnosed if:

- Two or more core clinical features of DLB are present, with or without the presence of indicative biomarkers or
- Only one core clinical feature is present, but with one or more indicative biomarkers.

Probable DLB should not be diagnosed on the basis of biomarkers alone.

Possible DLB can be diagnosed if:

- Only one core clinical feature of DLB is present, with no indicative biomarker evidence, or
- One or more indicative biomarkers is present but there are no core clinical features.

(continued)

TABLE 18-7 2017 DIAGNOSTIC CRITERIA FOR DEMENTIA WITH LEWY BODIES (Continued)

DLB is less likely:

- In the presence of any other physical illness or brain disorder including cerebrovascular disease, sufficient to account in part or in total for the clinical picture, although these do not exclude a DLB diagnosis and may serve to indicate mixed or multiple pathologies contributing to the clinical presentation, or
- If parkinsonian features are the only core clinical feature and appear for the first time at a stage of severe dementia.

DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism. The term Parkinson disease dementia (PDD) should be used to describe dementia that occurs in the context of well-established Parkinson disease. In a practice setting the term that is most appropriate to the clinical situation should be used and generic terms such as Lewy body disease are often helpful. In research studies in which distinction needs to be made between DLB and PDD, the existing 1-year rule between the onset of dementia and parkinsonism continues to be recommended.

Source: Used with permission from McKeith IG, et al. *Neurology*. 2017;89(1):88–100.

Clinical Pearls

- Be sure to follow the inclusion and exclusion criteria for administering tPA for acute stroke. If in doubt, call your nearest stroke-accredited hospital for recommendations.
- For acute ischemic stroke, if you have any concern of a large vessel occlusion (such as, right gaze deviation with right MCA syndrome), call the closest neurological intervention team for recommendations on potential endovascular thrombectomy. Thrombectomy can be done after tPA is given. Drip and Ship!
- Do not aggressively treat elevated blood pressures in an acute ischemic stroke as it decreases cerebral perfusion and puts ischemic brain at risk for further injury.
- Do not perform neuroimaging in an individual with a history consistent with typical migraine headaches or simple syncope with a normal neurological examination and no evidence of head trauma.
- Do not screen asymptomatic patients for carotid artery disease.
- Enquire about sleep apnea signs and symptoms in all adults presenting with daytime somnolence and order a polysomnogram or nighttime oxygen desaturation test for evaluation if there is suspicion for sleep apnea.
- Perform a lumbar puncture to rule out subarachnoid hemorrhage even in the context of a negative head CT as a head CT only detects about 50% of warning leaks.
- Routine narcotics are not recommended for treatment of neuropathic pain or migraine headaches.
- Routinely recommend good sleep hygiene as first-line therapy for insomnia and fatigue.
- Start antibiotics early if you have a high suspicion for bacterial meningitis. This includes before the lumbar puncture if suspicion is high enough.
- Use of triptans in patients with coronary artery disease is contraindicated due to increased risk of coronary vasospasm.

Ophthalmology

Austin R. Fox

► GLOSSARY OF TERMS

Accommodation: Change in the shape of the lens to compensate for changes in focal length. The term may also be used to refer to the compensation of the eye to adjust to focusing on objects at different distances.

Amblyopia: Decreased monocular (or more rarely binocular) vision cortical in nature and not attributable to a structural abnormality of the eye or visual pathway. This may be a result of strabismus, high uncorrected refractive error, or visual deprivation during the critical period of cortical visual development during childhood.

Esotropia: Deviation of an eye/the eyes inward when compared with normal alignment.

Exotropia: Deviation of an eye/the eyes outward when compared with normal alignment.

Relative afferent pupillary defect (RAPD): A RAPD is detected when there is a relative difference in the initial pupillary response to a light stimulus between the two eyes. The “swinging flashlight test” done in a darkened room may be used to test for a RAPD; the initial pupillary response should be equal in both eyes. An eye with a RAPD will (abnormally) dilate with direct light to the eye but constrict normally in response to light shined in the fellow eye. **A patient may have poor vision but not a RAPD.** One will NOT get a RAPD from a refractive error, corneal disease, cataract, hyphema, or *isolated* vitreous hemorrhage. However, there will often be optic nerve or retinal pathology coexisting with a vitreous hemorrhage. So if there is an RAPD + vitreous hemorrhage, the nerve and retina need to be evaluated (generally by ophthalmology... though they should be seeing most all patients with a vitreous hemorrhage anyway). Go to <http://www.webcitation.org/74lKatwTk> for a really cool interactive animation.

Strabismus: A general term that refers to a misalignment of the eyes. Esotropia, exotropia, and hypertropia (one eye deviated upward) are all examples of strabismus. The term strabismus

says nothing about etiology, which can be congenital, neurologic, or muscular.

► CASE 19.1

A mother presents with her healthy, 2-month-old male infant. She reports that for the past week his eyes have been noticeably crossed. He appears to fixate with either the right or left eye. She feels that aside from being cross-eyed, he seems to see well. On examination, his eyes are very crossed, but he has full motility. When either eye is covered, he fixes and follows with the fellow eye and appears to have normal motility.

Question 19.1.1 The most likely diagnosis in this patient is:

- A) Pseudoesotropia
- B) Congenital esotropia
- C) Accommodative esotropia
- D) Sixth nerve palsy

Answer 19.1.1 The correct answer is “B.” Esotropia is more common than exotropia. Congenital esotropia is generally found in children younger than 6 months. “C,” accommodative esotropia, which occurs when the patient tries to “accommodate” (both eyes move inward for convergence to look at something close at hand) is the most common cause of esotropia in childhood and develops between age 6 months and 7 years. In accommodative esotropia the eyes do not converge equally when accommodating, giving an esotropia. It is rare for accommodative esotropia to develop before 4 months or after 8 years of age. Pseudoesotropia is common in infants due to their flat nasal bridges and medial epicanthal folds, giving an appearance of esotropia. A simple way to assess children for a true strabismus is to shine a penlight in their eyes and evaluate the corneal reflection of your light (Hirschberg test). The light reflex will be in the same location on the eye bilaterally for pseudoesotropia,

FIGURE 19-1 Congenital esotropia. Note the large deviation with abnormal corneal light reflexes. The corneal light reflex of the left eye appears more temporal than that of the right eye. Therefore, the left eye is deviated inward.

but reflect on different parts of the cornea or sclera with true esotropia or other forms of strabismus (see Fig. 19-1).

HELPFUL TIP:

It is important to differentiate an esotropia due to sixth nerve palsy. A sixth nerve palsy affects the lateral rectus muscle, and the patient will have limited abduction (moving away from nose) on the affected side. This is usually the first cranial nerve affected in patients with increased intracranial pressure. In adults, the most common etiology is vasculopathic, and in children, the most common etiology is trauma. Other causes may include increased intracranial pressure, viral illness, brain tumor, inflammation, or infection.

Question 19.1.2 Which of the following statements is FALSE?

- A) Congenital esotropia is nearly always present at birth
- B) Alternating fixation (e.g., the ability to fix on an object with either eye) is characteristic of congenital esotropia
- C) Patients with congenital esotropia generally have normal amounts of hyperopia (farsightedness) for their age
- D) Patients with a high degree of uncorrected hyperopia (farsightedness) can develop an accommodative esotropia

Answer 19.1.2 The correct answer (and the false statement) is “A.” Congenital esotropia presents by the age of 6 months but is rarely present at birth. If true esotropia is observed at birth, it may be due to another neurologic disorder, and further evaluation is indicated. Any form of strabismus may result in vision loss, and for this reason, it is important to treat strabismus early in life. The rest of the answers are true. As for option “B,” since patients have two eyes with equal vision, neither is preferred, so they will use both eyes to focus on objects (although not at the same time, of course!). Option “C” is true; patients with congenital esotropia do

FIGURE 19-2 Accommodative esotropia improves when vision is corrected. Adaptation for near vision consists of accommodation (change in lens shape), miosis (constriction of the pupil), and convergence. This can eventually lead to an accommodative esotropia, which can easily be corrected with glasses. With glasses, the patient no longer uses the near response of accommodation and convergence so that the eyes resume normal alignment.

have a normal degree of hyperopia for their age. “D” is also a true statement regarding accommodative esotropia (see Fig. 19-2).

Question 19.1.3 Which of the following is NOT an appropriate treatment for strabismus?

- A) Surgical correction if correction of refractive errors with full hyperopic spectacle does not resolve the strabismus
- B) Patching the strabismic (misaligned) eye
- C) Atropine drops or patching the non-strabismic eye *without* surgery
- D) Atropine drops or patching the non-strabismic eye *plus* surgery

Answer 19.1.3 The correct answer is “B.” The goal of the treatment of strabismus is to prevent amblyopia. Amblyopia is commonly caused by strabismus (ocular misalignment), significant uncorrected refractive error, or disorders that distort images from the eye to the brain (i.e., congenital cataracts). In amblyopia, the brain “turns off” or suppresses the vision in the affected eye. In addition to surgical treatment (realignment, removal of cataract, etc.), *amblyopia therapy and prevention is accomplished by blurring or impeding the vision in the unaffected (good) eye to strengthen the affected (bad) eye.* This can be done by physically patching the good eye (not the strabismic eye as noted in “B”) or by pharmacologic “patching” of the good eye using atropine drops if compliance with a patch is an issue (although eye patches remind kids of pirates, and pirates are cool—aargh, mate!). NOTE: Terms such as “bad eye” and “good eye” are frequently confusing, so strabismic or deviated eye often replaces “bad eye” as no eye is truly bad, but rather a product of its environment, and “good eye” is usually reserved as a popular greeting in Australia (just say it like Russell Crowe would!).

Question 19.1.4 In which of the following situations would neuroimaging be necessary?

- A) A 6-month-old with longstanding esotropia and equal visual acuity bilaterally
- B) A 5-year-old with recent onset esotropia *correctable by glasses*
- C) A 12-year-old with normal refraction and acute onset esotropia with diplopia
- D) A newborn with a unilateral congenital cataract and an esotropia

Answer 19.1.4 The correct answer is “C.” ANY unexplained new onset strabismus mandates an evaluation. A 12-year-old with acute esotropia, diplopia, and no evidence of hyperopia requires neuroimaging to rule out any underlying neurological disorder. The age of the patient is older than that seen with congenital, acquired, or accommodative esotropia. The refraction is normal, so this does not fit with accommodative esotropia. Diplopia also suggests acute onset. Further workup is therefore necessary. “A” is incorrect because this is a classic history for congenital esotropia. “B” is incorrect because it is consistent with accommodative esotropia. Fixing uncorrected refractive error would be the appropriate first step here. Note that farsightedness (hyperopia) is a much more common cause of accommodative esotropia than is nearsightedness (myopia). “D” is incorrect because we have reason for the esotropia—a congenital cataract is causing poor binocular fusion and coordination.

HELPFUL TIP:

Acute acquired strabismus **always** requires a rapid and complete evaluation. It can be due to trauma, vasculopathic factors, tumor, intracranial hemorrhage, botulism, lead poisoning, etc. Any child (or adult, for that matter) with new onset strabismus requires a full ophthalmologic examination.

► Objectives: Did you learn to ...

- Describe the nomenclature of strabismus?
- Determine the underlying causes of esotropia?
- Recognize some unusual cases of strabismus that require further workup?
- Describe the risk and treatment of amblyopia?

► CASE 19.2

A 50-year-old Asian female presents to the emergency department (ED) with severe nausea, vomiting, right eye pain, and blurry vision. She reports the symptoms began only a few hours earlier. She has no significant past medical history. On gross examination, her visual acuity is OD 20/200, her right eye is injected, and her right pupil is larger than her left. There does NOT appear to be a relative afferent pupillary defect (RAPD).

Question 19.2.1 With regard to this patient’s presentation, which of the following would NOT be considered in the differential diagnosis?

- A) Trauma secondary to blunt injury from a softball
- B) Central retinal artery occlusion
- C) Contact lens–associated bacterial keratitis
- D) Acute-angle closure glaucoma
- E) Anterior uveitis

Answer 19.2.1 The correct answer is “B.” Among these choices, central retinal artery occlusion would be painless and also associated with a RAPD (from diffuse retinal ischemia). All of the

FIGURE 19-3 Acute-angle closure glaucoma. Note the injection, hazy cornea, and mid-dilated pupil.

others will present with pain or irritation and **WITHOUT** a RAPD. “A,” blunt injuries, may result in decreased vision secondary to corneal abrasions or edema, intraocular inflammation, hyphema, or retinal injuries. Injury can also cause injection and a traumatic mydriasis (dilation of the pupil). Direct and consensual pupillary reflexes would be normal (no RAPD) unless there was an associated traumatic optic neuropathy or significant retinal damage. “D,” acute-angle closure glaucoma, would cause diffuse injection with a hazy cornea and mid-dilated pupil and no RAPD. “E,” anterior uveitis, would also cause injection and no RAPD. There is often asymmetry of the pupils in chronic anterior uveitis secondary to central posterior synechiae (adhesions between the iris and lens).

Question 19.2.2 Which of the following is *helpful* in order to diagnose acute-angle closure glaucoma?

- A) Slit lamp
- B) Tonometer
- C) Fluorescein and appropriate UV light
- D) Snellen eye chart
- E) A and B

Answer 19.2.2 The correct answer is “E.” An important examination technique used to diagnose acute glaucoma is intraocular pressure measurement, which could be achieved by Tonopen, Goldmann applanation tonometry at the slit lamp, assessed via digital palpation (a gross measure at best. If the eye is rock-hard, there is a problem), etc. A slit lamp is useful for diagnosing acute-angle closure, and one may see a closed angle, corneal edema, conjunctival injection, and a mid-dilated pupil (see Fig. 19-3). “C,” fluorescein, is used to diagnose corneal injuries (de-epithelized cornea will take up fluorescein). “D,” a Snellen eye chart, is used to determine visual acuity but is not necessary for diagnosing glaucoma. It is always a good idea to check vision in each eye in every patient with eye complaints; think of checking visual acuity as taking a “vital sign” (“vital signs” of the eye include visual acuity, intraocular pressure, pupil examination).

Question 19.2.3 Which of the following is NOT a risk factor for acute-angle closure glaucoma?

- A) Hyperopia (farsightedness)
- B) Asian descent
- C) Male gender
- D) Pharmacologic dilation
- E) Advanced cataract

Answer 19.2.3 The correct answer is “C.” Associated risk factors for acute-angle closure glaucoma are hyperopia, Asian ancestry, *female* gender, and older age. Patients with hyperopia have smaller eyes and more shallow anterior chambers. Females and people of Asian descent also tend to have smaller eyes. As people age, cataracts may develop, become thicker, and crowd the anterior chamber, increasing the likelihood of developing pupillary block leading to glaucoma. A dimly illuminated environment, which leads to physiologic dilation, may precipitate attacks of acute-angle closure. Think of an older Asian female developing eye pain, blurry vision, nausea, and vomiting after sitting in a dark theater... it could be that she ate too much delicious buttery popcorn, but it is more likely acute-angle closure. Of note, medications, such as topical adrenergics or anticholinergics, sulfa medications, or oral topiramate may also precipitate attacks of acute-angle closure.

**HELPFUL TIP:**

Pharmacologic dilation may result in an attack of acute-angle closure glaucoma. But where better a place for it to show up than in your office or the ED? Neovascularization of the eye (such as from diabetes or retinal hypoxia) can lead to “neovascular glaucoma” from neovascularization of the iris and angle. Hyphema can cause glaucoma from a clot obstructing the outflow of aqueous humor.

Question 19.2.4 Which of the following is NOT a presentation of acute closed-angle glaucoma?

- A) Headache
- B) Abdominal pain
- C) Vomiting
- D) Limitation of extraocular motion
- E) Halos around light

Answer 19.2.4 The correct answer is “D.” Patients with acute closed-angle glaucoma can present with all of the above findings except for the limitation of extraocular motion. Severe eye pain and blurred vision are commonly noted due to corneal edema and clouding secondary to the increased intraocular pressure. “B” and “C” deserve special mention. A sudden increase in intraocular pressure and angle closure can cause abdominal symptoms including pain and nausea and vomiting. Remember your review of systems? Ask about the eye with abdominal pain in order to not miss this potential sign of eye pathology.

You call your local ophthalmologist or optometrist to see this patient with suspected acute-angle glaucoma. She is going to be delayed because of traffic—it’s Iowa, so she’s likely stuck

behind a big tractor ... we don’t have “rush hour,” only “rush minute.”

Question 19.2.5 Which of the following drugs is NOT appropriate to use as a temporizing measure?

- A) Topical carbonic anhydrase inhibitors
- B) Topical β -blockers
- C) Topical glycerin
- D) Topical atropine drops
- E) Topical prostaglandin analog drops

Answer 19.2.5 The correct answer is “D.” Atropine is **contraindicated** in acute glaucoma, since it will dilate the eye, exacerbating the problem. Topical β -blockers (“B”) and topical (“A”) or oral carbonic anhydrase inhibitors (e.g., acetazolamide) reduce aqueous production and thereby reduce intraocular pressure. In addition to the medications noted above, a topical α -adrenergic agonist (e.g., brimonidine, apraclonidine) lowers eye pressure by selectively affecting the α -2 receptors decreasing aqueous production and increasing aqueous outflow. Prostaglandin analogs (“E,” e.g., latanoprost) increase aqueous outflow decreasing intraocular pressure. One suggested regimen includes: timolol 0.5%, apraclonidine 1%, and pilocarpine 2%, one drop of each 1 minute apart followed by IV acetazolamide.

**HELPFUL TIP:**

In general, eye drops that dilate the eye have a red cap on them, so if you are in a panic and you’ve forgotten all the good advice from this awesome book, a good rule of thumb is to NOT to **use any eye drop WITH a red cap for glaucoma**. See Table 19-1 for details on glaucoma medications.

TABLE 19-1 DRUGS USED FOR ACUTE GLAUCOMA AND HOW THEY WORK

Drug	Mechanism of Action
Topical β -blockers (e.g., timolol)	Decreases aqueous humor production
Topical α -adrenergic agonists (e.g., brimonidine)	Decreases aqueous humor production
Prostaglandin analogs (e.g., latanoprost, bimatoprost, travoprost)	Increases aqueous humor outflow through uveoscleral channels
Topical carbonic anhydrase inhibitors (e.g., dorzolamide, brinzolamide)	Decreases aqueous humor production
Oral carbonic anhydrase inhibitor (e.g., acetazolamide)	Diuretic and, more importantly, decreases the production of aqueous humor
Mannitol (rarely used now for acute glaucoma, mostly OR cases only)	Osmotic diuretic draws aqueous humor from the eye

**HELPFUL TIP:**

If the cornea is edematous and cloudy due to the elevated intraocular pressure, topical agents will less effectively penetrate the eye and will be less effective in the reduction of intraocular pressure. In such a case, systemic medications will be indicated. If using acetazolamide, renal function should be tested prior to administration.

An ophthalmologist makes it to the hospital and recommends surgery.

Question 19.2.6 What is the definitive *treatment of choice* for acute-angle closure glaucoma?

- A) Laser peripheral iridotomy
- B) Tapping of the anterior chamber to lower intraocular pressure
- C) Aqueous suppressant therapy
- D) Surgical iridectomy
- E) Chiropractic manipulation

Answer 19.2.6 The correct answer is “A.” The treatment goal is to allow the free flow of aqueous so that it does not accumulate behind the iris to push it forward to obstruct the trabecular meshwork. A laser peripheral iridotomy creates a small hole in the peripheral iris that allows aqueous flow to improve and thereby decreases intraocular pressure. As long as this hole remains patent, the patient is no longer at risk for an attack of angle closure glaucoma, and it is unusual for the hole to close unless there is a history of intraocular inflammation. “B,” tapping the anterior chamber, can be used before laser therapy in order to clear the cornea so that visualization is better for the procedure. However, this is controversial and not the definitive treatment of choice. “C,” aqueous suppressant therapy, is discussed in the previous question. “D,” a surgical iridectomy, is performed for patients who are unable to sit still for the laser procedure (i.e., children, intellectually disabled). As to “E,” this might not be the right choice at this time.

Question 19.2.7 Which is FALSE regarding closed- and open-angle glaucoma?

- A) The main difference is that the drainage angle (trabecular meshwork) is closed in angle closure glaucoma and open in open-angle glaucoma
- B) Scopolamine and other agents with anticholinergic properties are contraindicated in open-angle glaucoma but not in closed angle
- C) Acute-angle closure glaucoma usually occurs in hyperopic individuals while myopia is associated with open-angle glaucoma
- D) The majority of people diagnosed with glaucoma have primary open-angle glaucoma

Answer 19.2.7 The correct answer (and false statement) is “B.” Agents with anticholinergic properties, which would cause dilation of the pupil, are actually **contraindicated** in those with

closed-angle glaucoma (and those with **narrow** angles who may not yet have obstructed). Once peripheral iridotomy is performed, anticholinergics are no longer an issue, since the patient is no longer at risk. All of the rest of the statements are correct.

Question 19.2.8 Which of the following does NOT increase a patient’s risk for primary open-angle glaucoma?

- A) Family history
- B) Caucasian race
- C) Elevated intraocular pressure (>21 mm Hg)
- D) Age >40

Answer 19.2.8 The correct answer is “B.” Patients of African heritage are much more likely to develop open-angle glaucoma than are Caucasians and are also more likely to suffer vision loss from glaucoma. Family history, high intraocular pressures, and thin corneas are all risk factors for the development of open-angle glaucoma. High intraocular pressures lead to optic nerve damage. Minor risk factors include diabetes and myopia (near-sightedness). All patients should be screened for glaucoma as part of their routine eye examination. This is usually done by assessing intraocular pressure, examining the optic nerve and corneal thickness, and performing any ancillary diagnostic tests such as visual field analysis.

Question 19.2.9 Which of the following is typical of early open-angle glaucoma?

- A) Central vision loss
- B) Peripheral vision loss
- C) Lack of symptoms
- D) Decreased contrast
- E) Blurring of vision

Answer 19.2.9 The correct answer is “C.” Most people with early open-angle glaucoma are asymptomatic. This is why screening is important. A significant number of the approximately one million axons of the optic nerve may be damaged before it manifests itself as visual field loss. Screening by examination of the optic nerve for abnormalities is the best way to diagnose *early glaucoma* (as opposed to increased ocular pressure which may result in optic nerve damage and thus glaucoma). Later symptoms involve loss of peripheral or central vision.

Question 19.2.10 Which of the following is necessary to diagnose a patient with open-angle glaucoma?

- A) Optic nerve head cupping or irregularity with corresponding visual field loss
- B) Thin corneas
- C) Elevated intraocular pressure
- D) Narrow but open drainage angle

Answer 19.2.10 The correct answer is “A.” Cupping of the optic nerve head is caused by thinning of the neural rim. There should be a corresponding visual field defect consistent with the appearance of optic nerve cupping in a patient with glaucoma.

FIGURE 19-4 Normal optic nerve.

Note that **elevated intraocular pressure is not diagnostic of open-angle glaucoma**. Elevated intraocular pressure by itself is considered a risk factor for glaucoma and is the only modifiable risk factor to date. When **not** accompanied by cupping or visual field loss, it is considered ocular hypertension. Patients with ocular hypertension still need to be monitored and treated to prevent the development of open-angle glaucoma. Conversely, some patients with glaucoma never develop high intraocular pressure, indicating that glaucoma may, in fact, be due to optic nerve damage arising from a variety of etiologies. Thinner corneas (“B”) increase the risk of glaucoma but are not required for diagnosis. “D” is incorrect. The drainage angle must be widely open—thus the name “open-angle glaucoma.”

Question 19.2.11 Which of the following statements regarding glaucoma is true?

- A) If treated early enough, normalizing the intraocular pressure can reverse the process of glaucoma and restore sight
- B) The fundusoscopic examination in patients with glaucoma will generally show small retinal hemorrhages in addition to optic nerve cupping
- C) Papilledema is seen with glaucoma as a result of increased pressure on the optic nerve
- D) There are no identified genetic markers that correlate to development of glaucoma
- E) None of the above

Answer 19.2.11 The correct answer is “E.” So, wrong, wrong, wrong... and wrong. Once there is visual loss, it cannot be restored (“A”). *Optic nerve hemorrhages*, and not retinal hemorrhages, are seen in glaucoma (“B”). Retinal hemorrhages can typically be seen with diabetic or hypertensive retinopathies. Papilledema results from increased **intracranial**—not intraocular—pressure (“C”). There are multiple genes that have been identified that contribute to the development of glaucoma (“D”). See Figure 19-4 for images of normal-appearing optic nerves, and compare these with Figure 19-5, which shows optic nerve findings in patients with glaucoma.

FIGURE 19-5 Glaucomatous optic nerve. Observe the cupping of the optic nerve head. The cup (central depression, seen as the bright part of the disc) of the optic nerve, which represents the axons diving down into the optic nerve, is larger compared with normal. A cup >50% of the disc width may be suggestive of glaucoma. Cupping represents damage to the optic nerve and fewer axons are present.

► **Objectives: Did you learn to ...**

- Recognize the signs and symptoms of acute-angle closure glaucoma?
- Identify risk factors associated with acute-angle closure glaucoma?
- Describe the pathology and basis for treatment for glaucoma?
- Differentiate between angle closure and open-angle glaucoma?
- Describe optic nerve findings in glaucoma?

QUICK QUIZ: GLAUCOMA AGENTS

Topical β -blockers lower intraocular pressure by decreasing aqueous production.

Which of the following is NOT considered a systemic side effect of these medications?

- A) Bronchospasm
- B) Bradycardia
- C) Worsening of congestive heart failure
- D) Increased low-density lipoprotein (LDL)

The correct answer is “D.” β -Blockers do not increase LDL. The take-home message here is that **topical β -blockers can have systemic effects including effects on congestive heart failure, bradycardia, or airway disease such as asthma or COPD**. Be aware of this, especially in the elderly.

QUICK QUIZ: VISION LOSS

A 70-year-old white female presents with sudden loss of the upper half of her vision in the left eye. *She reports no pain*. Her past medical history is significant for hypertension and type 2 diabetes.

Which of the following is the **LEAST** likely diagnosis given this history?

- A) Retinal detachment
- B) Branch retinal artery/vein occlusion
- C) Optic neuritis
- D) Anterior ischemic optic neuropathy

The correct answer is “C.” Retinal detachment, branch retinal artery/vein occlusion, and anterior ischemic optic neuropathy all cause **painless** sectorial loss of vision in this age group. Optic neuritis usually occurs in a younger age group and is associated **with pain**, especially with eye movement, color vision changes, and central, cecentral, altitudinal, or arcuate scotomas (blind spots).

HELPFUL TIP:

Many patients complain of pain when they move their eyes. Diagnoses to consider include optic neuritis, intra-orbital infection/inflammation, sinusitis, and orbital myositis of multiple etiologies such as orbital cellulitis, thyroid eye disease, orbital pseudotumor, sarcoidosis, polyarteritis nodosum, systemic lupus erythematosus, dermatomyositis, rheumatoid arthritis, and Wegener granulomatosis (now known as granulomatosis with polyangiitis).

which may become bilateral. As far as risk factors, think of NA-AION risk factors as being equivalent to those of peripheral vascular disease. It is associated with atherosclerosis, hypertension, hyperlipidemia, diabetes, anemia, and sleep apnea. Males and females are equally affected. While the age of patients with NA-AION overlaps with that of patients with giant cell arteritis, the patients with NA-AION tend to be younger. On exam, there may be an afferent pupillary defect, decreased visual acuity, or a visual field defect. There may be a pale disc with swelling, which is often segmental, and disc hemorrhages. In the contralateral eye, there may be a crowded disc with an absent cup (also known as a “disc at risk”), which has also been associated with NA-AION.

HELPFUL TIP:

Surgical intervention for NA-AION is not helpful and may lead to worsening blindness. In fact, there is no known effective therapy. Treatment of risk factors is paramount. Phosphodiesterase-5 inhibitors (e.g., sildenafil), which are often used for erectile dysfunction, can cause hypotension and may be associated with NA-AION, so though it may be a sensitive subject, do not shy away from asking about the use of such medications and advise against their use for patients at risk for NA-AION.

QUICK QUIZ: ANTERIOR ISCHEMIC OPTIC NEUROPATHY

Ischemic optic neuropathy is the most common cause of optic nerve pathology causing visual loss in patients older than 50 years. It is referred to as “anterior” when it affects the optic nerve head. It generally results from ischemia of the optic disc (sort of makes sense since it is called “anterior *ischemic* optic neuropathy”).

Which of the following is **CORRECT** regarding nonarteritic (not related to temporal arteritis) anterior ischemic optic neuropathy (NA-AION)?

- A) It is not associated with diabetes
- B) Women are affected five times as often as men
- C) As with giant cell arteritis, it responds quickly and dramatically to systemic corticosteroids
- D) Avoiding nocturnal hypotension is an important aspect of treatment

The correct answer is “D.” It is important to **avoid** nocturnal hypotension. In higher risk patients, it should be recommended to avoid anti-hypertensive administration at bedtime.

Midodrine can be used to support the blood pressure at night. The remaining statements are incorrect. NA-AION usually presents as painless, sudden unilateral vision loss,

▶ CASE 19.3

A 65-year-old white male complains of “seeing wavy lines” when looking at the doorway with his right eye. He has no pain or other ocular symptoms. His past medical history is significant only for hypertension. He has a 40-pack-year smoking history. On examination, his visual acuity is 20/400 in the right eye. He has no RAPD and slit-lamp examination reveals that his anterior segment is normal. Examination of his right fundus reveals a subretinal hemorrhage involving his fovea.

Question 19.3.1 Which of the following is the most likely cause of this patient’s vision loss?

- A) Age-related macular degeneration (AMD)
- B) Acute-angle closure glaucoma
- C) Cataract
- D) Diabetic retinopathy
- E) Malingering

Answer 19.3.1 The correct answer is “A.” This is a typical presentation for AMD (continue to the next question for more information). “B” is incorrect because acute-angle closure glaucoma presents with pain. “C” is incorrect since cataracts cause slowly progressive vision loss. “D” is incorrect as the patient has no known history of diabetes. Save “E” for the psychiatry chapter.

Question 19.3.2 Which of the following statements is FALSE?

- A) AMD is the leading cause of vision loss in persons older than 60 years in the United States
- B) Smoking has been shown to be a risk factor in the development of wet AMD
- C) AMD is less common in Caucasians when compared with other populations
- D) The Age-Related Eye Disease Study Part 2 (AREDS2) has shown a beneficial effect of vitamin E, vitamin C, lutein, zeaxanthin, zinc, and copper in delaying the progression to advanced AMD
- E) A common complaint of wet AMD is metamorphopsia, which is distortion or waviness centrally in the visual field

Answer 19.3.2 The correct answer is “C.” AMD occurs more commonly in Caucasian populations. “A” is correct as AMD is the leading cause of vision loss, primarily central vision, in patients older than 60 years. “B” is correct. Smoking is a significant risk factor in the progression to wet AMD; therefore, smoking cessation is highly recommended in any individual with early AMD findings or with a family history of AMD (and anyone, really). As to “D,” the listed micronutrients are beneficial in delaying the progression from dry to wet AMD according to the AREDS2 results. “E” is also correct. Patients with AMD complain of distortion and/or waviness in the central visual field.

**HELPFUL TIP:**

Dry AMD is the non-neovascular form of AMD. It is characterized by drusen (yellow-white lesions in the outer retinal layers of the macula) or atrophy within the macula. Dry AMD may lead to wet (neovascular) AMD, which is associated with a choroidal neovascular membrane (CNVM). The CNVM is an abnormal growth of subretinal blood vessels, which grow in the macula or fovea and affects vision due to fluid leakage.

**HELPFUL (BUT UNFORTUNATE) TIP:**

Micronutrients (AREDS2 vitamins) for the general population do not seem to prevent the development of AMD. However, they do seem to work to prevent progression to advanced AMD once the patient has early AMD.

**HELPFUL TIP:**

The primary treatment of wet AMD is intravitreal injection of vascular endothelial growth factor inhibitor (VEGF inhibitor) medications (e.g., bevacizumab, ranibizumab, or aflibercept). You may remember “photodynamic therapy,” the injection of verteporfin (a photoactive dye) followed by laser treatment to occlude the neovascular vessels. This has fallen out of favor with VEGF inhibitors being the first-line

treatment. Early detection of wet AMD and initiation of treatment with a VEGF inhibitor increases the likelihood of obtaining the best results. To help with early detection, patients with early AMD may monitor for metamorphopsia at home with an Amsler grid. In addition, all patients should be encouraged to cease smoking.

► Objectives: Did you learn to ...

- Recognize the signs and symptoms of AMD?
- Differentiate between dry and wet AMD?
- Recognize treatment modalities for wet AMD?

► CASE 19.4

A 55-year-old white male with a history of newly diagnosed type 2 diabetes mellitus presents for routine evaluation. He has no complaints, including vision. On non-dilated direct ophthalmoscopic examination, both fundi appear to be normal.

Question 19.4.1 When should this patient be referred for formal ophthalmologic examination?

- A) At the time of diagnosis
- B) Within 3 months
- C) Within 6 months
- D) Within 1 year
- E) When he develops visual symptoms, maybe 2 days before he goes blind

Answer 19.4.1 The correct answer is “A.” Patient with type 2 diabetes should be referred for a dilated examination immediately upon diagnosis, since they may have been undiagnosed for a long time period and may already have a degree of retinopathy. For type 1 diabetic patients, the recommendation is to refer within 3 to 5 years of disease onset and that they be evaluated annually thereafter.

Question 19.4.2 What are the common findings seen on direct ophthalmoscopic examination in nonproliferative diabetic retinopathy?

- A) Exudates
- B) Cotton wool spots
- C) Dot-blot hemorrhages
- D) Microaneurysms
- E) All of the above

Answer 19.4.2 The correct answer is “E.” Direct ophthalmoscopic examination may reveal all these findings in nonproliferative diabetic retinopathy. These are caused by the increased fragility of capillaries and arterioles of the retina with diabetes. While hemorrhages and microaneurysms appear red, exudates and cotton-wool spots are white and fluffy in appearance.

Question 19.4.3 What is the main cause of vision loss in *nonproliferative* diabetic retinopathy?

- A) Dot-blot hemorrhages
- B) Macular edema
- C) Cataract
- D) Neovascularization

Answer 19.4.3 The correct answer is “B.” Nonproliferative diabetic retinopathy by definition has no neovascularization (new, fragile blood vessel growth secondary to microvascular disease). The main source of decreased vision is macular edema. Treatment of focal non-center-involving macular edema consists of focal laser photocoagulation to leaking microaneurysms. VEGF-inhibitor intravitreal injections (e.g., bevacizumab, ranibizumab, or aflibercept) may also be used to treat diabetic macular edema.

Question 19.4.4 What is the main cause of vision loss in *proliferative* diabetic retinopathy?

- A) Cataract
- B) Macular edema
- C) Vitreous hemorrhage
- D) Neovascular glaucoma

Answer 19.4.4 The correct answer is “C.” Vision loss in proliferative diabetic retinopathy occurs when friable neovascular vessels break open and bleed (vitreous hemorrhage). Vision loss can also occur if the neovascular vessels grow over the drainage angle of the eye, causing neovascular glaucoma, although this is far less common than vitreous hemorrhage. See Figure 19-6 for an image of neovascularization.

The treatment of proliferative diabetic retinopathy consists of panretinal photocoagulation, which involves lasering the peripheral retina, thereby decreasing the ischemic drive for neovascularization. Treatment of vitreous hemorrhage includes observation with the head of bed elevated until the hemorrhage settles out and clears enough for laser treatment. Vitreous hemorrhages may be caused by other things, such as retinal detachments, so ultrasound is usually performed acutely, since

one will not be able to adequately examine the retina after a significant hemorrhage.

HELPFUL TIP:

Aspirin is safe in patients with neovascularization. The risk of bleeding does not increase significantly, and the cardiovascular benefit outweighs the risk of bleeding in the eye.

► **Objectives: Did you learn to ...**

- Identify when to refer patients for formal ophthalmologic examination in type 1 and type 2 diabetes?
- Recognize the signs of diabetic retinopathy on direct ophthalmoscopic examination?
- Understand the causes of vision loss in those with nonproliferative and proliferative diabetic retinopathy?
- Describe the basis for treatment of both nonproliferative and proliferative diabetic retinopathy?

► **CASE 19.5**

A 20-year-old male presents to the ED, complaining of a “bloody eye.” He was in a fight earlier in the evening and was hit in the eye (“... but you should see the other guy!” ... and with your luck, you probably will). You examine him and discover the findings in Figure 19-7. His visual acuity in the affected eye is hand motions only. He also has moderate edema of the lids but is able to open his eyes. On slit-lamp examination, the pupil appears normal. His motility is full and there is no diplopia.

Question 19.5.1 What is the single *most* important first step in evaluation of this patient?

- A) Detection of a RAPD
- B) Patching until the heme clears
- C) Evaluation for possible open globe
- D) Immediate CT scanning to evaluate for an orbital fracture
- E) Surgical anterior chamber washout of the heme

FIGURE 19-6 Proliferative diabetic retinopathy. Neovascularization of the optic nerve.

FIGURE 19-7 Traumatic hyphema. Blood settles into the inferior anterior chamber.

Answer 19.5.1 The correct answer is “C.” This is a hyphema, with blood filling about one-third of the anterior chamber in Figure 19-7. More important is the history of trauma. The first, and most important, step in ocular trauma is to look for evidence of an open or ruptured globe. **There should be no pressure placed on the eye until an open globe is ruled out.** Signs of ruptured globe would be 360 degrees of subconjunctival hemorrhage, a shallow anterior chamber, an irregular or “peaked” pupil, or low intraocular pressure. *However, a normal globe pressure does not rule out a ruptured globe.* The leak may be small or may be plugged with choroid. **NOTE: Intraocular pressure measurements should not be taken until an open globe is ruled out. If there is any doubt about whether there is an open globe, consult an ophthalmologist or optometrist.** “D” is incorrect and deserves special mention: CT is not sensitive enough to rule out an open globe, even with thin cuts through the globe.

**HELPFUL TIP:**

When evaluating for a ruptured globe, remember that the most common areas of rupture are the limbus (the margin of the cornea where it meets the sclera) and sclera behind the insertion of rectus muscles. This is where the sclera is thinnest.

**HELPFUL TIP:**

A “Seidel test” can be used to look for an open globe. A moistened fluorescein strip is gently placed at the site of injury. Slit-lamp examination is done with Cobalt blue light. If a rupture is present, the fluorescein dye will be diluted by the aqueous, which will appear as a dark stream through the green fluorescein.

Question 19.5.2 Which is NOT a complication of hyphema (bleeding into the anterior chamber)?

- A) Corneal blood staining
- B) Glaucoma
- C) Rebleeding
- D) Iris neovascularization

Answer 19.5.2 The correct answer is “D.” Complications of hyphema include rebleeding, which is most common in the first 3 to 5 days after injury. The hyphema may also stain the corneal endothelium, which may take months to clear. Glaucoma may also occur because of clogging of the trabecular meshwork by red blood cells, leading to a rise in intraocular pressure. “D,” iris neovascularization, which may be present in a diabetic patient, may be present in a patient with hyphema but is not a complication of hyphema.

You rule out ruptured globe and orbital fracture. He’s seen by the ophthalmologist on call who recommends treatment.

Question 19.5.3 Which of the following is the most appropriate treatment for this patient?

- A) Treat at home with bed rest and a cycloplegic agent
- B) Hospital admission and IV steroids
- C) Hospital admission and IV antibiotics
- D) Hospital admission and topical antibiotics
- E) Treat at home with topical antibiotics

Answer 19.5.3 The correct answer is “A.” This patient has a hyphema, which is blood in the anterior chamber, usually due to direct trauma. The goal of treatment is to prevent further bleeding into the anterior chamber and allow the blood to settle and resorb. While the party line in the past was that all of these patients require admission, sending a patient home with instructions for strict bed rest and avoiding strenuous activity is sufficient in **reliable** patients with limited disease. However, **an ophthalmologist or optometrist should be involved in this decision.** In addition, a cycloplegic agent, such as cyclopentolate or atropine, may be used to induce paralysis of the ciliary muscle and reduce movement of the iris. Patients should avoid antiplatelet or anticoagulant medications unless medically necessary. Topical steroids can be used if there are any signs of iritis, in which patients complain of an “eye ache” or photophobia or when inflammation with white blood cells or protein is present in the anterior chamber. You should check intraocular pressure and treat increased intraocular pressure if needed.

**HELPFUL TIP:**

If an African-American patient presents with a hyphema, one should inquire about sickle cell disease or trait, as ocular hypertension in patients with sickle cell disease is treated more aggressively and multiple agents *used to treat ocular hypertension* may induce sickling.

OK. Time for a joke. What is the definition of a double-blind study? Two orthopedic surgeons reading an electrocardiogram.

► **Objectives: Did you learn to ...**

- Recognize the complications of ocular trauma?
- Examine a patient at risk for open globe?
- Identify the complications of hyphema?
- Initiate management of a patient with hyphema?

► **CASE 19.6**

A 27-year-old male presents with irritation and redness of his right eye after hammering on an old iron fence. He was not wearing safety glasses at the time (they aren’t very cool looking, and he was hoping his attractive neighbor would see his big muscles!). He’s now 4 hours out from his injury. On examination, his visual acuity is 20/200. His right eye is injected, and his pupil is irregularly peaked to one side upon gross inspection. Slit-lamp examination reveals a laceration

of his cornea extending to the limbus with a wick of iris occluding the laceration site. You place a Fox shield on the eye to prevent any pressure on the globe, update the patient's tetanus vaccine, and start antibiotics.

Question 19.6.1 What would be the next step in the evaluation and treatment of this patient?

- A) Imaging for an intraocular foreign body by orbital CT scanning
- B) Evaluation for an intraocular foreign body by orbital ultrasound
- C) Try to remove the foreign body from the posterior chamber with a magnet
- D) Complete ocular examination, including intraocular pressure and dilated fundus examination

Answer 19.6.1 The correct answer is "A." Given his history, the patient needs to be evaluated for a possible intraocular foreign body. The best imaging modality is with orbital CT scanning. Orbital ultrasound ("B") would also be appropriate, but for surgical planning, CT scanning is preferred. Plus we do not want to put pressure on the eye with an open globe. "C" is incorrect because it is likely to cause more damage. This type of foreign-body removal is best left to a specialist in the operating room. Finally, it would be best to defer intraocular pressure measurements until the extent of the laceration is evaluated since no pressure should ever be placed on a potential open globe.

The patient undergoes an orbital CT. There appears to be a piece of metal within his vitreous cavity.

Question 19.6.2 Which of the following are inert intraocular foreign bodies?

- A) Iron
- B) Copper
- C) Glass
- D) Aluminum
- E) C and D

Answer 19.6.2 The correct answer is "C." Iron, copper, and aluminum are all reactive species and **must** be removed from the eye. Glass is inert and may be left in place, depending on the situation and the risk of surgery.

Question 19.6.3 Which is NOT a sign of a retained iron intraocular foreign body?

- A) Iris heterochromia
- B) Mydriasis
- C) Glaucoma
- D) Retinal degeneration
- E) High refractive error

Answer 19.6.3 The correct answer is "E," also known as severe myopia or nearsightedness, which has nothing to do with the retained iron foreign body. Although, the patient in this case

may have been *extremely nearsighted, metaphorically speaking*, in his decision to not wear safety glasses. All of the rest are signs of siderosis caused by a retained iron intraocular foreign body. Given the toxicity to the eye, the foreign body must be removed surgically.

HELPFUL TIP:

Corneal foreign bodies may be removed using a needle after the administration of topical anesthetic. Metallic foreign bodies in the cornea may leave a rust ring around the area of the foreign body, which can be removed using an ocular burr or an Alger brush. The rust ring may also be left in place if it is out of the visual axis since it does not cause any long-lasting problems.

► **Objectives: Did you learn to ...**

- Recognize the signs of a corneoscleral laceration?
- Manage a corneoscleral laceration in the emergency setting?
- Appreciate the effects of intraocular foreign bodies?
- Manage an intraocular foreign body in the emergency setting?

► **CASE 19.7**

A 55-year-old farmer presents to the ED complaining of ocular pain and irritation. He reports accidentally splashing ammonia in both eyes. (This is commonly due to cooking methamphetamine or farmers legitimately using ammonia as a fertilizer [both popular pastimes in Iowa].) He attempted to rinse his eyes with water prior to coming to the ED. His visual acuity is OD 20/100 and OS 20/80. Both eyes are injected with corneal edema.

Question 19.7.1 What is the immediate first step in the treatment of chemical injuries to the eye?

- A) Complete ocular examination, including dilated fundus examination
- B) Manual removal of particulate material followed immediately by irrigation with water or saline until the pH is 7
- C) Application of topical glycerin to clear the corneal edema
- D) Topical anesthetic with debridement of surface epithelium
- E) Build rapport by making small talk, asking about his tractor, etc.

Answer 19.7.1 The correct answer is "B." Step one: Immediately irrigate! Remove any particulate matter. The upper lid should be everted to check for any particulate matter. A moistened cotton swab may be used to sweep the superior and inferior fornices to remove any residual debris. Irrigation is extremely important and should be completed **before** the examination. Irrigation may be performed at an eyewash station, administered through IV tubing with an irrigation lens (Morgan Lens), or administered through pouring water or saline on the eyes. We have even had patients irrigate at the scene with beer (really...). To check

the pH, wait 5 minutes after discontinuing irrigation and use a pH strip in the superior or inferior fornix. Irrigation can be discontinued when you reach a neutral (7–7.4), but it may require multiple liters of irrigation. (To determine the correct pH, it can be helpful to compare patient's pH paper to pH paper used on a normal eye. Your eye!) A topical anesthesia can be applied to alleviate pain. After neutralizing the pH, you can complete the examination.

**HELPFUL TIP:**

Never try to treat an alkali burn with an acid or an acid burn with a base!

Question 19.7.2 Which of the following is a complication of chemical injuries to the eye?

- A) Corneal ulceration
- B) Inflammation
- C) De-epithelialization of the cornea
- D) All of the above
- E) None of the above

Answer 19.7.2 The correct answer is “D.” All of these are complications of chemical injuries to the eye. If you chose “E,” you should take a break now! You are tired.

**HELPFUL TIP:**

Alkali burns tend to be more severe than acid burns. Alkali burns cause ocular surface damage by saponifying fatty acids in cell membranes. Alkaline agents readily penetrate the cornea causing degradation. Acids cause protein denaturation, which creates a barrier to penetration. Therefore, acids cause less tissue destruction. Nerve destruction may cause a decrease in sensitivity to the eye, so absence of pain is not adequate to determine whether further irrigation is needed. **Check the pH as noted above.**

► Objectives: Did you learn to ...

- Describe the difference between acid and alkali injuries to the eye?
- Treat a chemical eye exposure in the emergency setting?
- Recognize the complications of chemical eye injuries?

► CASE 19.8

A 25-year-old college student complains of redness, sensitivity to light, and tearing of her right eye for the past day. She lives in the dorm but reports no exposure to others with a red eye. For the past few days, she has had a sore throat and slight cough. You suspect she may have the dreaded “pink eye” (conjunctivitis).

Question 19.8.1 Regarding conjunctivitis, which of the following is FALSE?

- A) Gonococcal conjunctivitis presents with severe, hyperacute, purulent discharge
- B) Adenoviral conjunctivitis generally begins in one eye and spreads to the other eye
- C) An enlarged preauricular node is a sign of allergic conjunctivitis
- D) Toxic conjunctivitis has been associated with the use of topical antibiotics, antivirals, and preservatives

Answer 19.8.1 The correct answer (and FALSE one) is “C.”

There is no enlargement of preauricular nodes with allergic conjunctivitis. **An enlarged preauricular node is a prominent feature of adenoviral conjunctivitis**—which is extremely contagious (and no matter what the school says, does not respond to antibiotic eye drops). Allergic conjunctivitis tends to itch and affect both eyes. All other statements are true.

Your patient has no purulent drainage. On examination, her visual acuity is 20/40. Her right eye is diffusely injected and tearing; the left eye appears normal to inspection. She has a slightly tender right preauricular lymph node about 1 cm in size.

Question 19.8.2 What do you recommend as the initial treatment of this patient's conjunctivitis?

- A) Symptomatic treatment with artificial tears four to eight times per day, cool compresses, and strict hygiene to prevent spread to the other eye or to other individuals
- B) Treatment with topical vasoconstrictors/antihistamines four times daily for 1 to 2 weeks
- C) Topical antibiotic treatment for 1 week so she can go back to class
- D) Administration of topical steroids, artificial tears, and cool compresses

Answer 19.8.2 The correct answer is “A.” This patient appears to have viral conjunctivitis, which is treated symptomatically. There is no need to treat with topical vasoconstrictors and/or antihistamines unless there is a significant itching component. **It's NOT bacterial, so antibiotics are NOT needed.** Additionally, *prophylactic* antibiotics are not necessary, since there is rarely a secondary bacterial infection. See Figure 19-8 for an image of hemorrhagic viral conjunctivitis generally from adenovirus, enterovirus, and coxsackie virus. It is highly contagious.

**HELPFUL TIP:**

Do antibiotics have magical powers in viral conjunctivitis? How else can you explain the fact that a single dose of topical antibiotics is enough to get a child back into school or day care? Most schools and day care policies require the child to be on some sort of drops (of any sort) in order to return. In reality, children should be kept

FIGURE 19-8 Viral conjunctivitis. Note the follicles that are round collection of lymphocytes in the inferior fornix.

out of school until the conjunctivitis symptoms resolve. Children may start yelling, “We don’t need no education,” but it will only last a few days as viral conjunctivitis is self-limiting and will resolve without antibiotics.

Question 19.8.3 If your patient is a part-time nursing assistant at a care facility, how long should she stay away from patient care?

- A) Two days
- B) Two weeks
- C) Until her eyes are clear
- D) Until she has taken antibiotics for 24 hours

Answer 19.8.3 The correct answer is “C.” Viral conjunctivitis is *highly* contagious and is thought to be infectious as long as the eye is red and producing discharge. Promote good hand hygiene and avoidance of contact with others until the eye clears. In many instances, complete removal from school and/or work is not feasible, but patient education regarding the highly contagious nature of viral and bacterial conjunctivitis remains important.

Question 19.8.4 Which of the following is appropriate in the management of acute gonococcal conjunctivitis?

- A) Conjunctival Gram stain and PCR/NAAT
- B) Ceftriaxone IM/IV
- C) Saline irrigation
- D) All of the above
- E) None of the above

Answer 19.8.4 The correct answer is “D.” The hallmark of acute gonococcal conjunctivitis is severe purulent discharge (lots of pus!), which occurs within 12 to 24 hours of infection. Preauricular adenopathy may also be seen. Management of gonococcal conjunctivitis consists of Gram stain and PCR/NAAT to document infection and the administration of ceftriaxone

FIGURE 19-9 Bacterial conjunctivitis. Note the mucopurulent discharge.

FIGURE 19-10 Ophthalmia neonatorum. Note the severe mucopurulent discharge.

(or spectinomycin if cephalosporin allergic) IM/IV **plus** azithromycin 2 g (for possible concurrent chlamydia infection). Alternative, **second line**, regimens include gentamicin + azithromycin (2 g) or Gemifloxacin + azithromycin (2 g) though there is much less data supporting these regimens. Irrigation is needed initially to remove discharge and regularly until discharge resolves. One should examine the cornea to rule out involvement. Topical fluoroquinolone drops should be started if there is corneal involvement (though resistance rates are high). See Figure 19-9 for an image of bacterial conjunctivitis and Figure 19-10 for an image of Gonococcal ophthalmia neonatorum.

Question 19.8.5 Which of the following is NOT indicated in the treatment of allergic conjunctivitis?

- A) Cool compresses
- B) Artificial tears
- C) Chronic topical vasoconstrictors/antihistamines
- D) Short-term topical steroids
- E) Diphenhydramine

Answer 19.8.5 The correct answer is “C.” Given the possibility of rebound hyperemia with prolonged use, chronic vasoconstrictors/antihistamines are never indicated. Topical steroids should be reserved for severe cases and tapered over 1 to 2 weeks. Topical NSAIDs (ketorolac) and antihistamines or mast cell stabilizers (levocabastine or olopatadine) may be used to alleviate intense itching but can be expensive. Ketotifen is an effective and less expensive OTC mast cell stabilizer and H1-antihistamine that, when used routinely, decreases allergic conjunctivitis symptoms.

► **Objectives: Did you learn to ...**

- Differentiate among viral, bacterial, and allergic conjunctivitis?
- Not prescribe ophthalmic antibiotics for viral conjunctivitis—you got that, right?
- Choose appropriate treatments modalities for the various causes of conjunctivitis?

► **CASE 19.9**

A patient complains of possible foreign body in her eye. She was scraping barnacles off the bottom of her multi-million dollar yacht currently dry-docked right next to one of Donald Trump’s yachts (Could she be a radiologist? Maybe a plastic surgeon?). She felt something fly into her eye and had immediate pain.

Question 19.9.1 Which of the following is FALSE regarding the use of topical fluorescein, which is used to highlight epithelial defects of the cornea?

- A) Fluorescein is a nontoxic, water-soluble dye
- B) It fluoresces under a cobalt blue filter
- C) It exhibits positive staining of epithelial defects
- D) Fluorescein does not penetrate the corneal stroma

Answer 19.9.1 The correct answer is “D.” Fluorescein does diffuse through and stain the corneal stroma if there is an epithelial defect. (The first layer of the cornea is epithelium, like on the rest of our skin, and an epithelial defect can be thought of as a scratch or gash on the skin.)

HELPFUL TIP:

Always evert the upper eyelid when there is concern for a foreign body. These can be removed using a cotton-tipped swab. Irrigation may also be useful.

During your complete examination, you notice a small fleck of what looks like paint on the cornea. After successfully removing the piece of paint, you plan to discharge the patient.

Question 19.9.2 Which of the following is NOT an appropriate treatment for corneal abrasions?

- A) Observation alone
- B) Topical antibiotics
- C) Cycloplegics

- D) Topical steroids
- E) Patching

Answer 19.9.2 The correct answer is “D.” In uncomplicated corneal abrasions in non-contact lens wearers, observation alone (“A”) is often adequate. Antibiotics (“B”) should be used for all contact lens-related abrasions or in non-contact lens-related abrasions which are large, involve the visual axis, or involve vegetative matter. Topical broad-spectrum antibiotics, such as polymyxin B/trimethoprim or erythromycin ointment, are good first-line choices in those without contact lenses. A topical fluoroquinolone can be used in contact lens wearers or for abrasions involving vegetative matter. The patients should also be advised to withhold contact lens use until the abrasion is healed and should be evaluated by their contact lens prescribing provider. Generally, bandage contact lenses and patching (“E”) are rarely needed and may increase risk of infection or cause further abrasion. Patching may also be used for patient comfort, but is unnecessary and may actually increase pain and prolong healing time. Topical steroids (“D”) may inhibit epithelial healing and promote infection and should be avoided. “C” deserves special mention. Use of a long-acting cycloplegic is acceptable for discomfort related to severe photophobia and blepharospasm secondary to corneal abrasions. However, the cycloplegic agents can be expensive and *do not help in healing*.

HELPFUL TIP:

Multiple vertical corneal abrasions suggest a foreign body under the upper lid (foreign-body “tracking”). Blinking and closing the eye will leave an abrasion on the cornea. Evert the eyelid and sweep the fornices with a moistened cotton swab to remove any residual foreign body.

As you already know, most corneal abrasion should heal within 24 to 48 hours. You ask the patient to follow up in 2 days to make sure that things are going well. On arrival, she notes increased ache in the eye with increased injection and photophobia. You place anesthetic drops in her eye, but the pain does not resolve. The corneal abrasion appears to be healing.

Question 19.9.3 What do you expect to see on slit-lamp examination in her anterior chamber?

- A) Cells and flare
- B) Opacity of the lens
- C) Foreign bodies of Schlemm
- D) A tear of the anterior lens capsule

Answer 19.9.3 The correct answer is “A.” This patient is presenting with typical posttraumatic iritis. Findings would be “cell and flare” in the anterior chamber. “B” and “D” are obviously not going to be a result of a superficial corneal abrasion. “C” is something we made up, but “Canal of Schlemm” is part of the eye and one of our favorite names in medicine—it is just humorous (aqueous humor, get it? ... ah, poor Schlemm).

**HELPFUL TIP:**

Iritis, also called anterior uveitis, characteristically presents with pain, photophobia, increased redness, or excessive tearing. On slit-lamp examination, the “cell and flare” are due to individual inflammatory cells and protein, respectively. Cell and flare can be viewed in the anterior chamber with a small, bright light beam at the slit lamp.

Question 19.9.4 Appropriate treatment for this patient with post-traumatic iritis includes which of the following?

- A) Topical antibiotics
- B) Cycloplegic agents
- C) Topical steroids
- D) A, B, and C
- E) B and C only

Answer 19.9.4 The correct answer is “E.” Post-traumatic iritis is generally treated with topical steroids and cycloplegic agents. Again, we usually do this in consultation with an eye care provider. While we all worry about the risk of infection with topical steroids, they can also increase intraocular pressure, and when used chronically, it can cause glaucoma. So, these patients require close follow-up.

Assume that this patient was presenting *de novo* with iritis, and it is not post-traumatic.

Question 19.9.5 Which of the following do you NOT have to worry about as an etiology of iritis?

- A) Rheumatoid arthritis
- B) Diabetes mellitus
- C) Syphilis
- D) Sarcoid
- E) Lyme disease

Answer 19.9.5 The correct answer is “B.” Iritis is an inflammatory process that can be caused by multiple underlying illnesses including ankylosing spondylitis, lupus (rarely), Behcet’s disease, syphilis, sarcoid, tuberculosis, Reiter syndrome, toxoplasmosis (common, even in non-immunosuppressed), juvenile idiopathic arthritis, and many others.

► **Objectives: Did you learn to ...**

- Remove a corneal foreign body?
- Use topical fluorescein in corneal abrasions?
- Manage uncomplicated corneal abrasions?
- Recognize iritis and its causes?

► **CASE 19.10**

A 65-year-old white male with a history of hypertension, adult-onset diabetes, rheumatoid arthritis, and rosacea presents with chronic complaints of redness, tearing, and irritation in both eyes. He sometimes also has “a film over his vision” that

comes and goes. His ocular examination appears normal. He does, however, have an oily tear film with rapid breakup of his tears over his ocular surface. There is evidence of capped (“plugged”) Meibomian glands (oil glands along the lid margins), but the eyelids are otherwise normal in appearance.

Question 19.10.1 Which of the following is the most likely diagnosis?

- A) Meibomian gland dysfunction
- B) Conjunctivitis
- C) Hordeolum
- D) Chalazion
- E) Steven–Johnson syndrome

Answer 19.10.1 The correct answer is “A.” Meibomian glands are the oil glands of the upper and lower eyelids, which are located along the posterior lid margin behind the lashes. These are punctate openings along the lid margin, which can become clogged with thick solid secretions. When coupled with chronic inflammation of the lid margin, this eventually leads to an unstable tear film, creating symptoms of burning, redness, foreign-body sensation, and filmy vision. It is considered blepharitis (inflammation of the eyelids). “B” and “E” are incorrect and typically have predominant signs of crusting or matting. “B,” “C,” and “D” are more focal inflammatory processes, which can occur in conjunction with Meibomian gland dysfunction. A hordeolum affects the anterior lid margin glands, which become acutely plugged and inflamed. A chalazion affects the posterior lid margin glands, which become plugged and chronically inflamed. Of note, a “stye” is typically synonymous with hordeolum; however, both hordeolum and chalazion may grossly appear similar on examination.

Question 19.10.2 What part of his past medical history is associated with Meibomian gland dysfunction?

- A) Hypertension
- B) Diabetes
- C) Rheumatoid arthritis
- D) Rosacea

Answer 19.10.2 The correct answer is “D.” Meibomian gland dysfunction is associated with rosacea. Typical findings of rosacea include: facial papules, pustules, telangiectasia, erythema, edema, and rhinophyma.

Question 19.10.3 What treatment do you prescribe for this patient?

- A) Observation and reassurance
- B) Daily warm compresses, lid scrubs with dilute baby shampoo, preservative-free artificial tears, and oral antibiotic if needed
- C) Erythromycin ophthalmic ointment PRN
- D) Daily warm compresses, topical steroids, and frequent use of artificial tears

Answer 19.10.3 The correct answer is “B.” The treatment of Meibomian gland dysfunction consists of lid hygiene, lubrication, and doxycycline or minocycline 50 to 100 mg daily to

BID for 3 to 6 weeks (which will also help treat the rosacea). The dosage may then be tapered according to symptoms. Gastrointestinal upset and photosensitivity are common side effects of doxycycline.

Question 19.10.4 Which of the following is a common complication of Meibomian gland dysfunction?

- A) Bacterial keratitis
- B) Preseptal cellulitis
- C) Chalazion
- D) Scleritis
- E) Chronic conjunctivitis

Answer 19.10.4 The correct answer is “C.” Meibomian gland dysfunction can cause a chronic granuloma to form at the plugged Meibomian gland, which is called a chalazion. The inflammation is sterile—unlike a hordeolum (“stye”), which is a painful purulent abscess. Treatment of a chalazion involves frequent warm compresses and massage. Topical antibiotics are of little value, since it is sterile. If these measures fail, an intralesional injection of steroids or incision and drainage is warranted. Hordeola (“styes”) often resolve spontaneously, but warm compresses and massage are often helpful. If there is any evidence of cellulitis, systemic oral antibiotics are indicated. Drainage using a needle may also be helpful. Topical antibiotics are often not effective.

► **Objectives: Did you learn to ...**

- Recognize the signs and symptoms of blepharitis and Meibomian gland dysfunction?
- Describe the etiologies of blepharitis and Meibomian gland dysfunction?
- Determine appropriate treatment for blepharitis and Meibomian gland dysfunction and the complications of hordeola and chalazion?

► **CASE 19.11**

A 7-year-old female presents with painful swelling and redness of upper and lower lids of her right eye. She reports having a bug bite near her right eye a week ago, and it's been very itchy. Now, it has become more erythematous and painful (infected, one might even say). On examination, her right eyelids are extremely edematous with a well-demarcated area of erythema. Her ocular examination is normal, including normal vision. She has no RAPD, proptosis, or motility deficit.

Question 19.11.1 This presentation is most consistent with:

- A) Orbital cellulitis
- B) Preseptal cellulitis
- C) Anaphylactoid reaction to the insect bite
- D) Blepharitis
- E) None of the above

Answer 19.11.1 The correct answer is “B.” The presentation of this patient is consistent with preseptal cellulitis, which is defined as inflammation/infection *anterior* to the orbital

septum. “A” is incorrect. Infection occurring *posterior* to the orbital septum is called orbital cellulitis. This is characterized by fever, proptosis, restriction of globe motility, chemosis, and pain on eye movements. Orbital cellulitis is considered more dangerous than preseptal cellulitis as it can be complicated by spread to adjacent structures and result in: subperiosteal abscess, cavernous sinus thrombosis, meningitis, or intracranial abscesses. “C” is incorrect since an anaphylactoid reaction is systemic.

Question 19.11.2 Which of the following is TRUE?

- A) The most common cause of preseptal cellulitis in children is sinusitis
- B) The most common cause of preseptal cellulitis in teens and adults is sinusitis
- C) Orbital cellulitis is most commonly caused by bacteremia from a secondary source, as opposed to direct spread from an adjacent structure
- D) The most common secondary source for orbital cellulitis is otitis media

Answer 19.11.2 The correct answer is “A.” The most common cause of preseptal cellulitis in children is sinusitis. In contrast, teens and adults usually have preseptal cellulitis from a superficial source, such as skin trauma with inoculation. As a rule of thumb, preseptal cellulitis should always have a source or cause. (So put on your detective cap and ask about and look for the bugs, bites, bumps, abrasions, and sinus symptoms!)

HELPFUL TIP:

Both orbital cellulitis and preseptal cellulitis are commonly secondary to sinusitis. Both preseptal and orbital cellulitis may also occur from direct inoculation or bacteremia from a distant source.

Question 19.11.3 The most common pathogen causing preseptal cellulitis from a skin trauma with inoculation is which of the following?

- A) *Staphylococcus epidermidis*
- B) *Haemophilus influenzae*
- C) *Staphylococcus aureus*
- D) *Streptococcus pneumoniae*

Answer 19.11.3 The correct answer is “C.” *S. aureus* is the most common pathogen of preseptal cellulitis from skin trauma. Some may have chosen “B.” Prior to the introduction of the HIB vaccine, children younger than 5 years often had preseptal cellulitis secondary to *H. influenzae*. However, this is no longer the most common pathogen. Most cases of preseptal and orbital cellulitis in children are caused by Gram-positive cocci. Orbital cellulitis in children may be caused by *H. influenzae*, but again this is rare in vaccinated children. In contrast, adults with orbital cellulitis frequently have infections due to Gram-positive cocci and *Bacteroides species*. Gram-negative rods may be the culprit after trauma. *Mucor* and *Aspergillus* should be suspected in diabetic patients and immunocompromised individuals.

**HELPFUL TIP:**

Orbital cellulitis is an ophthalmologic emergency. In addition to spread to other structures (e.g., cavernous sinus thrombosis), orbital cellulitis may cause an orbital compartment syndrome, compromising blood flow and leading to blindness. Orbital compartment syndrome can also be due to trauma and secondary to intraorbital (postseptal) bleeding or retrobulbar hematoma leading to proptosis. Signs of orbital compartment syndrome include: elevated intraocular pressure (>35 mm Hg), decreased vision, relative afferent pupillary defect or a fixed, dilated pupil, restricted extraocular motility (ophthalmoplegia), or proptosis with taut lids. The treatment is emergent lateral canthotomy and cantholysis. Time equals vision in these cases and you can find instructions online. One good source is from EyeRounds available through the University of Iowa (<https://webeye.ophth.uiowa.edu/eyeforum/tutorials/lateral-canthotomy-cantholysis.htm>). It is easy and should be done as quickly as possible.

► **Objectives: Did you learn to ...**

- Differentiate between orbital and preseptal cellulitis?
- Recognize conditions that predispose patients to these processes?
- Recognize orbital compartment syndrome?

► **CASE 19.12**

A 67-year-old white man with a history of coronary artery disease, hypertension, and peripheral vascular disease presents with the sudden onset of painless loss of vision OD several hours ago. He states he was watching TV when “things went black” in his right eye. He notes that this happened a few times before, but his vision always returned to normal after a couple of minutes. On examination, he has light perception vision, the presence of a RAPD, and a normal anterior segment of the eye. Upon funduscopic examination, the fundus appears diffusely white with a reddish hue within the macula (cherry-red spot) (see Fig. 19-11).

Question 19.12.1 The patient’s history and examination are most consistent with which of the following?

- A) Central retinal vein occlusion
- B) Anterior ischemic optic neuropathy
- C) Central retinal artery occlusion
- D) Choroidal ischemia

Answer 19.12.1 The correct answer is “C.” A central retinal artery occlusion is characterized by acute painless loss of vision. The ischemia and edema of the retina causes diffuse whitening. There is a cherry-red spot in the macula, which is the normal choroidal circulation amidst the ischemic retina (see Fig. 19-11). The extensive ischemia causes a RAPD and significant visual loss. His previous history of recurrent

FIGURE 19-11 A central retinal artery occlusion. Note the cherry-red spot in the macula, which is due to the choroidal circulation amid the ischemic retina.

episodes of loss of vision that returned to normal is consistent with amaurosis fugax.

Question 19.12.2 In a patient with this history, irreversible retinal damage occurs after what time frame?

- A) 10–15 minutes
- B) 30–60 minutes
- C) 90–120 minutes
- D) 6 hours

Answer 19.12.2 The correct answer is “C.” If central retinal artery occlusion is complete for more than 120 minutes, irreversible retinal damage and visual loss ensue. Patients should seek medical care immediately. Amaurosis fugax, or transient monocular blindness, is typically caused by carotid, vascular, or heart disease. It is often described as a curtain or shade coming over the vision. It lasts from a few seconds to 15 minutes or longer. The vision always returns back to normal in amaurosis fugax episodes. Patients with a history of amaurosis fugax should be evaluated for carotid and cardiac disease.

Question 19.12.3 Treatment for central retinal artery occlusion includes all of the following EXCEPT:

- A) Thrombolytics
- B) Digital compression/decompression of the globe
- C) Anterior chamber paracentesis
- D) Acetazolamide
- E) Oxygen

Answer 19.12.3 The correct answer is “A.” Therapy for central retinal artery occlusion is entirely aimed at dislodging the embolism, maintaining retinal viability, and reducing intraocular pressure (to increase the pressure gradient between the artery and the eye). This can be accomplished by digitally compressing (press hard!) then decompressing the eye with a

finger (to dislodge the embolism), and anterior chamber paracentesis or acetazolamide (to reduce intraocular pressure). To accomplish the goals of increasing oxygen and carbon dioxide (which dilates vessels) use carbogen (95% oxygen and 5% carbon dioxide) or try using a nonrebreather facemask with supplemental oxygen; neither have good support in the literature, however.

Question 19.12.4 Comparing central retinal artery occlusion to central retinal vein occlusion, which of the following is TRUE?

- A) Central retinal artery occlusion is more likely to be associated with giant cell arteritis
- B) The main feature of both is retinal whitening with a cherry red spot
- C) Central retinal vein occlusion usually results from atherosclerotic thrombosis, while central retinal artery occlusion results from hyperviscosity syndromes and hypercoagulable states
- D) A RAPD is characteristic of central retinal artery occlusion, but is not seen with central retinal vein occlusion

Answer 19.12.4 The correct answer is “A.” If a patient presents with symptoms of central retinal artery occlusion, but no embolus is visualized, he/she should be asked about symptoms of giant cell arteritis. “B” is incorrect because only central retinal artery occlusion is associated with retinal whitening and a cherry red spot. The appearance of a central retinal vein occlusion is one of tortuous dilated veins, optic nerve edema, and intraretinal hemorrhages/edema (the so-called “blood and thunder” appearance of the fundus—although since thunder is a sound, having something look like thunder does not make sense). “C” is incorrect because central retinal artery occlusion is usually caused by atherosclerotic thrombosis or emboli, while central retinal vein occlusion is associated more with hyperviscosity syndromes (e.g., polycythemia) and hypercoagulable states (e.g., protein C deficiency). In older patients with central retinal vein occlusion, the main risk factors include vasculopathic states such as hypertension and diabetes. “D” is incorrect because a RAPD can be seen with either syndrome. There will be a RAPD with a central retinal artery occlusion due to the diffuse distribution of ischemia. A RAPD may or may not be seen with a central retinal vein occlusion depending on the level of ischemia.

HELPFUL TIP:

Other causes of central retinal artery occlusion include vasculitides and blood dyscrasias. Other causes of central retinal vein occlusions include increased intraorbital or intraocular pressure, glaucoma, blood dyscrasias, lupus anticoagulant, antiphospholipid antibody, oral contraceptives, and protein C deficiency. See Figure 19-12 for an image of the retina in central retinal vein occlusion.

FIGURE 19-12 Central retinal vein occlusion. Note the dilated tortuous veins, optic disc edema, and retinal hemorrhage/edema.

Question 19.12.5 Further evaluation and treatment of a central retinal artery occlusion includes all of the following EXCEPT:

- A) Topical timolol
- B) ESR/CRP
- C) Carotid Doppler
- D) Orbital MRI/MRA
- E) Echocardiogram

Answer 19.12.5 The correct answer is “D.” There is no need for orbital imaging in the management of a central retinal artery occlusion. All of the other choices are important management steps. In addition, blood pressure, fasting blood sugar or glycosylated hemoglobin, CBC, and PT/PTT should be done. If there is a suspicion of giant cell arteritis, an ESR/CRP should be checked. Other tests might include a rheumatoid factor, syphilis serology, serum protein electrophoresis, and antiphospholipid antibodies. A similar workup is warranted in central retinal vein occlusion, except there is no need to search for an embolic source with a carotid Doppler and echocardiogram.

► **Objectives: Did you learn to ...**

- Recognize the symptoms of vascular disorders of the eye?
- Differentiate between central retinal artery and vein occlusions?
- Describe some causes of ocular vascular occlusions?
- Determine the appropriate systemic workup for artery and vein occlusions?

► **CASE 19.13**

A 40-year-old white female presents to your ED complaining of seeing “little floating black spots” in her vision in the left eye. She also notes little sparks of light in the temporal periphery of the left eye. She noted this while

shopping today at Wal-Mart. (First, you think this may be the revenge of the gods for shopping at Wal-Mart instead of buying locally. But then, you gather your wits about you.) On examination, her vision is 20/20 in both eyes, and there is no RAPD (she has normal direct and consensual pupillary reflexes). Confrontation visual fields demonstrate peripheral vision loss in the left eye. Dilated peripheral retinal examination reveals billowing gray folds. The macula appears normal.

Question 19.13.1 Which of the following is the most appropriate step in the management of this patient?

- A) Place a patch over the left eye
- B) Refer to an ophthalmologist immediately
- C) Lower blood pressure acutely with IV labetalol
- D) Apply timolol solution to the affected eye
- E) Offer reassurance

Answer 19.13.1 The correct answer is “B.” This patient is presenting with a macula-on retinal detachment, which requires urgent ophthalmology consult. She has classic symptoms of retinal detachment—flashing lights, floaters, visual field disruption, and corrugated retinal folds. The majority of her visual field, including her central vision, is still intact. In her current state, she has a high likelihood of retaining good vision if the macula remains attached. To decrease the changes of the macula detaching, patients should be on bedrest and positioned to decrease the extension of the retinal detachment toward the macula. None of the other treatments offered do anything for retinal detachment. Specifically, “A” does nothing, “C” is treatment for hypertensive emergency, “D” is for glaucoma, and “E” is just plain nuts in this case.

Question 19.13.2 Risk factors for retinal detachment include all of the following EXCEPT:

- A) Glaucoma
- B) Aphakia (surgical removal of the lens, such as in cataract surgery)
- C) Myopia
- D) Trauma
- E) Prior ocular surgery

Answer 19.13.2 The correct answer is “A.” Glaucoma is not a risk factor for retinal detachment. Both myopia (nearsightedness) and aphakia (surgical removal of lens) are risk factors. Trauma and previous surgery also predispose to retinal detachments. Most persons with retinal detachment are older than 50 years. As patients age, the vitreous liquefies and contracts, and this vitreoretinal traction or tugging can cause a tear, detaching the retina from the posterior wall of the eye.

► **Objectives: Did you learn to ...**

- Suspect retinal detachment in patients presenting with “floaters” and “flashes?”
- Identify patients who are at risk for retinal detachment?

► **CASE 19.14**

A 55-year-old white male complains of a gradual decrease in vision in both eyes. He notes glare with oncoming headlights while night driving. Despite this, he feels that he is able to read better without his bifocals.

Question 19.14.1 Based on the history given, which of the following is the most likely cause of this patient’s complaints?

- A) Retinal detachment
- B) Cataracts
- C) Glaucoma
- D) Diabetic retinopathy
- E) Presbyopia

Answer 19.14.1 The correct answer is “B.” Progressive visual loss and glare from oncoming headlights while driving at night are common complaints caused by cataracts. Patients may be able to read without bifocals, because cataracts cause a myopic shift and increases the power of the lens. The eye examination can confirm the diagnosis, as most significant cataracts are easily visualized. The red reflex is diminished bilaterally, and a haze of gray is observed over the lens. Symptoms of retinal detachment (“A”) are more acute. Glaucoma (“C”) and diabetic retinopathy (“D”) are less likely but could also be present. Intraocular pressures and a dilated eye examination should be completed to adequately assess and diagnose the patient’s condition.

Question 19.14.2 All of the following conditions/medications are risk factors for cataract formation EXCEPT:

- A) Corticosteroids
- B) Trauma
- C) Radiation
- D) Calcium channel blockers
- E) Diabetes mellitus

Answer 19.14.2 The correct answer is “D.” All of the other choices are associated with cataract formation. Other risk factors include: age, tobacco, alcohol, myotonic dystrophy, Down syndrome, or Wilson disease. Unfortunately, despite what we have been taught, UV blocking sun glasses do not seem to help.

Question 19.14.3 Of all of the patients with cataracts below, which is the best indication for cataract surgery?

- A) A patient with no visual complaints with a visual acuity of 20/50
- B) A patient with complaints of glare and inability to drive at night with a visual acuity of 20/40
- C) An older patient with a history of monocular congenital cataract and best-corrected visual acuity of 20/100 in that eye
- D) A patient with right monocular diplopia that resolves with new spectacle correction

Answer 19.14.3 The correct answer is “B.” There is no strict visual acuity that determines the appropriate timing of cataract surgery. It is really a functional definition. If there are significant

lifestyle limitations secondary to visual disability from a cataract, then cataract surgery may be indicated. “C” is incorrect. An older person with a history of congenital cataracts and poor best-corrected visual acuity most likely suffered from amblyopia; therefore, cataract surgery is unlikely to benefit such a patient. “D” is incorrect. Monocular diplopia (double vision from one eye only) should be evaluated to rule out other causes such as dry eye or irregular corneal surface.

Question 19.14.4 Complications of cataract surgery include all of the following EXCEPT:

- A) Endophthalmitis
- B) Retinal detachment
- C) Glaucoma
- D) Hemorrhage
- E) Meibomian gland dysfunction

Answer 19.14.4 The correct answer is “E.” Meibomian gland dysfunction is a chronic condition as discussed previously in this chapter. Modern day cataract surgery is typically done by phacoemulsification (ultrasound fragmentation) of the cataract with implantation of an intraocular lens. Although cataract surgery techniques have been advanced over the years to become a safe surgery with relatively low risks, risks and potential complications still exist. Additional complications include: wound leaks, uveitis, macular edema, dislocation of lens, retained lens material, corneal edema, vitreous loss, and retinal detachment.

HELPFUL TIP (AND ONE THAT MAY BE ON THE BOARDS):

One of our favorite disease names (besides “exploding head syndrome” ... really, look it up) is “floppy iris syndrome.” This occurs when patients on alpha-blockers (usually men for BPH) go for cataract surgery. The result is a poorly dilating iris that is irreversibly floppy and may prolapse during cataract surgery. This effect of alpha-blockers may last years after last usage, so be careful when suggesting surgery to these patients.

► **Objectives: Did you learn to ...**

- Identify patients at risk for cataract development?
- Describe indications for cataract surgery?
- Recognize the symptoms and visual disability in those with progressive cataracts?

QUICK QUIZ: SOMETHING ON THE EYE

A patient presents to your clinic without vision symptoms, but complains of a growth from the white onto the colored part of his eye (Fig. 19-13). The growth is painless and has been present for several years but is now getting to the point that it is pretty obvious. Strangers tend to stare. Children run the other way when they see him coming. He cries himself to sleep every night because of this.

FIGURE 19-13 Pterygium. Note the fleshy, pink conjunctival tissue crosses onto the cornea.

This growth is most likely due to:

- A) Systemic inflammatory illness
- B) Exposure to UV light and dust
- C) Foreign-body granuloma
- D) Trauma to the sclera and cornea with scarring
- E) Any of the above can lead to this finding

The correct answer is “B.” This is a pterygium, an overgrowth of conjunctival tissue, which is a result of recurrent exposure to UV light and high winds with dust. It is of no clinical significance unless it encroaches on the visual field or causes cosmetic distress. It is characterized by involvement of the cornea nasally or temporally as opposed to a pinguecula, which has a similar appearance but does not infringe upon the cornea. Careful history taking often uncovers a patient history of outdoor lifestyle (farming, construction, boating, etc.) or whether they are snowbirds who travel south in the winter. Another name for pterygium is “surfer’s eye” (really), not only because surfers are in the sun and are prone to pterygium, but it is a pretty gnarly looking growth!

QUICK QUIZ: PAINFUL EYE

A 40-year-old patient presents with a painful, red area on the eye (Fig. 19-14). He notes the gradual onset of severe pain of a boring nature with pain in the periocular area as well. He has a history of rheumatoid arthritis.

What is the diagnosis?

- A) Episcleritis
- B) Pterygium
- C) Scleritis
- D) Pinguecula
- E) Epidemic hemorrhagic conjunctivitis

The correct answer is “C.” This is scleritis. Note the erythema and inflammation, which differentiates it from a pterygium. Scleritis may also be nodular in nature or diffuse. Scleritis can be easily

FIGURE 19-14 Scleritis. Note the sectoral inflammation of superficial conjunctival vessels and deep scleral vessels.

mistaken for episcleritis, which may appear similar. Episcleritis is inflammation of the tissues overlying the sclera, the episclera. Although the more superficial conjunctival and episcleral vessels are often inflamed as well the deeper scleral vessels, scleral vessels can be identified because they cannot be moved with a cotton tip and do not blanch with phenylephrine as conjunctival and episcleral vessels do. Another thing that differentiates episcleritis from scleritis is that patients with episcleritis do not have the severity of pain noted with scleritis. Pain of scleritis is typically boring achy pain and is worse with movement of the eye. A pinguecula (“D”) appears as yellowish, slightly raised nodule(s) that is found on the conjunctiva nasal or temporal to the cornea. A pinguecula generally appears in middle age, has similar risk factors as pterygium, and removal is rarely indicated.

HELPFUL TIP:

Episcleritis will generally resolve spontaneously or with a bit of topical steroid. **Scleritis can be serious and result in globe rupture**, and should be referred urgently.

QUICK QUIZ: SCLERITIS

Which of the following is NOT commonly associated with scleritis?

- A) Wegener granulomatosis
- B) Lupus
- C) Gout
- D) Nephrotic syndrome
- E) Rheumatoid arthritis

The correct answer is “D.” Nephrotic syndrome does not generally represent ongoing inflammation. More than 50% of cases of scleritis have an associated systemic inflammatory disease such as: gout, lupus, rheumatoid arthritis, ankylosing spondylitis, or infectious etiologies such as herpes zoster, syphilis, *Pseudomonas*, fungi, *Nocardia*, or atypical mycobacteria.

QUICK QUIZ: MY IMPLANTED LENS ISN'T WORKING

A 70-year-old female presents for a routine medical evaluation. She reports no problems, but on review of systems she states that she has had a gradual decrease in vision in the right eye over the past several months. She had successful cataract surgery of both eyes 3 years ago. After the surgery, she had 20/20 vision OU. Now on examination, her vision is OD 20/50 and OS 20/20. She has no RAPD. The slit-lamp examination of her anterior segment of both eyes reveals well-positioned bilateral posterior chamber intraocular lens (PCIOL) implants. There seems to be a hazy membrane behind her lens implant in the right eye.

The most likely diagnosis is which of the following?

- A) Posterior capsular opacity
- B) Endophthalmitis
- C) Retinal detachment
- D) Posterior uveitis
- E) Intraocular lens dislocation

The correct answer is “A.” Months to years after successful cataract surgery, patients may experience a gradual decline in their vision due to an opacification of the posterior capsule behind their intraocular lens implant (“secondary cataract”). During cataract surgery, most of the normal capsule of the lens remains and holds the intraocular lens implant. In successful cataract surgery, only the anterior portion of the capsule is removed. The posterior portion of this capsule may become hazy over time due to the proliferation of residual lens epithelial cells. The patient does not have any symptoms of infection or inflammation and reports no flashes or floaters that would eliminate most of the other choices. An intraocular lens dislocation is rare and is usually seen in the setting of trauma. Treatment for capsular opacification is YAG laser capsulotomy, which is a simple procedure performed in an outpatient setting at a slit lamp.

▶ CASE 19.15

A 56-year-old white male with a history of hypertension and diabetes complains of double vision and pain for the past 2 days. On examination, his vision is OD 20/50 and OS 20/25. He has a larger pupil with a RAPD OD. The lid of his right eye is slightly lower than the left. His right eye is deviated slightly temporally and inferiorly, and he has difficulty adducting and elevating the eye.

Question 19.15.1 The most likely diagnosis is which of the following?

- A) Graves' disease
- B) Horner syndrome
- C) Third nerve palsy
- D) Myasthenia gravis

Answer 19.15.1 The correct answer is “C.” The case presented is a typical scenario of a third nerve palsy. Patients with a third nerve palsy present with diplopia (from ocular muscle paralysis),

ptosis, and a dilated pupil with or without pain. Recall that the ocular muscles are innervated by CN3 except for the lateral rectus (CN6) and the superior oblique (CN4), so the eye will be “down and out” when the lateral rectus and superior oblique act unopposed in a third nerve palsy. A third nerve palsy may also present as an incomplete picture as an incomplete palsy may depend on whether the superior or inferior division of the third cranial nerve is involved. **Often the pupil is spared in diabetic patients. Pupil involvement should prompt an investigation for an intracranial aneurysm.** “A,” Graves’ disease, may present with motility deficits and compression of the optic nerve resulting in a RAPD. However, Graves’ disease is less likely in this patient because it should present with gradual onset with lid retraction and proptosis, not ptosis. Graves’ disease also may cause restriction of the medial and inferior rectus muscles, which causes difficulty abducting and elevating the eye. “B,” Horner syndrome, may present with ptosis, but the affected side would have miosis (not mydriasis as in this patient), and it does not present with motility deficits. “D,” myasthenia gravis, may present with fluctuating ptosis and motility deficit, but these findings are usually elicited with fatigue. The pupil is never involved in myasthenia gravis.

Question 19.15.2 The workup of this patient should involve:

- A) Cerebral angiography
- B) CT/CTA
- C) MRI/MRA
- D) Orbital ultrasonography

Answer 19.15.2 The correct answer is “C.” Although cerebral angiography has long been the gold standard in detecting cerebral aneurysms, the first line and less invasive diagnostic test is MRI/MRA. Obtain CBC and ESR/CRP if there is concern for GCA.

► **Objective: Did you learn to ...**

- Diagnose a third cranial nerve palsy and initiate management?

Clinical Pearls

- Always evert the eyelids in any patient who may have a foreign body in the eye.
- Do not delay urgent consultation with an ophthalmologist in a patient suspected of having a retinal detachment.
- In the case of chemical burn injuries to the eye, irrigate, irrigate, irrigate!
- The vital signs of the eye are visual acuity, pupils, and intraocular pressure. (It is similar to temperature, heart rate, blood pressure, and if you have these three pieces of information when you talk to an ophthalmologist, they will be impressed!)
- Do not prescribe antibiotics for viral conjunctivitis.
- Perform a complete and thorough ophthalmologic examination and consider imaging for any patient presenting with new onset strabismus.

- Refer patients with type 2 diabetes for dilated eye examination at initial diagnosis. Patients with type 1 diabetes should have a dilated funduscopic examination within 3 to 5 years of diagnosis.
- Proptosis and ocular hypertension associated with trauma should be immediately evaluated for possible lateral canthotomy and cantholysis.

Otolaryngology

C. Blake Sullivan and Scott R. Owen

► CASE 20.1

A 2-year-old is brought to your office by her mother who is concerned that she has been pulling at her left ear since late last night and has a fever of 101.3°F. She has had recurrent bouts of these symptoms, the last of which was 9 months ago. Each time, the symptoms resolved with one “shot of medicine.” She is alert and interactive. She has some evidence of mucoid discharge from her nares bilaterally.

Question 20.1.1 Each of the following findings is diagnostic of acute otitis media (AOM) EXCEPT:

- A) Profuse, purulent ear discharge without other evidence of otitis externa
- B) Air–fluid level behind the tympanic membrane (TM) with marked redness of the TM and poor movement with pneumatic otoscopy
- C) Bulging, thickened yellow, and red TM that does not move well with pneumatic otoscopy
- D) Bubbles in fluid behind the TM with impaired mobility of the TM on pneumatic otoscopy
- E) Yellow, opaque TM, poor movement with pneumatic otoscopy, and substantial ear pain

Answer 20.1.1 The correct answer is “D.” Suspected ear infections drive many parents to bring their children to a family physician. There may be fluid in the middle ear that is not infected (otitis media with effusion [OME]). In order to diagnose AOM, you need evidence of fluid in the middle ear **and** inflammation, and the symptoms should be acute (starting in the last few days and lasting less than 3 weeks). A middle ear effusion is diagnosed by bubbles and/or air–fluid level behind the TM **OR two** or more of the following: decreased or absent TM movement with pneumatic otoscopy, opacification of the TM, and discoloration of the TM (yellow, white, blue). These findings describe OME, but not AOM. To diagnose AOM, you will need to meet criteria for OME with evidence of acute inflammation such as: marked pain, thickened and/or bulging TM, and erythematous TM. For these reasons, “B,” “C,” and “E” are examples of AOM.

“A,” purulent otorrhea without evidence of otitis externa, would be the one exception where you can diagnose AOM without even seeing the TM. “D” describes OME without inflammation.

HELPFUL TIP:

Don’t believe a red eardrum. By itself, erythema of the TM has a 15% positive predictive value for diagnosing AOM. **Use pneumatic otoscopy**, which is the standard of care for diagnosing AOM. **Tympanometry** (testing volume of middle ear and mobility of TM) is an alternative to pneumatic otoscopy. Of course, you still need to look in the ear.

Your patient’s left TM is opaque, erythematous, and immobile upon pneumatic otoscopy.

Question 20.1.2 Each of the following factors increases her risk for developing otitis media EXCEPT:

- A) She attends day care
- B) Her mother smokes inside the house
- C) The patient is a female
- D) Patient still uses a pacifier
- E) She was exclusively breastfed as an infant

Answer 20.1.2 The correct answer is “C.” The following are known risk factors for the development of AOM: day care attendance, smoking inside the home, **male gender**, pacifier use, children in developing countries, age between 6 and 18 months, lack of breastfeeding, and going to bed with a bottle.

Question 20.1.3 Which of the following findings is reliably found in patients with AOM?

- A) Fever
- B) Ear pulling
- C) Irritability
- D) Rhinitis
- E) None of the above

Answer 20.1.3 The correct answer is “E.” None of the above is reliably found in patients with AOM. Other unreliable factors include vomiting, diarrhea, and cough. The presence or absence of any of these findings is **NOT** helpful in making the diagnosis of otitis media. Note that while ear pain is a symptom of inflammation, it is a relatively weak predictor of AOM and must be accompanied by other findings as listed previously. However, **pneumatic otoscopy or otoscopy plus tympanometry is the way to make the diagnosis**; but always make sure that you have a good seal or you run the risk of a “false-positive” finding.

HELPFUL TIP:

All children <6 months of age with otitis media should be treated with antibiotics. Patients from 6 months to 2 years should receive antibiotics if **the diagnosis is suspected and the patient meets high-risk criteria** (moderate-to-severe ear pain, fever >39°C, immunosuppressed). In patients 6 months to 2 years, observation is an option if they meet low-risk criteria (fever <39°C, mild otalgia, immunocompetent, unilateral AOM, parental education, and shared-decision provided **and** follow-up assured within 48–72 hours). Patients with proven AOM who are older than 2 years may be observed rather than treated with antibiotics as long as they meet low-risk criteria. Analgesics should be given to all patients. There’s also the option of providing a “backup” antibiotic prescription (endorsed by the American Academy of Pediatrics) for the patient to start if the symptoms are persisting longer than 2 to 3 days.

This patient has not had any problems with otitis media for at least 9 months, has not been on antibiotics during that time, is not in day care, and has no allergies. You opt to treat her with an antibiotic.

Question 20.1.4 What is the most appropriate treatment for this patient?

- A) Amoxicillin 40 mg/kg/day divided TID
- B) Amoxicillin 80 to 90 mg/kg/day divided BID
- C) Ceftriaxone 50 mg/kg IM once
- D) Azithromycin 10 mg/kg for 1 day then 5 mg/kg for days 2 to 5
- E) Amoxicillin/clavulanate 40 to 80 mg/kg/day divided BID

Answer 20.1.4 The correct answer is “B.” Amoxicillin is the first-line treatment of AOM. The dose is 80 to 90 mg/kg/day in all patients whether antibiotic-naïve or not. More broad-spectrum drugs such as ceftriaxone and amoxicillin/clavulanate should be reserved for patients who fail initial therapy with a first-line drug or have a penicillin allergy.

HELPFUL TIP:

Remember that you can treat children older than 6 years with a 5-day course of amoxicillin. Amoxicillin/

clavulanate should be reserved for treatment failures. Cefdinir, cefuroxime, or clindamycin are backups in case of penicillin allergy.

HELPFUL TIP:

No antibiotic has been proven superior to amoxicillin in the treatment of otitis media. Other antibiotics will work but are more expensive and/or have greater side effects. This is likely secondary to the fact that most OM is viral and will get better regardless of what we do.

Question 20.1.5 Which of the following statements best characterizes the role of antibiotics in the treatment of AOM?

- A) Antibiotics have been shown to reduce suppurative complications of AOM, such as mastoiditis, in developed countries.
- B) The majority of patients with AOM benefit from the use of antibiotics.
- C) The use of antibiotics for AOM reduces hearing loss and benefits language development.
- D) With or without antibiotics, about 75% of children have resolution of AOM symptoms after 7 days.
- E) All of the above are true.

Answer 20.1.5 The correct answer is “D.” The benefit of antibiotics for most children with AOM is marginal and the number needed to treat (NNT) is about 12; thus, the option exists to observe and not even give antibiotics in children ≥2 years who have mild symptoms, are immunocompetent, and have good follow-up (and, as stated above, observation can even be extended to kids as young as 6 months). The rest of the statements are incorrect. Antibiotics do **not** reduce suppurative complications in **developed** countries, but they do seem to prevent suppurative complications in developing countries where sanitation and healthcare access are not optimal. “B” is incorrect. The benefit is limited to a 5% absolute reduction in those who have pain at days 2 to 3 (11.6% without antibiotics vs. 15.9% with antibiotics). “C” is incorrect as well, since treating with antibiotics does not impact these outcomes in any way.

HELPFUL TIP:

AOM is usually caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and various viruses. Most are viral, and the majority of cases—bacterial or viral—will resolve spontaneously.

You prescribe amoxicillin for 10 days and suggest acetaminophen for comfort. A few days later, the patient’s mother calls to say that she is no better. You ask her to come in to clinic for evaluation.

Question 20.1.6 When treating AOM, which of these individuals should be considered a treatment failure and switched to another antibiotic?

- A) A patient with a fever that continues at 24 hours after starting an oral antibiotic
- B) A child who is still tugging at his ear 5 days into a course of antibiotics
- C) A symptomatic child who still has a bulging, erythematous, immobile TM 3 days after starting antibiotics
- D) A child who continues to have rhinorrhea 1 week after starting antibiotics
- E) All of the above

Answer 20.1.6 The correct answer is “C.” You should consider switching to a different antibiotic in patients who remain symptomatic at 3 days **and who continue to have positive findings on pneumatic otoscopy**. Symptoms are not enough; they are unreliable. Remember, since most of these are viral infections, you are not doing a whole lot of good with your antibiotics anyway. “A” is incorrect because 24 hours is not sufficient to determine if a particular antibiotic will be effective. “B” is incorrect because children pull at their ears for a number of reasons besides AOM (such as “Ha! I just discovered I have ears!”). “D” is incorrect. If you chose this one, back to Microbiology 101 for you! Rhinorrhea does not respond to antibiotics and is most likely not bacterial in origin.

HELPFUL TIP:

For treatment failures, amoxicillin/clavulanate is recommended by the AAFP and AAP. Other options include: cefdinir, cefpodoxime, ceftriaxone, and cefuroxime. Macrolides and TMP/SMX are less effective as second-line therapy because of bacterial resistance (this includes the ever-popular azithromycin, folks). Remember the number needed to harm is about 8 with amoxicillin/clavulanate; the diarrhea and resultant diaper rash are often more distressing than the otitis.

She returns with persistent pain and fever after taking amoxicillin for 3 days. On examination, you find evidence of persistent AOM. You switch the patient to your favorite second-line antibiotic. You see her back in 2 weeks for an ear check and find complete resolution. The mother asks what she could do to avoid these troublesome infections in the future.

Question 20.1.7 All of the following have been shown to reduce the incidence of recurrent otitis media EXCEPT:

- A) Antibiotic prophylaxis
- B) Conjugate pneumococcal vaccine
- C) Tympanostomy tubes
- D) Tonsillectomy
- E) Influenza vaccine

Answer 20.1.7 The correct answer is “D.” Primary tonsillectomy has not been shown to reduce the recurrence of otitis media. However, *adenoidectomy* (due to obstruction of the

Eustachian tube, or harboring otitis-causing bacteria) with or without tonsillectomy may reduce the rate of recurrent otitis media in patients *who already have tympanostomy tubes*. “A,” the use of antibiotic prophylaxis, will reduce recurrent otitis media. Antibiotic prophylaxis should be considered in the patient who has had ≥ 3 episodes of otitis media in 6 months or ≥ 4 episodes in 12 months. Reasonable choices for antibiotics include amoxicillin and trimethoprim/sulfamethoxazole. Give half of the usual daily dose. This is generally given at bedtime. Often, antibiotics can be stopped during the summer since an upper respiratory infection (URI) is the precipitant of most cases of otitis media. Pneumococcal vaccine (e.g., Prevnar) will reduce the risk of recurrence in children with severe and recurrent AOM. The same is true of influenza vaccine. Also recommended to reduce the frequency of AOM: avoid pacifier use, avoid bottle propping at night, avoid smoke exposure, and encourage breast feeding for at least the first 6 months of life.

HELPFUL TIP:

Although it is traditionally done, there is no reason to follow up AOM in patients >15 months of age who are asymptomatic. Clearly, if they are still symptomatic, follow-up is warranted.

HELPFUL TIP:

Adding Cortisporin **suspension** (the solution burns) or ciprofloxacin otic suspension is appropriate if there is AOM with a ruptured TM (manifested by purulent ear drainage). Other antibiotic/steroid combination drops (e.g., Ciprodex) can be used as well but are more expensive. No ... Cortisporin won't cause hearing loss.

The patient returns 4 weeks later with the mother saying, “She is still pulling at her left ear.” There are no other complaints. On examination, you find the left TM is without erythema or opacity but there is still a fluid level. The right ear examination is unremarkable.

Question 20.1.8 What is your next diagnostic step?

- A) Pneumatic otoscopy
- B) Hearing test
- C) Tympanostomy
- D) No further diagnosis needed—treat with antibiotic

Answer 20.1.8 The correct answer is “A.” Even though we all think we can do it well, the diagnosis of otitis media is fraught with problems. Pneumatic otoscopy should be done in essentially all patients but especially in those in whom long-term therapy is being considered. Remember that fluid can persist for a month or more after an otitis media.

On your examination, the TM does not move with insufflation. The patient's mother asks you if the child should have tubes placed.

Question 20.1.9 Which of the following is NOT a criterion for tympanostomy tubes?

- A) Chronic bilateral effusions for more than 3 months with unilateral hearing loss
- B) Failure of antibiotic therapy to prevent recurrent otitis media
- C) Language delay secondary to otitis media
- D) Greater than 20 dB hearing loss bilaterally

Answer 20.1.9 The correct answer is “A.” Patients should meet the criteria listed above before being considered for tympanostomy tubes. Note that this requires that patients **also** meet the criteria for prophylactic antibiotic therapy (≥ 3 episodes of AOM in 6 months or ≥ 4 episodes in 12 months). A modification of “A” is also a criterion: chronic bilateral effusions for more than 3 months with **bilateral** hearing loss. Although included as a criterion, there is no evidence that tympanostomy tubes improve language development in the short or long term.

If fluid persists in the middle ear after AOM, it is termed “otitis media with effusion,” (OME) aka “serous otitis media.”

Question 20.1.10 Which of the following interventions has proven benefit in patients with OME?

- A) Oral decongestants
- B) Oral antihistamines
- C) Prolonged treatment (≥ 1 month) with oral antibiotics
- D) Oral corticosteroids
- E) None of the above

Answer 20.1.10 The correct answer is “E.” For persistent OME (the most common cause of pediatric hearing loss), there are no useful medical interventions. Autoinflation (“Eustachian tube exercises” or forced exhalation with closed nose and mouth) is often recommended, but has not shown a benefit (and try explaining how to do this to a 6-month-old). Patients may benefit from surgical intervention with tympanostomy tube placement ... and then there’s always the good, old-fashioned “tincture of time.”

▶ Objectives: Did you learn to ...

- Diagnose otitis media appropriately?
- Initiate treatment in a patient with otitis media?
- Recognize failed antibiotic therapy and choose a new antibiotic for otitis media?
- Describe prevention strategies for recurrent otitis media?
- Recognize indications for tympanostomy tube placement?

**QUICK QUIZ: EAR PAIN****Which of the following can cause ear pain?**

- A) Temporomandibular joint (TMJ) syndrome
- B) Cervical spine degenerative arthritis
- C) Cranial nerve lesions (5, 7, 9, or 10)
- D) Bell’s palsy
- E) All of the above can cause ear pain

The correct answer is “E.” All of the above can cause ear pain. A more complete list is given in Table 20-1. The main point here is that not all ear pain is otitis media—or even originating from the ear.

▶ CASE 20.2

A 23-year-old female college student presents to your clinic complaining of ear pain. She is on the swimming team and notes that this pain occurs during swimming season. The pain is increased by motion of the pinnae. The external auditory canal is erythematous, edematous, and exquisitely tender when you try to use the otoscope to examine her TM. There is whitish debris in the external auditory canal.

Question 20.2.1 The most likely organism involved in this patient’s disease is:

- A) *Streptococcus*
- B) *Haemophilus*
- C) *Moraxella*
- D) *Pseudomonas*
- E) *Parainfluenza*

Answer 20.2.1 The correct answer is “D.” This patient likely has otitis externa. The most common pathogenic organism isolated in cases of otitis externa is *Pseudomonas* (20–60%) followed closely by *Staphylococcus aureus*. However, up to one-third of cases of otitis externa are polymicrobial.

Question 20.2.2 Which of the following is/are considered first-line treatment for otitis externa?

- A) Oral ciprofloxacin
- B) Acetic acid ear drops
- C) Polymyxin and neomycin combination ear drops
- D) A and C
- E) B and C

TABLE 20-1 CAUSES OF EAR PAIN

- Auricular disease
- Canal disease
 - Otitis externa
 - Foreign body
 - Trauma
 - Eczema
 - Ramsay–Hunt syndrome
- Middle ear disease
 - Otitis media
 - Mastoiditis
 - Ménière disease
- Referred pain
 - Dental disease (e.g., abscess)
 - Temporomandibular joint syndrome
 - Carotidynia
 - Pharyngeal disease (e.g., pharyngitis)
 - Cranial nerve lesions (CN V, VII, IX, X)
 - Upper cervical nerve disease, any causes (e.g., disk disease)
 - Bell’s palsy and other neurologic diseases (e.g., trigeminal neuralgia)

Answer 20.2.2 The correct answer is “E.” Otitis externa can be treated with a wide array of topical agents. One option is to acidify the external ear canal. Neither *Pseudomonas* nor *Staphylococcus* species can thrive at an acidic pH. Thus, acetic acid drops (e.g., VoSol®) can be used: they are cheap and effective. Another approach is to use a topical antibiotic. Polymyxin/neomycin combinations (e.g., Cortisporin) are safe and effective. A number of other antibiotic preparations are available as well. Alcohol-based solutions are another alternative. “A” is incorrect because oral treatment is not indicated for simple otitis externa. However, topical ciprofloxacin may be used but is more expensive. Avoid aminoglycoside drops in patients with tympanostomy tubes due to risk of ototoxicity.

HELPFUL TIP:

There are a number of much more expensive treatments for otitis externa on the market, including fluoroquinolone otic drops. These have no advantage and are very expensive. In fact, there is no treatment advantage to using antibiotics at all. Topical drying agents, alcohols and acetic acid, have just as good an outcome as antibiotics.

Question 20.2.3 This patient is concerned about recurrences of her otitis externa. What advice can you give her?

- A) Avoid exposure by putting a petroleum jelly (e.g., Vaseline) impregnated cotton plug in her ear before swimming
- B) Use a blow dryer on her ear after swimming
- C) Instill a 50/50 mixture of alcohol and vinegar in her ears after swimming
- D) Avoid swimming when she has active disease
- E) All of the above

Answer 20.2.3 The correct answer is “E.” All of the above can be used to minimize disease recurrence. The benefit of “C” is less certain.

HELPFUL TIP:

Remember that **necrotizing (malignant) otitis externa** is a different creature altogether that occurs primarily in diabetic patients, but also in those with HIV and other immunosuppressing diseases/meds. It is an invasive pseudomonal (95%) cellulitis that causes erythema and tenderness around the ear. Complications include osteomyelitis, meningitis, abscess formation, and cranial nerve palsies. It is a true emergency requiring IV antibiotics and surgical consultation.

You treat the patient with neomycin/polymyxin drops, and the symptoms persist and possibly worsen a little after 5 days. The patient has no fever and no signs of cellulitis around the ear.

Question 20.2.4 Of the following possibilities, which is the **LEAST** likely to explain her persistent symptoms?

- A) Resistant organisms
- B) Noncompliance with medical recommendations
- C) Misdiagnosis of otomycosis
- D) Development of contact dermatitis

Answer 20.2.4 The correct answer is “A.” Several things could explain her persistent symptoms. First, the patient should be questioned regarding compliance. Is she still swimming despite advice to the contrary? Is she using the drops at least TID and letting them soak into her ear? Another issue is the development of an allergic reaction, especially in response to neomycin (up to 35% of patients treated chronically with topical neomycin develop a dermatitis). Patients may also “fail” treatment for otitis externa due to misdiagnosis. Otomycosis, a fungal infection of the auditory canal, causes erythema, discharge, itching, and sometimes pain. With respect to “A,” treatment failures due to antibiotic resistance are uncommon, and as noted above, antibiotics are not even necessary in the treatment of most cases of otitis externa.

On examination, you notice fine, white, cotton-like fibers filling the ear canal along with the other debris. The examination is otherwise unchanged.

Question 20.2.5 What is your next step?

- A) Admit for intravenous (IV) antibiotic and antifungal therapy
- B) Clean the ear canal under direct otoscopy and add oral amoxicillin/clavulanate to her medication regimen
- C) Clean the ear canal under direct otoscopy and add topical clotrimazole 1% to her medication regimen
- D) Order CT or MRI of the head and neck to rule out abscess
- E) Refer to an otolaryngologist

Answer 20.2.5 The correct answer is “C.” On examination, you have identified signs of otomycosis. It could be that the otomycosis was present initially or developed in the interval with antibiotic administration. Otomycosis is usually due to *Aspergillus*; *Candida* only represents 10% to 20% of cases. Thorough debridement of the external ear canal is an important part of therapy. A topical antifungal that is active against *Aspergillus* is recommended (e.g., clotrimazole, miconazole, and nystatin).

HELPFUL TIP:

Ear wicks can be a helpful tool to aide in delivery of medication and to prevent canal stenosis, but they must be removed/changed 3 to 5 days after placement.

► **Objectives: Did you learn to ...**

- Identify bacterial pathogens implicated in otitis externa?
- Diagnose and treat a patient with otitis externa?
- Recommend prevention strategies for otitis externa?
- Determine why treatment for otitis externa may fail?

► CASE 20.3

A 59-year-old male presents with a 3-week history of hoarseness. He denies sore throat or heartburn. He has had no fevers, night sweats, or weight loss. When he initially presented a week ago, your partner treated him empirically for postnasal drainage. He smokes two packs of cigarettes per day and drinks alcohol daily. On examination, his vital signs are normal. His voice sounds husky. You find no other abnormalities (besides the burn holes in his shirt and the pint of whisky in his back pocket).

Question 20.3.1 The best next step in the management of this patient is:

- A) Empiric antibiotic treatment
- B) Empiric proton pump inhibitor treatment
- C) Laryngoscopy
- D) Esophagogastroduodenoscopy (EGD)
- E) Neck MRI

Answer 20.3.1 The correct answer is “C.” The first concern is to rule out malignancy, and a thorough head-and-neck examination is warranted. Laryngoscopy is a straightforward office procedure frequently performed within a few minutes using a flexible laryngoscope or mirror. If the equipment and expertise are not available in your office, the patient should be referred to an otolaryngologist. Although there are no firm guidelines, some authors recommend laryngoscopy after 2 weeks of hoarseness in patients who are at risk (older patients and those who have a history of tobacco and alcohol use). Since laryngoscopy is such an available, low-cost, low-risk procedure, it is hard to justify postponing it for any patient at risk for malignancy. Therefore, “A” and “B” are incorrect, as further empiric medication trials will only delay laryngoscopy. Besides, antibiotics are not indicated for the lone symptom of hoarseness. In other instances (e.g., low-risk patient with heartburn and hoarseness), empiric proton pump inhibitor therapy may be more practical, since gastroesophageal reflux is a common cause of hoarseness. “D” is incorrect. In this case, laryngoscopy is preferred to EGD. Finally, “E” is incorrect. Neck MRI is not indicated in the initial evaluation of hoarseness, but it might be used for follow-up after laryngoscopy or to investigate a neck mass.

Question 20.3.2 All of the following are potential causes of hoarseness EXCEPT:

- A) Vocal cord mass
- B) Infectious laryngitis
- C) Hypothyroidism
- D) Lung malignancy
- E) A vow of silence

Answer 20.3.2 The correct answer is “E.” Far from being a cause of hoarseness, voice rest is often recommended for patients with hoarseness due to overuse (e.g., singers). All of the other options are known to cause hoarseness. Of particular note is “C”: hypothyroidism can result in an accumulation of connective tissue

elements, basically myxedema, in the vocal cords. Intrathoracic processes such as lung cancer can present with hoarseness (see “Helpful Tip” below).

Characterizing the nature of the patient’s hoarseness can narrow the differential diagnosis. The voice changes may be further characterized as breathy, low-pitched, strained, tremulous, or hoarse. A “breathy” voice may be seen with vocal cord paralysis, abductor spasm, or functional dysphonia. “Low-pitched” voice changes might be due to edema (seen in smokers), vocal abuse, reflux laryngitis, vocal cord paralysis, or muscle tension dysphonia. A “strained” voice may occur with adductor spasm, muscle tension dysphonia, or reflux laryngitis. A “tremulous” voice occurs in parkinsonism, essential tremor, spasmodic dysphonia, or muscle tension dysphonia. A “hoarse” voice may be due to vocal cord lesions, muscle tension dysphonia, and reflux laryngitis. Vocal fatigue (loss of volume over time) may also be noted (especially during presidential campaigns) and is often caused by muscle tension dysphonia, vocal cord paralysis, reflux laryngitis, or vocal abuse. However, one cannot eliminate a cause of hoarseness based on these characteristics.

HELPFUL TIP:

The intrinsic muscles of the larynx (the muscles that make the vocal cords move) are innervated by the recurrent laryngeal nerve, a branch of the vagus nerve (cranial nerve X). The cricopharyngeus muscle, essential to changing vocal pitch (i.e., necessary for singing), is the exception as this is innervated by the superior laryngeal nerve (another branch of CN X). The superior laryngeal nerve also provides sensation to the glottis. In addition to being fun and interesting medical trivia, knowing the innervation of the laryngeal muscles is important because chest malignancy, aneurysms, complications of thoracic surgery, etc., can potentially present with hoarseness.

On laryngoscopy, you notice a mass lesion on the right vocal cord. You refer the patient to an otolaryngologist. The patient asks if you think that the mass is cancer. Because you are compassionate and also not entirely certain, you avoid saying, “Oh, heck yeah. That’s cancer all right.” You try to be more optimistic.

Question 20.3.3 However, you want to remind him of risk factors for laryngeal cancer, which include all of the following EXCEPT:

- A) Tobacco smoking
- B) Alcohol use
- C) Epstein–Barr virus (EBV)
- D) Family history of head-and-neck cancers
- E) Male sex

Answer 20.3.3 The correct answer is “C.” EBV infection is associated with the development of nasopharyngeal cancer, not laryngeal cancer. Additionally, EBV infection has been associated

with Burkitt lymphoma (children in Africa), Hodgkin disease, and non-Hodgkin lymphoma. Tobacco and alcohol use are independent risk factors for the development of most types of head-and-neck cancers (oral, laryngeal, etc.), and the two substances may act synergistically in the promotion of these cancers. A family history of head-and-neck cancer has a weaker association, but the association is still present. Males are two to four times more likely to have head-and-neck cancers compared with females. These risk factors sound a lot like our patient.

Question 20.3.4 If this patient is found to have cancer, what pathologic variant is most likely?

- A) Adenocarcinoma
- B) Squamous cell carcinoma
- C) Schneiderian papilloma
- D) Neuroblastoma

Answer 20.3.4 The correct answer is “B.” Upon pathologic examination, the great majority of head-and-neck cancers are found to be squamous cell carcinomas. Adenocarcinoma may arise from the gastrointestinal tract and could be seen on laryngoscopy but would rarely occur on the vocal cords. Schneiderian papillomas (“C”) are polyps that arise from the nasal and sinus mucosae, are associated with HPV, and may transform into carcinomas. Neuroblastomas (“D”), which arise from the sympathetic nervous system, rarely occur in the head-and-neck region.

During your examination of the oral cavity, you also encountered a small, white, indurated plaque on the lateral and ventral surfaces of the tongue. The plaque was not able to be scraped off with a tongue blade (see Fig. 20-1).

Question 20.3.5 This lesion is most appropriately described as:

- A) Squamous cell carcinoma
- B) *Candida albicans*
- C) Leukoplakia
- D) Geographic tongue
- E) Aphthous ulcer

Answer 20.3.5 The correct answer is “C.” Primary leukoplakia is a premalignant lesion of the oral cavity and oropharynx (about 10–30% will progress to cancer over 10 years). It occurs in response to trauma and/or exposure to irritants and carcinogens, having an especially strong association with smokeless tobacco (e.g., “snuff,” “chew”) use. In fact, the lesion **could** be squamous cell carcinoma (“A”), and it should be biopsied. However, it would be premature to diagnose the patient with squamous cell carcinoma, and the lesion is more accurately described as leukoplakia. “B,” *C. albicans* lesions, may look just like leukoplakia (white plaques on oral mucosa with an erythematous base and bleeding once scraped), but you should be able to scrape the plaques off with a tongue blade (although thrush can be remarkably adherent and may cause some bleeding). A trial of antifungal therapy may be appropriate if the lesion is low-risk and you suspect thrush but cannot scrape it

FIGURE 20-1. From Usatine RP et al., eds. *Color Atlas of Family Medicine*. 2nd ed. New York: McGraw-Hill; 2013. Courtesy of Richard P. Usatine, MD.

off; but the patient needs close follow-up for serial monitoring. “D,” geographic tongue, is so named because of the meandering white-bordered patches that occur on the dorsum of the tongue. It is most often asymptomatic, and the lesions vary in shape (or completely resolve) over time. Finally, “E,” an aphthous ulcer, is just that—an ulcer, not a plaque. You should not confuse leukoplakia for an aphthous ulcer.

HELPFUL TIP:

No interventions have been shown to be useful in promoting the regression of leukoplakia.

HELPFUL TIP:

Increasingly, a history of human papilloma virus (HPV) infection is being recognized in oropharyngeal cancers (tonsils and base of tongue). As much as 70% of these cancers, usually squamous cell carcinomas, may be caused by HPV infection. HPV type 16 and 18 carries the strongest association with head-and-neck cancers and are covered by modern vaccines. These tumors generally present in younger patients without common risk factors for head-and-neck cancer (heavy tobacco/alcohol use), typically as a neck mass and possible tonsil/tongue base ulcer. HPV vaccination is expected to reduce the incidence of oropharyngeal cancers in future generations—just one more reason to call the HPV vaccine an “anticancer” vaccine and not a “safer sex” vaccine.

You receive a letter from the otolaryngologist stating the patient does indeed have squamous cell carcinoma of the larynx. The patient will be seen in consultation with an oncologist and presented at tumor board. His treatment may consist of surgery, chemotherapy, and/or radiation. Unfortunately, he lost the roll of the cosmic dice.

► **Objectives: Did you learn to ...**

- Generate a differential diagnosis for hoarseness of voice?
- Evaluate a patient with a voice complaint?
- Identify oral lesions, particularly leukoplakia?
- Recognize important issues in the prevention and treatment of head-and-neck cancers?

► **CASE 20.4**

A 61-year-old man presents to your office complaining that over the past few months he cannot seem to understand what people are saying when they are standing to his left side. He also has episodes of “dizziness,” that last hours, unchanged with position change. He denies nausea and vomiting. He worked for 30 years in a factory and has had bilateral tinnitus for the last 10 years. He has had no previous hearing problems or evaluation. His past medical history is significant for CAD and hypertension. He takes atenolol, atorvastatin, chlorthalidone, and aspirin. There is no family history of ear disease. On examination, both ears are normal in appearance. Weber test is best heard by the patient on his right side (remember that his hearing loss is on the left). Rinne test on both sides was negative (air conduction was greater than bone conduction).

Question 20.4.1 These findings are consistent with which type of hearing loss on the left?

- A) Conductive
- B) Sensorineural
- C) Mixed
- D) Selective
- E) Unable to tell

Answer 20.4.1 The correct answer is “B.” Hearing can be assessed in the office using the Weber and Rinne tests. The Weber test is performed by putting the tuning fork on the forehead and seeing if the sound lateralizes to one side or the other. In conductive hearing loss (“A”), the sound will be **louder** (i.e., the test will lateralize) to the “bad” side (e.g., the side with wax occluding the canal, middle ear effusion, otosclerosis). However, in sensorineural hearing loss, the sound will lateralize to the “good” side (e.g., the side not affected by a hearing problem).

The Rinne test is performed by comparing bone conduction (on the mastoid) to air conduction. Patients will notice poor air conduction versus bone conduction if there is a conductive hearing loss. Normal Rinne tests in both ears suggest that neither ear has **conductive** loss. Our patient (or more likely his family) complains about decreased hearing on the **left** and the Weber test lateralizes to the **right**, and these findings point to a problem with sensorineural hearing loss in the **left** ear.

Question 20.4.2 Which of the following is LEAST likely to be responsible for this patient’s hearing loss?

- A) Ménière disease
- B) Vestibular schwannoma (acoustic neuroma)
- C) Presbycusis

- D) Otosclerosis
- E) Noise exposure

Answer 20.4.2 The correct answer is “D.” Otosclerosis is a bony remodeling that involves the stapes and leads to a **conductive** loss. Your patient has a sensorineural hearing loss. Ménière disease (“A”) presents with the classic triad of fluctuating low-frequency hearing loss, tinnitus, and vertigo. These manifestations may be temporally separated with hearing loss, tinnitus, and vertigo occurring at different times. Patients with Ménière disease will note aural fullness, which resolves with the onset of vertigo. Typically, the vertigo will last for minutes (at least 20 minutes by definition) to hours. “B” is true. Sensorineural hearing loss can also be caused by a vestibular schwannoma (a benign tumor that arises from cranial nerve VIII), and symptoms include unilateral hearing loss, tinnitus, imbalance, and vertigo. “C,” presbycusis, is one of the most common causes of sensorineural hearing loss and is often thought of as the “normal” age-related hearing loss. Presbycusis manifests as an inability to hear high frequencies. This leads to problems with speech discrimination, especially in noisy environments. It is typically symmetrical and may be associated with tinnitus. However, it may be unilateral, especially in those who have one ear turned toward noisy equipment in their job (e.g., farmers driving tractors and having one ear closer to the engine, hunters with one ear cocked toward the gun). See Table 20-2 for some causes of conductive and sensorineural hearing loss.

Question 20.4.3 What is the next step in the evaluation of this patient?

- A) Audiogram
- B) Brainstem evoked responses
- C) MRI
- D) Tympanogram

Answer 20.4.3 The correct answer is “A.” An audiogram can further define the air versus bone conductance relationship, word understanding scores, and define the frequency pattern of hearing loss. Brainstem-evoked responses evaluate the neural pathways of hearing and, along with MRI, could be useful if a tumor or retrocochlear lesion was suspected. A tympanogram,

TABLE 20-2 CAUSES OF CONDUCTIVE AND SENSORINEURAL HEARING LOSS

Conductive Hearing Loss	Sensorineural Hearing Loss
Trauma: ossicle disruption, TM perforation	Presbycusis
Cerumen in the canal	Ménière disease
Otosclerosis	
Barotrauma	Stroke
Otitis media	Tumor (e.g., acoustic neuroma)
Middle ear effusion	Infection (e.g., syphilis, CMV, etc.)

which evaluates mobility of the TM, might be useful if a conductive hearing loss were suspected.

HELPFUL TIP:

Brainstem-evoked potentials measure how long it takes an auditory signal to reach the brain stem. If a vestibular schwannoma (acoustic neuroma) is present, the brainstem-evoked potential will be prolonged. However, the false-negative rate is up to 30%, and brainstem-evoked potentials have been all but replaced by high-resolution MRI in the diagnosis of vestibular schwannoma.

The audiogram confirms sensorineural hearing loss in the left ear. Because of the associated symptoms of vertigo, you order an MRI brain to rule out a vestibular schwannoma, and the results are negative. The patient continues to have episodes of vertigo, and the hearing loss on his left side persists. When probed further, he does in fact have an increase in tinnitus during his vertiginous episodes.

Question 20.4.4 You should consider all of the following treatments for this condition EXCEPT:

- A) Salt, caffeine, and tobacco restriction
- B) Diuretics (e.g., hydrochlorothiazide)
- C) Intracochlear injection of gentamicin
- D) Labyrinthectomy or endolymphatic sac shunt
- E) H₂-blockers (e.g., cimetidine)

Answer 20.4.4 The correct answer is “E.” The clinical picture now looks most like Ménière disease—a disease for which only symptom control is possible. Luckily not all patients with Ménière disease will experience worsening of their condition over time, and up to 90% are able to maintain normal daily activities with optimal medical management. Few patients progress to debilitating disease. The mainstays of therapy include diet/lifestyle modification and diuretics. Outside the United States, betahistine, an H₁-blocker, is commonly used (to theoretically reduce endolymphatic hydrops), but H₂-blockers have no role in therapy. A more aggressive approach is indicated in patients with more severe disease, and this might include intracochlear gentamicin (to kill the nerve and reduce vertigo), labyrinthectomy, vestibular neurectomy, or endolymphatic sac shunt.

HELPFUL TIP:

Treating Ménière disease can be problematic. Studies of this condition are frequently of poor quality with a significant placebo effect (including the studies of diuretics and betahistine). This, along with spontaneous remissions and exacerbations, limits the usefulness of data about treatment.

HELPFUL TIP:

Things to remember about tinnitus: It can be caused by a number of medications including NSAIDs, calcium

channel blockers, diuretics, etc. It can rarely be caused by a vascular lesion (bruits, A-V shunts, etc.). Other causes include TMJ syndrome, Eustachian tube dysfunction, and—most commonly—sensorineural hearing loss (especially presbycusis).

► Objectives: Did you learn to ...

- Evaluate a patient with hearing loss?
- Describe differences between conductive and sensorineural hearing loss?
- Generate a differential diagnosis for hearing loss?
- Diagnose and treat a patient with Ménière disease?

QUICK QUIZ: PERIPHARYNGEAL INFECTION

A 7-year-old female is brought to your office by her concerned parents. Over the last 24 hours, the patient has developed pain in her mouth, drooling, and fever. She refuses to eat. On examination, she is febrile and slightly tachycardic. The sublingual, submandibular, and submental spaces are swollen, tender, and are “woody” bilaterally. The tongue is elevated in the mouth. There are no ulcerations. Her respirations are normal, and her lung sounds are clear.

What is the next step in the evaluation and management of this patient?

- A) Reassurance, oral rehydration, and analgesics
- B) Oral antibiotics
- C) MRI of the head and neck
- D) IV antibiotics
- E) Intubation and mechanical ventilation

The correct answer is “D.” This patient is presenting with classic signs and symptoms of Ludwig’s angina (related neither to angina nor to Ludwig von Beethoven). These include brawny edema, tenderness, and warmth in the submandibular region along with elevation of the tongue. Ludwig’s angina is a rare cellulitis of the bilateral submandibular, sublingual, and submental spaces. The most common cause is from an abscessed tooth, but may also occur from a piercing, mandible fracture or salivary stone. **The status of the patient’s airway needs urgent attention** as the infection of the submandibular space may rapidly spread to the parapharyngeal space resulting in airway compromise. Consideration of emergent intubation is important, but this patient is stable, and her airway appears patent; therefore, “E” is incorrect. Even so, patients should be monitored closely for airway issues. “A” and “B” are incorrect because patients with Ludwig’s angina may experience rapid progression of symptoms and should be treated with IV antibiotics and admitted to the hospital. Finally, “C” is incorrect because Ludwig’s angina is a clinical diagnosis. Also, MRI may delay antibiotic treatment and is unlikely to be of any value, unless you suspect the presence of an abscess, but even then, CT would be the examination of choice. Surgical intervention may be necessary.

**HELPFUL TIP:**

Trismus is usually absent in Ludwig's angina as opposed to peritonsillar abscess, etc.

▶ CASE 20.5

A 30-year-old man comes to your office complaining of a swollen neck. He noticed it after a bee sting 3 weeks ago on the right side of his anterior neck. The area has continued to enlarge. It is no longer tender. It was erythematous after the nick, but the redness has resolved. He notes no other symptoms. On examination, you find a 2-cm firm, somewhat tender, enlarged lymph node in the right anterior cervical chain. The node is mobile, non-fluctuant, and without surrounding erythema. There is shotty anterior and posterior cervical adenopathy in addition to the larger lymph node described. You find neither splenomegaly nor lymphadenopathy of the supraclavicular, axillary, and inguinal regions.

Question 20.5.1 What elements of the presentation make malignancy LESS likely?

- A) The node is freely mobile
- B) The node is only 2 cm
- C) The node is associated with trauma (bee sting 3 weeks ago)
- D) The node is tender
- E) All of the above help to rule out malignancy

Answer 20.5.1 The correct answer is "A." Non-malignant nodes are generally *less than* 1 cm in size, freely mobile, and rubbery in consistency. Malignant nodes tend to be larger, rock-hard in consistency, and fixed to adjacent structures. Remember that pain in a node, "D," is not always indicative of an inflammatory or benign process. Hemorrhage into, or necrosis of, a malignant node can cause capsular distention leading to pain. "C" is of particular note. This patient's bee sting was quite a while ago and is unlikely to be a useful part of the history unless there is infection or ongoing inflammation. Patients will often attribute a physical malady to something in their lives whether or not it makes sense from a biological and medical perspective (one of us had a patient who swore that his purulent sputum was because his lungs were connected to his gallbladder). Of course, lymphadenopathy is not the only source of neck masses. See Table 20-3 for the differential diagnosis of neck masses in adults.

Question 20.5.2 What is the most appropriate next step in the management of this patient?

- A) Empiric antibiotics
- B) Observation for 2 weeks
- C) Open biopsy of the node
- D) Fine needle aspiration of the node
- E) Incision and drainage

Answer 20.5.2 The correct answer is "B." According to the Clinical Practice Guidelines published in 2017 (*Journal of*

Otolaryngology—Head and Neck Surgery, Vol. 157), patients with lymphadenopathy and without symptoms of malignancy (e.g., fever, night sweats, and weight loss) can be observed for 2 weeks. The patient should be reassessed at 2 weeks, and if the lymphadenopathy is not resolved, the patient should be referred for neck CT or open biopsy or fine needle aspiration (FNA). "A," empiric therapy with antibiotics, is possibly correct if you suspect a lymphadenitis or a bacterial infection causing secondary lymphadenopathy. However, in our patient, there are no signs of infection, arguing against lymphadenitis.

Question 20.5.3 Which of the following tests is NOT helpful in arriving at a diagnosis in a patient with GENERALIZED lymphadenopathy?

- A) CBC
- B) Chest radiograph
- C) Glucose, BUN, creatinine
- D) HIV
- E) Heterophile antibody

Answer 20.5.3 The correct answer is "C." Glucose, BUN, and creatinine are not likely to help you with the diagnosis of generalized lymphadenopathy. Generalized lymphadenopathy in primary care is malignant approximately 1% of the time. After a period of observation, the workup should proceed in stages. First step: CBC, chest radiograph. Second step: PPD, HIV, syphilis test (RPR or other), ANA, heterophile antibody. Final step:

TABLE 20-3 DIFFERENTIAL DIAGNOSIS OF NECK MASS IN ADULTS

Congenital Anomalies

- Lateral neck: branchial cysts and fistulae, cystic hygromas, dermoids
- Central neck: thyroglossal duct cyst, thyroid masses, thymic rests, dermoids

Infection/Inflammation

- Mononucleosis
- Tuberculosis
- Toxoplasmosis
- Cat-scratch disease (*Bartonella henselae*)
- Staphylococcus
- Streptococcus
- Other viral, bacterial, and fungal infections
- Sialadenitis
- Abscess
- Inflammatory or reactive lymphadenopathy

Neoplasm

- Benign masses: lipoma, hemangioma, neuroma, fibroma
- Malignant masses: mucosal head-and-neck cancers, lymphoma, thyroid cancer, salivary gland cancer, sarcoma, distant metastases

Trauma

- Hematoma (acute or fibrosed)
- Pseudoaneurysm
- AV fistula

Idiopathic and Others

- Metabolic: gout, CPPD (pseudogout)
- Inflammatory pseudotumor
- Castleman disease (a benign lymphoproliferative disorder)
- Kimura disease (a chronic subcutaneous inflammatory condition, cause unknown)

biopsy. Use your clinical judgment to determine the extent of testing necessary in any individual case.

HELPFUL TIP:

Just like in real estate, lymph nodes are all about location, location, location. Supraclavicular nodes are malignant up to 50% of the time in those older than 40 years.

HELPFUL TIP:

Benign lymphadenopathy is common in young children. In patients younger than 5 years presenting for a health maintenance examination, up to 44% have palpable lymph nodes. Occipital and posterior auricular nodes are common in infants but not in children older than 2 years of age.

► Objectives: Did you learn to ...

- Describe features of malignant and non-malignant lymph nodes?
- Evaluate a patient with lymphadenopathy?

► CASE 20.6

A 42-year-old businesswoman presents to your office with the chief complaint of 2 days of headache, sore throat, and nasal congestion productive of green mucus. She denies any fever, contact with ill persons, and gastrointestinal symptoms, but she does have a history of seasonal allergies. On examination, she has completely normal vital signs. Her posterior oropharynx has mild erythema and postnasal drainage but no exudates. There is nasal mucosal erythema and swelling with clear rhinorrhea. Her neck is supple with no adenopathy. Respirations are clear.

Question 20.6.1 The most likely agent causing her symptoms and the most common cause of acute rhinosinusitis is:

- A) Rhinovirus
- B) *S. pneumoniae*
- C) *H. influenzae*
- D) *M. catarrhalis*
- E) Norwalk virus

Answer 20.6.1 The correct answer is “A.” Viruses are the most common cause of URIs (colds or rhinosinusitis). Up to 50% of colds are caused by the 100 different serotypes of rhinoviruses. Other viruses that commonly cause “colds” include: coronaviruses, RSV, parainfluenza, and influenza. Norwalk virus typically causes an intestinal illness. The bacteria listed (“B”–“D”) are also associated with infections of the upper respiratory tract, particularly otitis, and sinusitis, but are much less common than viruses.

HELPFUL TIP:

Resident bacteria in the nasopharynx include *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. While most causes of sinusitis are viral, these bacteria make up the great majority of organisms causing bacterial sinusitis. Sinusitis may also result from extension of dental root infection into the sinus cavity. These infections are caused by microaerophilic and anaerobic bacteria.

Question 20.6.2 Initial treatment for this patient includes:

- A) Oral decongestants
- B) NSAIDs
- C) Oral antibiotics
- D) A and B
- E) A and C

Answer 20.6.2 The correct answer is “D.” Most cases of rhinosinusitis are viral and need only symptomatic treatment. Analgesics and systemic and nasal decongestants are reasonable options. Other treatment options include nasal saline irrigations, ipratropium nasal spray (which will also help to decrease mucus production), nasal steroids (should be administered on a daily basis for several weeks to see improvement ... of course by then the cold is better anyway), and first-generation antihistamines with anticholinergic activity (e.g., diphenhydramine).

HELPFUL TIP:

Yeah, yeah ... we know. The party line is that first-generation antihistamines are not useful for rhinorrhea from a URI. However, this is technically incorrect. A Cochrane review showed some benefit of first-generation antihistamines and some effect of combination products (*Cochrane Database Systematic Rev.* 2003;3; 2012;2.).

Question 20.6.3 Which of the following does NOT increase the likelihood that a patient has a bacterial sinusitis?

- A) Persistence of symptoms for greater than 7 days
- B) Thickened nasal mucosa or effusion on CT scan
- C) Maxillary tooth pain
- D) Unilateral maxillary sinus pain

Answer 20.6.3 The correct answer is “B.” Radiography is particularly poor at differentiating bacterial sinusitis from a simple URI. Thickened nasal mucosa is only 40% to 50% specific for sinusitis (flip a coin, it’s cheaper). The other problem with imaging is that essentially all patients with a URI will have fluid in the sinuses. Clinical criteria are more helpful in predicting the presence of bacterial sinusitis; thus, “A,” “C,” and “D” are correct. Additionally, a biphasic course, sometimes referred to as “double sickening,” is a helpful predictor of bacterial sinusitis—if the patient initially improves and then gets worse, consider a secondary infection. The color of nasal drainage is meaningless. **Thick, green, nasal drainage does not necessarily mean**

that bacteria are present. Secretions will turn green with a viral illness, as with anything else that concentrates protein in the mucous (e.g., anticholinergics).

HELPFUL TIP:

A viral URI can last up to a month. In fact, 25% of patients with a URI are still symptomatic at 14 days, so duration of symptoms **alone** is not diagnostic of bacterial sinusitis. So, don't tell your patient that she will be better in 4 to 5 days. Give your patients realistic expectations: 10 to 14 days.

The patient is initially convinced that only antibiotics will make her better. Through skillful negotiation (and a hefty dose of haloperidol), you manage to avoid prescribing antibiotics for what you strongly suspect is a viral infection. Two weeks later, the patient returns. Initially, she improved, but then she developed subjective fever, facial pressure, maxillary tooth pain, and copious green nasal drainage. You now suspect that a bacterial sinusitis has developed. The look on her face says, "I told you so ... and I am not taking any more of that haloperidol stuff." She has no drug allergies.

Question 20.6.4 Which of the following treatments do you offer as first-line therapy?

- A) Azithromycin
- B) Trimethoprim/sulfamethoxazole
- C) Prednisone
- D) Ceftriaxone
- E) Amoxicillin/clavulanate

Answer 20.6.4 The correct answer is "E." According to 2012 Infectious Diseases Society of America guidelines addressing the treatment of acute bacterial sinusitis, amoxicillin/clavulanate should be used as first-line treatment for adults and children—although the evidence is weak versus simple amoxicillin. Of note, in 2015 the AAFP endorsed the American Academy of Otolaryngology—Head and Neck Surgery guidelines that promote amoxicillin with or without clavulanate as first-line therapy in suspected bacterial sinusitis. Previously trimethoprim/sulfamethoxazole ("B") would have been the best choice, but there is increasing resistance. Azithromycin ("A") is not recommended due to resistance patterns and poor penetration into the sinuses. "C" is incorrect. There is no reason to prescribe steroids here. "D," ceftriaxone, might be considered in cases of treatment failure, but oral antibiotics are generally preferred. Per guidelines, doxycycline is recommended as second-line therapy, followed by cefixime or cefpodoxime +/- clindamycin. Respiratory fluoroquinolones will work but use at your own peril; there are several FDA warnings advising not to use these for simple sinusitis. Of course, you should continue to recommend that the patient use decongestants and other symptom-oriented therapies.

HELPFUL TIP:

Even with bacterial sinusitis, the NNT for antibiotics to benefit one patient is 9. Most patients are getting no

benefit from your careful ministrations—or knee-jerk reaction to prescribe antibiotics (whichever applies ...).

HELPFUL TIP:

Remember that when treating sinusitis you are basically treating an abscess. Draining it is the key: use topical oxymetazoline (Afrin) for limited periods, systemic decongestants, and saline irrigation.

HELPFUL TIP:

All noses that run are not infectious. Remember allergic rhinitis, vasomotor rhinitis (now termed idiopathic rhinitis), etc. Idiopathic rhinitis is an exaggerated response to stimuli such as cold, recumbency, and air pollution. It can be differentiated from allergic rhinitis by the absence of other allergic symptoms (itching, eye involvement, perhaps asthma, etc.) and the absence of eosinophils on Hansel stain of mucus (who looks at snot under a microscope anyway?). Other considerations include rhinitis medicamentosa as a result of withdrawal from topical vasoconstrictors (e.g., oxymetazoline (Afrin), cocaine).

► Objectives: Did you learn to ...

- Describe the most common pathogens involved in rhinosinusitis?
- Recognize clinical signs and symptoms that are more consistent with bacterial sinusitis than viral rhinosinusitis?
- Prescribe treatment for viral and bacterial sinusitis?

► CASE 20.7

A 65-year-old male presents with dizziness that started a few days ago. He reports that he is otherwise healthy and takes no medications.

Question 20.7.1 Which of the following is the best question to ask him in order to elicit a better characterization of his dizziness complaint?

- A) "Is the room spinning round and round?"
- B) "Do you feel that you are going to faint?"
- C) "Can you describe the dizziness using any other words?"
- D) "Do you feel as though you are drunk?"
- E) "Are you really just drunk right now?"

Answer 20.7.1 The correct answer is "C." When exploring a complaint of dizziness, insist that the patient characterizes the nature of the dizziness further without using the word "dizzy." Is the room spinning? Do they feel light headed? Faint? Weak? This is a good time for that old technique learned in medical school but rarely used in practice: the open-ended question. There are

essentially four types of dizziness: vertigo, presyncope, imbalance (disequilibrium), and undifferentiated dizziness. Patients will usually come up with their own terminology that will allow you to categorize their dizziness into one of these four types. Issues with the vestibular system will result in a true vertigo. Vertigo is a hallucination of movement: something seems to be moving that isn't. It doesn't matter if the room is spinning, the patient is spinning, or the floor seems to be coming up toward the patient. It should be associated with nystagmus.

The patient describes a sensation of the room spinning, usually lasting less than a minute. Further, this sensation comes on in different positions and has led to a fall, which resulted in minor injuries. He denies any upper respiratory symptoms, fevers, hearing loss, or tinnitus. He sometimes feels nauseated with the dizziness but has not vomited. He first noticed the dizziness while in bed and rolling over, but it now occurs more frequently and in various positions. Sudden turning of the head definitely exacerbates his symptoms. It tends to be worse in the morning and better in the evening. You are comfortable calling this type of dizziness vertigo.

Question 20.7.2 Which of the following is LEAST likely to cause vertigo (in a general sense ... not in this particular patient)?

- A) Labyrinthitis
- B) Ménière disease
- C) Migraine aura
- D) Otitis media
- E) Perilymphatic fistula

Answer 20.7.2 The correct answer is "D." There are many causes of vertigo, but otitis media should not generally be thought of as one of them (or at least should be a diagnosis of exclusion). Labyrinthitis ("A") is usually caused by viral infection and results in severe vertigo that lasts for days. That said, in our experience, dizzy patients always expect an otoscopic exam, so looking in the ear may at least serve as a patient satisfier. Ménière disease ("B") results in episodic vertigo that lasts for minutes (at least 20 by definition) to hours. Migraine aura ("C") can present with vertigo as well as many other symptoms (e.g., scotoma, diplopia, blindness, and paresthesias). Perilymphatic fistula ("E") occurs when perilymph leaks through a tear in the oval window (secondary to a fall or barotrauma—including sneezing). It typically resolves on its own. Although a perilymphatic fistula often results in vertigo, it is a relatively uncommon cause of vertigo.

Question 20.7.3 Which of the following is the best next step in the diagnosis of this patient?

- A) Dix–Hallpike maneuvers
- B) Obtain blood for CBC, electrolytes, BUN, and creatinine
- C) MRI brain and brainstem
- D) CT brain
- E) Audiometry

Answer 20.7.3 The correct answer is "A." A complete evaluation of the patient with vertigo includes examination of the neurological and cardiovascular systems as well as the ears, eyes, nose, and throat. On physical exam, look for nystagmus. The Dix–Hallpike maneuver is designed to differentiate central from peripheral vertigo and can be a useful tool (more on this later ...). In order to perform the maneuver, quickly move the patient from a seated to a supine position, turning the head to the left or right, and observe for nystagmus. The patient is helped into a seated position, and the maneuver is repeated, turning the head to the other side. If nystagmus occurs within 30 seconds of performing the maneuver, it is considered a positive test. "B" is incorrect. Laboratory tests are rarely helpful. "C" and "D" are not correct because neuroimaging should only be performed if the history and/or examination indicate the need for it. In this case, the examination is not even complete yet! Likewise, audiometry (although helpful in the diagnosis of Ménière disease) is premature.

Dix–Hallpike maneuver is positive with rotation of the head to the left. The rest of the physical examination is unremarkable. The patient gets vertiginous and then it resolves in less than 1 minute.

Question 20.7.4 Given the history and examination, the most likely diagnosis in this patient is:

- A) Labyrinthitis
- B) Benign paroxysmal positional vertigo (BPPV)
- C) Vertebrobasilar stroke
- D) Motion sickness
- E) Cerebellar stroke

Answer 20.7.4 The correct answer is "B." The history of episodic, positional vertigo and the positive Dix–Hallpike maneuver makes BPPV the most likely diagnosis. Note that the Dix–Hallpike maneuver is not specific for BPPV. The Dix–Hallpike maneuver is designed to differentiate central from peripheral vertigo. In this case, the history is probably the most important aspect in making the diagnosis. BPPV is more common in older patients but can occur at any age. Women, especially peri-menopausal, are more commonly affected than men. BPPV is caused by calcium stone deposition in the posterior semicircular canal. BPPV tends to be worse in the morning and better toward evening because, being of peripheral origin, the vertigo response fatigues as the day goes on (see Table 20-4). The other diagnoses listed are less likely. However, "C" and "E" deserve special mention. Stroke should be considered in any patient presenting with sudden onset, persistent vertigo, and risk factors (e.g., hypertension and atrial fibrillation, age, etc.). In general, there should be other findings such as diplopia, dysmetria, and ataxia; only 1% of patients with a stroke have vertigo (*Neurol Clin.* 2012;30(1):61–74). However, not every elderly patient with vertigo needs an MRI. If the history is consistent with BPPV, then neuroimaging is not necessary.

**HELPFUL TIP:**

"Past pointing" on finger-to-nose testing usually indicates a peripheral lesion. And, patients generally fall toward the side of peripheral dysfunction.

Question 20.7.5 For this patient with BPPV, the **LEAST** appropriate treatment at this time is:

- A) Prednisone
- B) Lorazepam
- C) Meclizine (Antivert)
- D) Rehabilitation exercises
- E) Dimenhydrinate (Dramamine)

Answer 20.7.5 The correct answer is "A." Steroids are not likely to improve symptoms in BPPV. Benzodiazepines, anticholinergics, and antihistamines have all been employed in treating the symptoms of BPPV but *should all be second-line therapies after rehabilitation and repositioning exercises*. Vestibular rehabilitation exercises, physical therapy, and physician-directed head positioning (e.g., Epley maneuvers to help reposition stones out of the posterior semicircular canal) may be successful. Most patients will improve with time, although many will have relapses and can complete the Epley maneuver at home.

**HELPFUL TIP:**

Simply treating the patient with medications to suppress the vertigo *can actually prolong the course of the disease*. The brain needs to learn to adapt to the signal causing vertigo. If your brain were talking (a scary prospect), it would say, "OK, I am not falling. I can ignore that input." Suppressing the vertigo delays this adaptation. However, medications may be necessary for symptom control in some patients. That said, your editors implore you to recommend or prescribe medications as a second- or third-line therapy, especially in the elderly patient who is at risk from the anticholinergic and sedative effects of these drugs.

Here are some easy associations with very common causes of vertigo:

- **Benign paroxysmal positional vertigo:** Frequently happens after trauma but can be spontaneous. Symptoms are brought on by rapid head movement, lasting **seconds to about a minute**, and are **fatigable** (repeat movement immediately afterward results in less severe symptoms). This is caused by displaced

otoliths most commonly into the posterior semi-circular canal from its home in the utricle. Clinical test: Dix–Hallpike maneuver. Treatment: Epley repositioning maneuvers. These can be performed in clinic or at home and may require multiple maneuvers. However, they may cure patient immediately.

- **Meniere disease:** Recurrent episodes of vertigo lasting minutes (at least 20) to hours, but not typically longer than 24 hours. **Vertigo is associated with sensorineural hearing loss.** Patient will describe decreased hearing at the time of the event in one ear. Hearing improves as the episode resolves, but over time/repeat episodes patients typically progressively lose low-frequency hearing. Pathophysiology is somewhat poorly understood, but described as endolymphatic hydrops, with a pressure imbalance between perilymph and endolymph in the inner ear. The thought is that as the pressure differential increases, it results in a small tear in the delicate membranes separating the compartments, and loss of the ion differential that allows the balance organ to function, which makes the ear think that it is spinning. Treatment: prevention involves salt restriction and diuretic therapy, acute episodic relief frequently with benzodiazepines. Ultimately in severe cases it may warrant referral to otolaryngologist for surgical intervention. Hearing aids and ultimately cochlear implants may be indicated.
- **Superior semi-circular canal dehiscence:** Fistula formed between the superior semi-circular canal and the intracranial space. Patients frequently experience seconds of vertigo with loud noise or pressure change in the ear. Nystagmus can be produced in clinic with pneumatoscopy. Associated commonly with obesity. Treatment: Referral to neuro-otologist for surgical repair.
- **Vestibular neuritis/labyrinthitis:** Most commonly viral but can be suppurative with a bacterial infection of the vestibule. Patients complain of debilitating vertigo lasting **days**. May be associated with purulent otitis media, but can have a normal ear exam/no hearing loss with viral labyrinthitis. Bacterial cases should be treated aggressively with myringotomy and antibiotic drops and otolaryngology involvement. Viral neuritis is frequently managed symptomatically.
- **Vestibular migraines:** Generally these have recurrent episodes of vertigo lasting hours, and may also have other typical migraine features such as aura and headache with photophobia. Generally these are treated with preventative/abortive migraine therapy.
- See Table 20-5 for a summary of causes of vertigo.

► **Objectives: Did you learn to ...**

- Describe types of dizziness?
- Generate a differential diagnosis for vertigo?
- Diagnose and treat a patient with BPPV?

TABLE 20-4 DIX–HALLPIKE MANEUVER

Suggestive of Peripheral Vertigo

- Delayed onset of nystagmus and symptoms
- Nystagmus always in same direction
- Vertigo reflex fatigable after multiple maneuvers
- Nystagmus suppressible by patient

Suggestive of Central Vertigo

- Nystagmus in multiple directions
- No latency to onset of nystagmus
- Reflex not fatigable

► **CASE 20.8**

A 15-year-old male wrestler presents to the ED with a nose-bleed and a swollen ear. He clearly did not win this round. Prior to coming to the ED, he held pressure to his nose for

TABLE 20-5 VERTIGO BY DURATION AND ASSOCIATED FINDINGS^A

Disease State	Duration of Vertigo	Timing of vertigo	Antecedent Event	Fatigable	Treatment	Notes
Barotrauma/ ruptured oval window	Variable	Worse in evening (from perilymph leak while upright, better in AM after recumbency)	Fall, diving	No	Referral to otolaryngology if not spontaneously resolving	Can make worse with pneumo-otoscopy (pump the eardrum to change pressure and will get perilymph leak)
BPPV	Seconds to minutes	Worst in morning (fatigues on repetition)	Perhaps mild trauma, often nothing	Yes	Epley maneuvers	
Drug related/ Alcohol	Variable	Related to time of ingestion	Ingestion	n/a	Remove offending agent	
Labyrinthitis	Days	Continuous or waxing/waning	Often URI but history of viral infection not always present	No	Steroids (variable effectiveness), antibiotics if bacterial	Debilitating vertigo, severe nausea and vomiting
Meniere disease	Minutes to hours (less than 24 hours)	Variable	None	No	Diuretics, low salt diet	Associated tinnitus, ear fullness, hearing loss
Posterior circulation stroke/TIA	Generally > 10–15 minutes (differentiate from BPPV which is seconds to a minute)	Variable	DM2, HTN, other risk factors for vascular disease	No	See Chapter 18	Only 1% of posterior strokes present with isolated vertigo
Vestibular migraine	Hours	Variable	Variable triggers (menstruation, stress, fatigue, acute illness, etc.)	No	As for migraine (Chapter 18)	May have migraine aura, headache, photophobia, etc.

^aAll should also have nystagmus.

30 minutes. He has had nosebleeds before, but none were this bad. When asked how much blood he lost, his father shrugs and says it was “all over the mat.” On examination, you see blood oozing slowly from the anterior nasal septum.

Question 20.8.1 Which of the following is a source of anterior epistaxis?

- A) Ethmoid artery
- B) Sphenopalatine artery
- C) Kiesselbach arterial plexus
- D) Palpatine artery

Answer 20.8.1 The correct answer is “C.” Kiesselbach plexus is a collection system involving several terminal arteries (anterior ethmoidal, greater palatine, and superior labial arteries) in the anterior nose. It is the most common site of nasal bleeding. Don gloves, retract the patient’s nasal tip, shine a light, and you will see it. The ethmoid and sphenopalatine arteries supply the posterior area of the nose, and bleeding from these sites is more difficult to control. Of special note is “D.” Emperor Palpatine, also known as “Darth Sidious,” converted Anakin Skywalker to the

Dark Side using hatred, anger, and lies (sounds like a contemporaneous political figure)—not epistaxis caused by an eponymous artery. Also, don’t confuse the Kiesselbach plexus with the Kessel Run, which the Millennium Falcon allegedly completed in under 12 parsecs.

Question 20.8.2 What is the best next step in managing this patient’s nosebleed?

- A) Continue to hold pressure against the septum
- B) Gently pack the anterior naris with gauze
- C) Spray the mucosal surface with oxymetazoline (Afrin)
- D) Chemical cautery with silver nitrate
- E) Any of the above can be used

Answer 20.8.2 The correct answer is “E.” Any of the options listed could be used alone or in combination to try to stop the bleeding. Generally speaking, over 90% of nosebleeds in healthy patients can be stopped by spraying oxymetazoline (Afrin) along the septum bilaterally and holding firm pressure along the soft/cartilaginous portion of the nose for 15 solid minutes (with no peeking!). If these methods are not successful, consider chemical

cautery (silver nitrate), topical tranexamic acid (*Acad Emerg Med.* 2017 Nov 10) or packing (“Rhino rocket,” etc.). A coagulopathy workup (e.g., CBC, PT/PTT) and otolaryngology consultation can be considered in select cases. Laboratory studies will rarely be helpful, though.

**HELPFUL TIP:**

If you pack a patient’s nose, plan on leaving the packing in place for 3 to 5 days. Also, prescribe anti-staphylococcal/streptococcal antibiotics to prevent a bacterial super infection/toxic shock syndrome while packing is in place.

With oxymetazoline and direct pressure, you were able to stop the bleeding. You now turn your attention to his left ear. You find a purplish, tender, fluctuant swelling at the left pinna.

Question 20.8.3 The best treatment for this condition is:

- A) Analgesics, protection, and observation
- B) Compressive dressing, using a headband (preferably that sweatband in your gym bag)
- C) Oral antibiotics
- D) Incision and drainage, leaving the wound open to drain and heal by secondary intention
- E) Needle drainage followed by compressive dressing sutured into the pinna

Answer 20.8.3 The correct answer is “E.” With a traumatic auricular hematoma/seroma, fluid collects between the perichondrium and underlying cartilage, predisposing the cartilage to loss of vascular supply and necrosis. In order to avoid “cauliflower ear” deformity, the hematoma or seroma must be evacuated via incision or needle drainage. However, you cannot stop there: a compressive dressing must then be sutured into the pinna, or the fluid is likely to re-accumulate. “B” is incorrect because compressive dressing alone is insufficient. “D” is incorrect only because it does not include compressive dressing. “A” and “C” are incorrect because taking these actions will delay definitive treatment—and antibiotics are not needed anyway. If the patient were to present late (10 days or more after the injury), he will not benefit from incision or needle drainage, and instead should be referred for otoplasty.

**HELPFUL TIP:**

Repeat after me, “The nose is not the release valve of the cardiovascular system.” Most nasal bleeding is venous and not directly related to elevated blood pressure, though long-term hypertension may cause vasculopathy predisposing to epistaxis.

**QUICK QUIZ: MOUTH SORES**

A 20-year-old female presents with three painful ulcerations on her inner lip and tongue. She has no other symptoms. Although she has never had such sores before, everyone else in her family has had similar mouth sores. She only smokes when drinking cheap wine coolers, which occurs about once per week. When asked about sexual activity, she shrugs and says, “My sex life is DOA. I’m the original Jane the Virgin.” She is afebrile, and her examination is otherwise unremarkable.

The most likely diagnosis is:

- A) Aphthous ulcers
- B) Behcet disease
- C) Crohn disease
- D) Gluten enteropathy
- E) Squamous cell carcinoma

The correct answer is “A.” This otherwise healthy young woman with a family history of “similar sores” most likely has aphthous ulcers or “canker sores.” The etiology of aphthous ulcers is not well understood, and they are alternatively explained as viral, autoimmune, genetic, traumatic, or due to chemical irritants or other processes (also, karmic retribution, divine punishment for sin, etc.). “B,” Behcet disease, is uncommon in the United States. It is thought to be an autoimmune disease, and it presents with recurrent oral and genital ulcerations and skin and eye lesions among other findings. “C” and “D” can both present with isolated oral ulcers but are less common than idiopathic aphthous ulcers, and one would also expect other GI symptoms. “E” is incorrect because it is highly unlikely that this young, healthy person has developed cancer ... in three places ... simultaneously. Finally, lupus pemphigoid, pemphigus, and multiple infections (e.g., Hand-Foot-Mouth, HIV, herpes, and syphilis) may present with oral ulcers.

▶ **CASE 20.9**

A 34-year-old male dentist presents to your office with a 1-week history of right facial weakness and a bit of tongue numbness. He states that he “just woke up this way one morning.” He would have come in sooner, but he was busy with his practice and he has felt fine. He has not noticed any other neurological symptoms. He denies pain, fever, or upper respiratory symptoms. He reports being healthy and taking no medications. On examination, his vital signs are normal. You note that his right eyebrow sags, as does the right corner of his mouth. He cannot close the right eye completely or raise his right eyebrow, and the right nasolabial fold is less prominent than the left. The remainder of the neurological examination is normal.

Question 20.9.1 The neurological finding in this patient that most suggests a cranial nerve process (as opposed to a central brain lesion) is:

- A) Normal strength in the upper extremities
- B) Inability to smile on the right

▶ **Objectives: Did you learn to ...**

- Evaluate and treat a patient with epistaxis?
- Treat a patient with auricular trauma?

- C) Inability to wrinkle the forehead
- D) Normal blood pressure
- E) Normal speech rate and rhythm

Answer 20.9.1 The correct answer is “C.” Partial sparing of the forehead muscles suggests a brain lesion because innervation of the forehead contains crossed fibers from both sides of the brain; a bilateral brain lesion is possible but unlikely. Thus, a dense paralysis is more likely to be peripheral (CN7) since all innervation is knocked out when this is involved. This patient’s entire right face, including the forehead, is paralyzed, which suggests a lower motor neuron (CN7) palsy. While “A” and “E” are found in a normal neurologic examination and are reassuring, they are not as helpful in isolating the location of the lesion to a lower motor neuron source. “B,” lower facial muscle weakness or paralysis, can occur with upper or lower motor neuron disease. “D,” normal blood pressure, is not helpful.

HELPFUL TIP:

Of note, taste alterations are not unusual in Bell’s palsy. The seventh nerve is involved in taste sensation on the anterior two-thirds of the tongue (chorda tympani nerve runs through the middle ear space). Patients may note a headache in the retroauricular area before the onset of weakness symptoms.

You tell the patient that you suspect he has Bell’s palsy. He asks what causes this problem.

Question 20.9.2 Which of the following is the most likely cause of this patient’s Bell’s palsy?

- A) Herpes virus
- B) Tick-borne illness
- C) Diabetes
- D) Adenovirus
- E) Idiopathic

Answer 20.9.2 The correct answer is “E.” Bell’s palsy is by definition idiopathic, with unknown causes. We know that it can be associated with diabetes or a recent upper respiratory tract infection, but an actual cause is still unknown. Most experts believe it may be caused by a viral infection or other inflammatory insult that results in swelling of the nerve and compression/vascular compromise in the narrow bony canal as it leaves the skull through the stylomastoid foramen. Lyme disease is occasionally implicated, but most commonly presents as a bilateral facial nerve weakness. Ramsay–Hunt Syndrome is a similar condition that is caused by activation of geniculate varicella zoster. Ramsey–Hunt, while similar to Bell’s palsy, is much more inflammatory and is associated with severe otalgia, a vesicular rash (usually in the ear canal/concha) and sensorineural hearing loss/vertigo. While the vast majority of Bell’s palsy patients will have a complete recovery, prognosis for facial function after Ramsay–Hunt syndrome is worse (45% chance of facial nerve synkinesis after Ramsay–Hunt).

HELPFUL TIP:

Bell’s palsy is more likely to occur in pregnancy, especially the last trimester and the first week postpartum.

Question 20.9.3 Which of the following treatments is most likely to benefit this patient?

- A) Acyclovir
- B) Prednisone
- C) Artificial tears and eye patching at night
- D) B and C
- E) None of the above

Answer 20.9.3 The correct answer is “D.” In a patient with Bell’s palsy and weakness to eye closure, good eye care and protection from trauma must be employed to prevent corneal damage (remember that this patient cannot close his right eye). There is strong evidence for starting high-dose oral steroids in Bell’s palsy. These are most efficacious if started in the first 72 hours but may still improve outcomes if started later. Antiviral therapy is recommended if a viral etiology is suspected (e.g., Ramsay–Hunt). In true Bell’s palsy, antiviral therapy alone is not helpful with several double-blind studies failing to show benefit. However, benefit has been demonstrated with combination therapy (corticosteroids PLUS antiviral therapy) if the patient has severe disease (cannot entirely close eye, disfiguring asymmetry). The bottom line is that steroids should always be used, and adding antivirals for *severe disease* is low-risk and may improve patient outcomes.

Question 20.9.4 The patient can expect which of the following?

- A) Complete resolution (~100% likelihood) with nearly zero risk of recurrence
- B) Likely resolution (>50% likelihood) with nearly zero risk of recurrence
- C) Likely resolution (>50% likelihood) with about 10% risk of recurrence
- D) High probability (~95% likelihood) of persistent paralysis

Answer 20.9.4 The correct answer is “C.” Most patients will recover (71% complete, 13% minor impairment with the rest having significant sequelae), but it may take months. If a patient with suspected Bell’s palsy has no improvement in symptoms after a few months, reconsider the diagnosis. Patients with complete paralysis are more likely to have persistent symptoms, whereas those with partial paralysis usually recover more quickly and completely. Surgical decompression is an option for *some* patients with Bell’s palsy. If a patient’s facial nerve is completely paralyzed (no discernible movement), they should be referred for electroneurography (ENoG)/EMG and otolaryngology consultation. If degeneration of nerve is greater than 90% on ENoG, there is evidence that surgical decompression will improve outcomes if performed within the first 2 weeks.

**HELPFUL TIP:**

Ramsay–Hunt syndrome is the name given to zoster oticus complicated by hemifacial paralysis. If identified early, antivirals may help the patient with Ramsay–Hunt syndrome. You may see blisters in the ear canal, in conjunction with sensorineural hearing loss/vertigo. These patients should be treated aggressively with corticosteroids and antivirals and should have an audiogram.

► **Objectives: Did you learn to ...**

- Differentiate Bell's palsy from a central lesion?
- Describe causes of Bell's palsy?
- Manage a patient with hemifacial paresis?

**QUICK QUIZ: OH, MY ACHING JAW**

A 30-year-old female presents with several months of pain and stiffness in her jaw. When asked to localize the pain, she points to the temporomandibular joints (TMJ) bilaterally. She notes that the pain is worse with stressful situations, driving, and chewing. Her husband complains that she grinds her teeth at night. She is otherwise healthy. On physical examination, you find palpable popping in the TMJs bilaterally, and the remainder of her examination is unremarkable.

You make all of the following recommendations EXCEPT:

- A) Start chewing gum daily
- B) Use ibuprofen as needed
- C) Use a bite block at night
- D) Learn relaxation techniques

The correct answer is "A." This patient's history is consistent with TMJ syndrome. In addition to those described in the case, symptoms of TMJ may include ear pain, headache, "sinus" headache, limited jaw mobility, and crepitus and tenderness on palpation of the joint. TMJ syndrome may occur unilaterally or bilaterally. No single therapy appears to have greater efficacy than any other, and many different interventions have been tried, although poorly studied. "A," increased use of the joint by chewing gum, is the exact opposite of what the patient should be doing. Jaw rest is important. All of the other interventions are reasonable. Also, you might recommend a softer diet, hot packs, and TMJ massage.

**HELPFUL TIP:**

The headache of TMJ may be felt in the midfacial region, retro-orbitally, or as an earache. Check for TMJ when patients present with these types of symptoms.

► **CASE 20.10**

A 22-year-old female presents to your office complaining of severe facial pain for the past 3 days. She has poor

dentition and you find that on examination, there is mandibular swelling and tenderness.

Question 20.10.1 All of the following are causes of mandibular area swelling EXCEPT:

- A) Submandibular duct stone
- B) Dental abscess
- C) Retropharyngeal abscess
- D) Ludwig angina
- E) Branchial cleft cyst

Answer 20.10.1 The correct answer is "C." Retropharyngeal abscesses generally are not visible but present with fever, throat pain, and symptoms due to swelling of the retropharyngeal space (dysphagia, drooling, odynophagia, and airway obstruction). All of the other options can cause swelling around the mandible.

Question 20.10.2 One of the diagnoses you are considering is parotitis. Which of the following is true regarding parotitis?

- A) You will only see mumps in science-denying, anti-vaccine, whack jobs
- B) Mumps can be associated with pain and inflammation of the meninges, pancreas, and gonads as well as the parotid glands
- C) Bacterial parotitis is mostly caused by pan-sensitive streptococcus and can be treated with penicillin
- D) Mumps is usually treated with IVIG

Answer 20.10.2 The correct answer is "B." Mumps can lead to inflammation of other tissues including the meninges, pancreas, and gonads (possibly leading to decreased fertility in males but not in females) and will occasionally require hospitalization. Thankfully, most people recover spontaneously with good supportive care, including NSAIDs and warm compresses. IVIG would be reserved for those with severe complications. "A" is incorrect. While the MMR vaccine is about 88% effective after two doses, this still leaves over 10% of the population susceptible to outbreaks. Therefore, you may see mumps in immunosuppressed patients as well as anyone who is more than 10 years out from their last vaccination. Bacterial parotitis ("C") is usually caused by *Staphylococcus aureus* and anaerobes. In the hospital setting, approximately 40% of the *Staphylococcus aureus* is methicillin resistant, so first-line therapy is usually IV vancomycin pending culture results. Parotitis secondary to stones is often treated with ceftazidime, dicloxacillin, or amoxicillin/sulbactam. Use clinical judgment and assure good follow-up.

Question 20.10.3 Which of the following is NOT typical of sialolithiasis (salivary duct stones)?

- A) Intermittent swelling of the salivary gland
- B) More than 80% of stones involve the parotid gland
- C) The majority resolve with conservative, nonoperative treatment
- D) Anti-staphylococcal antibiotics should be used in their treatment
- E) Sialogogues (e.g., lemon drops) should be used as part of the treatment

Answer 20.10.3 The correct answer is “B.” In actuality, more than 80% of cases of sialolithiasis involve the submandibular gland. Saliva in the submandibular gland is more viscous and contains more mucous and dissolved salts than the parotid glands. Additionally, these glands rely more on muscular contraction in the ducts to function as they need to express saliva against gravity. “A” is true. Swelling tends to occur when patients eat and tends to resolve between meals as saliva slowly makes its way through the duct. “C” is true. Most salivary duct stones pass spontaneously. “D” is true. Think of this as an abscess. If there is any sign of infection, anti-staphylococcal antibiotics should be used until the stone passes. Finally, sialogogues such as lemon drops promote saliva formation. The effectiveness is questionable, but it is worth a try and it gives the patient something to do.

Question 20.10.4 Which of the following is considered good practice with regard to salivary duct stones?

- A) Patients should be counseled to drink lots of water, use hot compresses/salivary gland massage, use sialogogues such as lemon drops and be followed closely
- B) Stones can be removed using sialolithotomy (using a probe and/or scalpel to nick the outlet)
- C) Patients should be referred for sialography/sialendoscopy if stones do not pass within 4 days
- D) Surgical excision of the duct/gland may be performed with multiply recurrent or complicated cases
- E) All of the above

Answer 20.10.4 The correct answer is “E.” First line for sialadenitis/sialolithiasis is to encourage passing of the stone conservatively. This is performed by increasing the amount of saliva passing through the duct. Hydration, massage, warm compresses, and sialogogues will help wash out pus in either a gland or a stone. A probe can be used to “dilate” the duct. Occasionally, the outlet needs to be nicked using a scalpel blade to allow the stone to egress. In other cases, sialography may help visualize the stone and may therapeutically dilate the duct by cannulation/injection of contrast dye. Sialendoscopy may be used to perform lithotripsy and remove the stone in a minimally invasive manner. In recurrent or complicated cases, removal/marsupialization of the duct, or even salivary gland excision may be necessary.

You check the patient’s mouth and decide that there is likely a dental abscess, not a salivary duct stone, so you wasted a lot of energy thinking about stones. She needs to have her tooth extracted, but the dentist will not be able to see the patient until the morning...of the first Tuesday...of next month. She requires antibiotics but is penicillin-allergic.

Question 20.10.5 The antibiotic of choice for this patient is:

- A) Erythromycin
- B) Clindamycin
- C) Azithromycin
- D) Levofloxacin
- E) Trimethoprim/sulfamethoxazole

Answer 20.10.5 The correct answer is “B.” Clindamycin is the drug of choice as an alternative to penicillin. The drug used for a dental abscess should cover anaerobes. There is resistance to erythromycin and azithromycin. Neither levofloxacin nor trimethoprim/sulfamethoxazole covers anaerobes.

During your examination, you also noticed a firm nodule in the submental area in the midline (definitely not this patient’s day!). It moves up and down when she swallows. She says that it has been there for years—as long as she can remember.

Question 20.10.6 The most likely cause of this midline nodule is:

- A) Submandibular gland infection
- B) Thyroglossal duct cyst
- C) Infected frenulum
- D) Branchial cleft cyst
- E) An accumulation of mid-chlorians

Answer 20.10.6 The correct answer is “B.” This is likely a thyroglossal duct cyst. The rest are not likely. Submandibular glands (“A”) and branchial cleft cysts (“D”) are lateral to the midline. “C” is incorrect. The frenulum is under the tongue. As for “E,” another *Star Wars* reference—midi-chlorian levels are high in Force-wielding beings. Maybe there will be a Wookiee at the end of the chapter. Keep reading.

You start the patient on clindamycin, but she returns in the morning with severe submandibular swelling. The tongue is elevated in the mouth and there is brawny edema; she is having trouble talking. You make the diagnosis of Ludwig’s angina. (“Didn’t we just do this?” you ask. “Yes, we are going to do it again,” we reply.)

Question 20.10.7 At this time, the most appropriate treatment for this patient is:

- A) Continue PO clindamycin and add saltwater gargles
- B) Continue PO clindamycin and add PO metronidazole
- C) Incise and drain the swollen area under the tongue
- D) Refer immediately for surgical evaluation for I&D, securing of the airway with intubation vs. possible tracheostomy
- E) Administer IV fluids and ceftriaxone in the office and follow up tomorrow

Answer 20.10.7 The correct answer is “D.” This patient’s situation has become fairly desperate overnight even while on an appropriate antibiotic. Securing an airway should be your first concern. Unfortunately, these patients do not respond to local incision and drainage, as the swelling is usually diffuse, quickly spreading, and does not result in discrete pus pocket formation until late in the course. She should be admitted for IV fluids, appropriate IV antibiotics (not levofloxacin), and possible securing of her airway. Patients with advancing Ludwig’s angina may be challenging to intubate; thus, an alternative airway is sometimes provided with tracheostomy.

► **Objectives: Did you learn to ...**

- Diagnose salivary stones?
- Treat salivary stones?
- Recognize the presentation of submandibular masses?

► **CASE 20.11**

A 21-year-old male presents for a sore throat. His symptoms started 3 days ago. He has had subjective fevers, sweats, fatigue, and mild nausea. He has no cough or rhinorrhea. His temperature is 38.5°C. His vital signs are normal otherwise. He has symmetrically enlarged tonsils with exudates present and tender anterior cervical lymphadenopathy.

Question 20.11.1 At this point, you:

- Reassure and recommend saltwater gargles
- Obtain a routine aerobic culture of the oropharynx
- Prescribe penicillin 500 mg BID for 10 days
- Prescribe levofloxacin 500 mg daily for 7 days

Answer 20.11.1 The correct answer is “C.” This patient has four of four signs/symptoms suggestive of streptococcal (group A strep or *Streptococcus pyogenes*) pharyngitis. These are the Centor criteria: (1) fever, (2) tender cervical adenopathy, (3) exudative pharyngitis, and (4) lack of other URI symptoms (especially cough). In this case, the most appropriate step would be empiric antimicrobial treatment. “B,” performing a culture, will take a few days and does not add much, given the strength of the clinical argument for strep throat. Furthermore, the oropharynx is colonized by many kinds of flora that do not cause disease, and we only really care about group A streptococcus, so a routine aerobic culture is of no value. Alternatively, a rapid assay or a specific “rule-out” culture for group A strep could be done rather than treating based on clinical grounds (the rapid strep has a 5% false-negative rate). While saltwater gargles seem to help reduce the pain of pharyngitis, “A” is incorrect because you would want to do more than that for this patient who likely has strep throat. “D” is incorrect because levofloxacin and other fluoroquinolones are not indicated for treatment of strep throat.

Here are three strategies for the patient you think might have strep throat:

Strategy 1: No testing (or minimal testing)

In this strategy, one treats based on clinical symptoms. You are looking for four things: fever, exudate, absence of other URI symptoms, and tender anterior cervical adenopathy. Treat patients with 3 or 4 criteria, and do not treat others. Another approach is to treat patients with 4 criteria, do a rapid strep test on those with 3 (and maybe 2) criteria, and avoid treatment and testing of others. The CDC has recommended this for non-immunosuppressed patients in the absence of an outbreak of rheumatic fever in the community.

Strategy 2: Testing

Test all patients and treat those with a positive strep screen. Do not culture others.

Strategy 3: Test +/- Culture and Treat (For Children)

The majority of group A strep pharyngitis occurs in children between ages 5 and 15 years. In this age group, 15% to 30% of acute pharyngitis is caused by group A strep. In children, doing a rapid strep test is considered the standard (although many argue convincingly that it is not even necessary here in the older child). Cultures are again optional depending on the reliability of your rapid antigen test. Many would culture *all* rapid strep test *negative* patients, and this is certainly an acceptable strategy as well.

So, now you are quite confused. So is everyone else ...

Question 20.11.2 Which of the following is true about antibiotic therapy of streptococcal pharyngitis?

- Azithromycin is the drug of choice because of resistant streptococci
- There is no significant resistance seen in Group A β -hemolytic streptococci, and penicillin is still the drug of choice
- Cephalexin is the preferred drug because it covers *H. influenzae*, which is a frequent co-infecter with streptococci
- Amoxicillin is preferred for strep throat because it does not cause a rash if the patient happens to have mononucleosis

Answer 20.11.2 The correct answer is “B.” There is no significant resistance among group A β -hemolytic streptococci to penicillin. Thus, penicillin remains the drug of choice despite drug detailing. There is no reason to use **anything else**, except in the case of allergy where **erythromycin or cephalexin** can be used. Remember that there is now resistance to erythromycin, azithromycin, and clarithromycin. “D” is important. Amoxicillin can cause an uncomfortable rash should your patient turn out to have mononucleosis rather than strep throat.

**HELPFUL TIP:**

Penicillin VK can be used BID in streptococcal pharyngitis, and this administration frequency increases compliance.

Question 20.11.3 Antibiotics should be started within what time period to reduce the risk of rheumatic fever from streptococcal pharyngitis?

- Less than 2 days after presentation
- 2 to 4 days after presentation
- 4 to 6 days after presentation
- 6 to 8 days after presentation
- 8 to 10 days after presentation

Answer 20.11.3 The correct answer is “E.” Antibiotics should be started within 9 days after presentation in order to prevent rheumatic fever, which is really our goal when we treat streptococcal pharyngitis. Thus, there really is no reason to hurry treatment.

Your patient is a student teacher and wants to know how long to stay out of the classroom.

Question 20.11.4 A patient with streptococcal pharyngitis should be considered infectious and kept out of school for what period after beginning antibiotics?

- A) 12 hours
- B) 24 hours
- C) 36 hours
- D) 48 hours

Answer 20.11.4 The correct answer is “B.” Patients should be considered infectious for 24 hours after the initiation of therapy for streptococcal pharyngitis. The risk of transmission goes down markedly after this point. Unfortunately, the patient is actually infectious for the 3 to 5 days before they become symptomatic, so removing the patient for 24 hours after treatment is closing the barn door after the horses have left. There is some preliminary data that it is OK to return to work/school 12 hours after starting treatment but this is not yet the standard of care (*Pediatr Infect Dis J.* 2015;34(12):1302).

You see the same patient 3 weeks later. He took all of his penicillin even though he felt fine a few days after he left your office. (Wow! A compliant patient!) However, he now has the same symptoms, starting 2 days ago. His examination is the same.

Question 20.11.5 Which of the following is the most likely cause for his current symptoms?

- A) Gonococcal pharyngitis
- B) Infection with a resistant *streptococcal* organism
- C) Mononucleosis
- D) Staphylococcal pharyngitis
- E) None of the above

Answer 20.11.5 The correct answer is “E.” Since his symptoms resolved, you either got the diagnosis and treatment right or he had some other self-limited infection. Therefore, it would be unlikely that he had gonococcal pharyngitis or resistant *streptococcal* organisms. Besides, “B,” penicillin-resistant Group A *Streptococcus* organisms causing pharyngitis, like the Tooth Fairy, are nonexistent. Nonetheless, sexual history is important—even when confronted with pharyngitis; if a patient with exudative pharyngitis is not improving, think about gonococcal disease. Remember that gonococcal disease will be missed for two reasons in this scenario: the history is never obtained regarding oral sex and gonococcus requires Thayer–Martin agar to grow, so it will not show up on routine culture, and there are a lot of false-negative cultures; obtain a swab for PCR if you are considering gonococcal pharyngitis. “C” is unlikely in this case because his symptoms resolved, but mononucleosis can cause prolonged symptoms of sore throat and fatigue and can be confused with strep throat. In this case, recurrent strep throat is most likely, and he should be advised appropriately: retreat with penicillin, not a more broad-spectrum antibiotic; consider testing and/or treating cohabitants; have the patient replace his toothbrush.

HELPFUL TIP:

Many causes of throat pain are acute infections (strep throat, other bacterial infections, viral pharyngitis, mononucleosis), but consider other noninfectious causes as well—carotidynia, viral thyroiditis, mouth-breathing, peritonsillar abscess. Non-group A streptococci (especially *Streptococcus agalactiae*, a group B strep) are increasingly being cultured from the pharynx. *S. agalactiae* can cause invasive disease and is probably worth treating if found. It will respond to cephalexin or clindamycin (among others).

It’s a “two for Tuesday” at your clinic. The next patient comes in for a sore throat and tender anterior and posterior cervical adenopathy. He is febrile and relatively stoic. He has been sick for 2 weeks with significant fatigue and just isn’t getting better. In addition to the adenopathy, you notice left-sided abdominal tenderness with minimal guarding but no rebound tenderness. You believe that you feel a spleen edge. However, the patient’s heterophile antibody (monospot) is negative. You decide to get anti-EBV (Epstein–Barr virus) antibodies. The results of the anti-EBV antibody test are as follows (VCA is against the capsid): IgM-VCA positive, IgG-VCA negative, anti-EBV nuclear antigen antibody negative.

Question 20.11.6 How do you interpret these results?

- A) The patient has acute EBV infection
- B) The patient has had EBV at least 6 weeks ago
- C) The absence of anti-EBV nuclear antigen antibody makes acute infection highly unlikely
- D) The patient has never been infected with EBV

Answer 20.11.6 The correct answer is “A.” The patient has an EBV infection, starting in the last few weeks. Here is why. IgM-VCA is produced acutely and is elevated in the acute infection for 2 to 4 weeks. Since this patient’s IgM-VCA is positive, he has had an acute EBV infection within the past month. IgG-VCA is measurable 3 to 4 weeks after acute infection and persists for life. Thus, it gives no information about when infection occurred. The absence of IgG-VCA means either (1) the patient has no history of EBV infection or (2) the patient has had a recent EBV infection. Antibodies against the EBV nuclear antigen show up at 6 to 12 weeks after infection. If this antibody is present in the blood, it suggests that there has not been an acute infection; the infection had to have been at least 6 weeks ago.

Question 20.11.7 Of the following, which DOES NOT cause a mononucleosis-like syndrome?

- A) Human immunodeficiency virus (HIV)
- B) Cytomegalovirus (CMV)
- C) Toxoplasmosis
- D) West Nile virus (WNV)
- E) Leptospirosis

Answer 20.11.7 The correct answer is “D.” WNV is characterized by fever, headache, myalgias, back pain, and anorexia lasting 3 to 6 days. Much less common manifestations are nausea, vomiting, diarrhea, encephalitis, etc. Thus, WNV does not cause a mononucleosis-like syndrome because it does not last as long and rarely includes pharyngitis. One thing to note is that WNV may include lymphadenopathy. All the other answers can cause a mononucleosis-like syndrome. Other causes of mononucleosis-like syndromes include adenovirus, parvovirus B19 (erythema infectiosum), herpes virus 6 (roseola infantum), Zika, and ehrlichiosis (Asian form only). Remember these diagnoses in heterophile-negative mono-like illness.

HELPFUL TIP:

Depending on what population is studied, 1% to 2% of patients with a mononucleosis-like syndrome who are heterophile negative are HIV positive.

Question 20.11.8 There is some concern of splenic rupture in patients with mononucleosis who have splenomegaly. If splenomegaly were confirmed in this patient, what would be the generally accepted recommendation with regard to athletic participation (e.g., cage fighting)?

- A) No participation until negative acute titers for EBV
- B) No participation for 2 weeks after the diagnosis is made, assuming complete resolution of symptoms, and then full participation
- C) No participation until 3 weeks after the diagnosis is made, assuming complete resolution of symptoms, and then only noncontact training for another week
- D) Full practice and competition allowed immediately unless abdominal pain occurs
- E) Full practice and competition immediately with body armor (e.g., Kevlar vest)

Answer 20.11.8 The correct answer is “C.” It is generally thought that return to practice or **noncontact training** is safe 3 weeks after the diagnosis of mononucleosis, provided that all other symptoms have also resolved. If there are no clinical concerns for splenic enlargement at 4 weeks, then the athlete may be cleared to return to full competition. This recommendation is based on the observation that most cases of splenic rupture in athletes have occurred when those athletes returned to competition in less than 4 weeks from the time of diagnosis.

The patient returns 2 days later and is noting increased pharyngeal swelling and difficulty swallowing. You look into his throat and note “kissing tonsils.” There is no stridor, but he feels as though there is something in his throat.

Question 20.11.9 What is the best treatment for this patient at this time?

- A) Observation
- B) Amoxicillin
- C) Clindamycin

- D) Prednisone
- E) Tonsillectomy

Answer 20.11.9 The correct answer is “A.” You may want to give steroids (“D”), but you will find little data to back you up. A Cochrane Collaboration Review updated in 2015 found insufficient evidence for steroids for symptom control in patients with mononucleosis (and other causes of “glandular fever” and sore throat). However, many physicians still prescribe steroids for patients with significant symptoms. Antibiotics are not indicated for mononucleosis. Tonsillectomy is also not indicated. The patient likely has paratracheal node swelling, as well. In this patient, hospital admission may be indicated if there is concern for airway obstruction.

Question 20.11.10 What is the approximate sensitivity of the heterophile antibody test (“monospot”) for mononucleosis within the first 2 weeks of symptoms?

- A) 10%
- B) 30%
- C) 50%
- D) 70%
- E) >90%

Answer 20.11.10 The correct answer is “D.” The sensitivity of the monospot ranges from 60% to 80% about 2 weeks into the illness. The point here is not the number per se but the fact that there are heterophile-negative mononucleosis syndromes **and** not everyone with EBV mononucleosis will have a positive monospot when tested. However, they should have atypical lymphocytes on WBC differential.

HELPFUL TIP:

Consider peritonsillar abscess in a patient with a sore throat. There will generally be a muffled, “hot potato,” voice, deviation of the uvula away from the side of the abscess, and protrusion of a tonsil toward midline. This may be an extension of a prior pharyngitis but may also arise de novo. Treatment is antibiotics and drainage (needling it is OK—no need for surgical involvement in all cases). It is also important to pay attention to the airway since there is the possibility of obstruction.

HELPFUL TIP:

The monospot is not as sensitive in children. It will become positive in less than 40% of children younger than 5 years when they are infected with EBV. However, anti-EBV antibodies will be positive.

HELPFUL TIP:

Arcanobacterium haemolyticum is a bacterium that causes pharyngitis especially in young adults (teens, early

twenties). It clinically looks like strep throat but often has an associated rash especially on the arms (50% only). It does not cause long-term sequelae, so testing for it is not necessarily indicated (but it is cool to identify when the patient comes in with the appropriate rash!). If you choose to treat (which some practitioners do), it is generally sensitive to penicillins, cephalosporins, and tetracyclines.

► Objectives: Did you learn to ...

- Describe different strategies to approaching the patient with symptoms of *streptococcal* pharyngitis?
- Treat a patient with *streptococcal* pharyngitis and recurrent pharyngitis?
- Develop a broad differential for sore throat?
- Diagnose and treat mononucleosis?

QUICK QUIZ: IN THE SAME VEIN ...

Uh, oh. You have treated a 19-year-old college student for presumed streptococcal pharyngitis with azithromycin (didn't we say not to do this?!). In your defense, he wanted to get better fast because he landed the lead role in the new musical *You Had Me at Arrrhg: A Wookie Love Story*. He returns 1 week later with high fever and a cough, looking quite ill. Chest radiograph shows small pulmonary abscesses and he is tender over a swollen carotid sheath. His throat looks awful

The most likely diagnosis is:

- A) Lemierre syndrome
- B) Complication of EBV mononucleosis
- C) Cardiac valvular disease from rheumatic fever
- D) Aspiration pneumonitis from his pharyngitis
- E) Scarlet fever

The correct answer is "A." This is a classic case of Lemierre syndrome, or septic thrombophlebitis of the jugular vein from (generally) *Fusobacterium necrophorum*. This is an anaerobic infection of the posterior pharynx that may be misdiagnosed as streptococcal disease. Generally, patients look ill with a temperature of $>39^{\circ}\text{C}$, have tenderness in the neck, and have septic emboli in the lungs. The basic problem is a septic thrombophlebitis of the jugular vein. It is being increasingly recognized especially in young adults (teens–early twenties). This patient must be admitted for IV antibiotics and may require anticoagulation and/or surgical intervention. In the pharyngitis stage, it is sensitive to penicillin. See, if you would have listened to us and used penicillin in the first place you wouldn't be in this bind!

Clinical Pearls

- *Arcanobacterium* and *Fusobacterium* pharyngitis can look just like Strep throat although the rapid Strep will be negative. *Arcanobacterium* is often associated with a rash. *Fusobacterium* can lead to a septic thrombophlebitis of the jugular vein (Lemierre syndrome).

- Consider mumps in a patient with salivary gland swelling even in patients who have had both MMR vaccinations; immunity wanes with time and there are yearly outbreaks in the United States.
- Do not suggest ear tubes for patients with unilateral serous otitis. The main function of ear tubes in this situation is to assist with language development. This is not an issue with unilateral serous otitis.
- Infections of the cartilaginous ear pinnae from piercings are often from *Pseudomonas*. This is an emergency.
- Most nasal trauma need not be addressed at a first visit: you can get a better cosmetic result in 3 to 5 days once the swelling has subsided. However, a septal hematoma is an emergency that requires prompt attention to prevent septal cartilage necrosis.
- Penicillin is still the drug of choice for Strep throat. There is no resistance and if the patient has mononucleosis you haven't fated them to 6 weeks of a rash, which might occur with amoxicillin.
- A wick can be used when treating otitis externa with topical drops. This will help assure that the medication gets to where it is needed.

Care of the Older Patient

Victoria Linares and Nicholas R. Butler

► CASE 21.1

An 83-year-old female patient whom you have followed for many years has just been admitted to a nursing home following a short hospitalization. Because of a steady decline in function and lack of family and social support, you and the patient have come to the realization that she can no longer safely live alone in her home and her needs were too great for assisted living. Her medical problems include: heart failure, chronic atrial fibrillation, osteoarthritis, and depression. Her current medications are: warfarin, furosemide, acetaminophen, calcium carbonate, lisinopril, metoprolol, and fluoxetine. Both the patient and the nursing staff report poor sleep and depressed mood for the last 2 weeks, and the nurses are asking for a sleep aid.

Question 21.1.1 What is the best next step in the management of her insomnia?

- A) Add diphenhydramine 50 mg PO nightly
- B) Add diazepam 5 mg PO nightly as needed
- C) Add amitriptyline 25 mg PO nightly
- D) Recommend increased activity during the day, avoidance of naps, warm milk before bed, and waking at the same time each morning
- E) Add 2 shots of bourbon PO nightly

Answer 21.1.1 The correct answer is “D.” There are no great medicines for promoting sleep in elderly nursing home residents. Given the lack of efficacy data of most hypnotics coupled with the known adverse effects, a trial of good sleep hygiene should be undertaken first. “Good sleep hygiene” generally consists of the following: eliminate or reduce daytime naps, add daily activities, maintain a set waking time, increase aerobic exercise (but not within a few hours of bedtime), and maintain a quiet, comfortable sleeping environment. Nighttime rituals, such as meditation and warm milk, may help insomnia and are unlikely to cause any harm, but avoid the bourbon as alcohol interferes with normal sleep architecture. If these initial efforts fail, a low dose of a hypnotic (e.g., zolpidem, zaleplon) or

trazodone is an appropriate choice. Trazodone has fewer anticholinergic and blood pressure effects than other options, such as tricyclics and benzodiazepines, but should still be used with caution while monitoring for adverse effects. Diphenhydramine (“A”) has powerful antihistaminic and anticholinergic properties that may result in increased confusion and falls. Diazepam (“B”) has an exceptionally long half-life in elderly patients and may cause daytime somnolence. Amitriptyline (“C”) is listed by the Centers for Medicare and Medicaid Services (CMS) as a medication to be avoided in nursing home patients due to high potential for severe adverse drug reactions (falls, confusion, constipation, etc.).

HELPFUL TIP:

Melatonin receptor agonists (e.g., ramelteon) are another option for insomnia but are not great. Patients sleep about 7 minutes more per night compared to placebo (let's talk about statistically significant vs. clinically significant now!). They are relatively safe and do not lead to a “hangover” as with many hypnotics. The use of ramelteon and melatonin has also been shown to be beneficial in preventing the onset of delirium in acutely ill elderly patients. Melatonin has poor evidence for primary insomnia treatment but low chance of harm, so some physicians will try it first. And then there are orexin receptor antagonists, such as suvorexant (Belsomra), which possess a side effect profile that is not favorable for older patients (e.g., suicidal ideation, “sleep driving,” daytime somnolence). Suvorexant has a 12-hour half-life in the non-elderly, leading to significant dysfunction the day after taking the drug.

HELPFUL TIP:

There are many potential causes of sleep disturbance in the nursing home. The following are sources of sleep problems that you may want to investigate or treat

empirically: pain, anxiety, depression, delirium, dementia, primary sleep disorders (e.g., sleep apnea, restless leg syndrome), environmental issues (e.g., alarms and lights).

The nurses grudgingly accept your recommendation to try sleep hygiene (“Can’t we just give her a pill?”), and over the next month your patient’s sleep improves, as does her mood. There’s one in the win column for the doctor! Unfortunately, she experiences two falls with minor injuries while ambulating in her room. When you see her one week later, she recalls the falls and can describe what happened with each—essentially, she tripped. Upon examination, you find normal vital signs, no orthostatic hypotension, and no focal neurological deficits.

Question 21.1.2 Which of the following is the most appropriate next step?

- A) Discontinue warfarin
- B) Employ bed and chair alarms
- C) Obtain a computerized tomography (CT) scan of the head
- D) Reduce or discontinue fluoxetine
- E) Restrict activities and prescribe a wheelchair

Answer 21.1.2 The correct answer is “D.” As often happens in life, there is no great answer here. Falls are usually multifactorial in origin, so simple interventions do not generally solve the problem. SSRIs have been shown (in imperfect studies) to increase the risk of falls in the elderly, so reducing or discontinuing fluoxetine is prudent, but you will have to watch for mood and anxiety symptoms. “A,” discontinuing warfarin, may be appropriate if she continues to fall but this action is not likely to reduce her fall risk. “B,” the use of bed and chair alarms, is helpful when patients have cognitive impairment and cannot remember to ask for help when getting up; however, these devices can act as tethers to further restrict a patient’s movement. Likewise, further restriction of activities and mandatory wheelchair use (“E”) may lead to deconditioning, loss of muscle strength, and an increased risk of falls. A CT scan of the head may be warranted if the patient sustained a head injury or had an abnormal neurological examination, but it’s unlikely to determine the cause of her falls.

Over the next year, you observe a steady decline in your patient’s function, with a series of falls despite interventions. Ultimately, your patient has a devastating thromboembolic stroke, which results in right hemiparesis and dysphagia. After a short hospital stay, she returns to the nursing home and undergoes therapy. You order a swallow study (as you do for all stroke patients). She continues to have difficulty with her swallowing but is able to tolerate thickened liquids without aspirating. She has a 5% weight loss over the next 2 months, and her nurse reports poor oral intake. Her medications are now warfarin, furosemide, acetaminophen, calcium carbonate, and lisinopril.

Question 21.1.3 In this malnourished, elderly nursing home patient, which of the following interventions or diagnostic studies will most likely lead to improvement in her condition?

- A) Admit to the hospital and initiate parenteral feeding
- B) Refer for esophagogastroduodenoscopy (EGD)
- C) Screen for depression
- D) Add megestrol acetate
- E) Add marijuana

Answer 21.1.3 The correct answer is “C.” Depression is one of the most common causes of weight loss in the nursing home, and stroke survivors are at high risk for depression. Also, this patient has a history of depression with no current treatment (since we stopped the fluoxetine earlier). Consider using a screening tool, such as the Geriatric Depression Scale. A positive screen requires further investigation. Now that she is bedridden, falls are not as much of an issue, so an antidepressant may be appropriate. “A” is incorrect. We are not sure of the patient’s wishes regarding intravenous (IV) nutrition, and more conservative measures should be instituted before considering parenteral nutrition. “B” is incorrect. While an EGD may be important at some point, proceeding to EGD immediately is premature. “D,” megestrol acetate, has been reported to improve food intake in patients with cancer cachexia, but its value in the nursing home is questionable, and it may be associated with an increased risk of mortality. “E” is also incorrect. Even if you practice in one of the token states, we cannot have her lighting up in the nursing home.

HELPFUL TIP:

The initial evaluation of a nursing home patient with weight loss should focus on medication review, gastrointestinal symptoms, dental and mouth problems, swallowing dysfunction, ability to feed one-self, and neuropsychiatric disorders (e.g., depression, dementia, psychosis). Hyperthyroidism, hyperparathyroidism, malignancy, and chronic infection should be considered as causes of weight loss, albeit less likely. Factors associated with aging, such as decreased olfaction, taste, and salivation (and nursing home food), may decrease the enjoyment of eating. Patients with dementia commonly develop apathy and lose interest in eating in latter stages.

You diagnose depression and initiate treatment. You also encourage the nursing staff to observe your patient while eating and assist her if necessary. You add a daily multivitamin. Her mood improves slightly and her weight stabilizes. However, over the next 6 months, your patient becomes more withdrawn and spends most of her time in bed. Because of her stroke, she is not very mobile, and she requires assistance with transfers and movement in bed. Ultimately, she develops a skin ulcer on her sacrum. Nursing staff reports a sacral pressure ulcer measuring 3 × 2 cm. There is interruption of the epidermis, like an abrasion.

TABLE 21-1 PRESSURE ULCER STAGES

Stage I	Stage II	Stage III	Stage IV	Unstageable
Nonblanchable erythema	Partial-thickness skin loss	Full-thickness skin loss	Full-thickness skin loss	Ulcer covered in eschar and depth unknown
Intact skin	Epidermis and/or dermis	Damage or necrosis of subcutaneous tissues, extending to underlying fascia	Extensive destruction, tissue necrosis, or damage to muscle, bone or supporting structures	
Changes in skin temperature, consistency, or sensation	Presents as abrasion, blister, or shallow crater	Presents as deep crater		

Question 21.1.4 According to conventional staging criteria, what stage is this pressure ulcer?

- A) Stage I
- B) Stage II
- C) Stage III
- D) Stage IV
- E) Unstageable

Answer 21.1.4 The correct answer is “B.” Pressure ulcers (in older parlance, decubitus ulcers, pressure sores, or bed sores) are caused by unrelieved pressure resulting in ischemic damage to underlying tissue. Stage II ulcers are partial thickness injuries that are shallow and appear as open ulcers. Anatomic areas of concern in bed-bound patients include sacrum, coccyx, heels, and occiput. Chair-bound patients are more likely to develop ulcers over the ischial tuberosities. Risk factors for pressure ulcers include advancing age, immobility, moisture (e.g., urinary or fecal incontinence), malnutrition, and decreased sensory perception. Ulcers are staged by clinical appearance (see Table 21-1).

Because of miscommunication within the nursing home staff, the ulcer goes untended over the weekend. An alarmed nurse calls you to report full thickness skin loss. You arrange to visit the patient in the evening ... here comes another “above and beyond” award.

Question 21.1.5 In the meantime, you prescribe what treatment?

- A) Foam pad with occluding dressing (e.g., Allevyn, Mepilex)
- B) Wet-to-dry dressing
- C) Topical antibiotics
- D) Transparent, occlusive dressing (e.g., Tegaderm)
- E) Chemical enzyme debridement (e.g., Accuzyme)

Answer 21.1.5 The correct answer is “A.” In treating pressure ulcers, there are several principles to follow: relieve pressure, protect the wound and surrounding skin from further trauma, maintain a clean wound bed, provide a moist wound environment, eliminate dead space, control exudates, ensure adequate nutrition, and diagnose and treat infection. Your

patient’s ulcer has worsened and is now at least stage III. Without further information, foam dressing is a safe choice for initial treatment of a stage III ulcer. Foam pads are useful for deeper wounds with moderate exudate and may also protect the wound from further pressure. In most cases, the wound should be kept moist, so wet-to-dry dressings are not appropriate (they debride the wound of **both** necrotic and healthy tissues—ouch, and are not helpful). If moist gauze packing is used, it should be kept moist with intermittent reapplication of saline or changed before drying. Wet-to-dry dressings (“B”) have fallen out of favor due to tissue trauma secondary to removing the dry dressing. From the nurse’s report, there is no evidence of necrosis, excessive drainage or infection, so antibiotics (“C”) and debridement (“E”) would not be helpful at this time. A transparent, occlusive dressing (“D”) is used for stage II ulcers, but is insufficient for stage III or IV. In addition to dressing the wound, you should employ the following measures: repositioning every 1 to 2 hours, use pressure-relieving mattress and cushions, and optimizing nutrition. Consultation with a wound care specialist or a surgeon may be necessary if these measures fail.

HELPFUL TIP:

There is minimal evidence of benefit for the use of most adjunctive therapies for pressure ulcers (electrical stimulation, ultrasound, hyperbaric oxygen, ultraviolet light, vasodilators, vacuum devices, etc.). In general, stick with pressure relief, good wound care, and nutrition.

HELPFUL TIP:

To prevent pressure ulcers, schedule regular and frequent repositioning for bed- and chair-bound individuals. Turn at least every 2 to 4 hours on a pressure-reducing mattress or every 2 hours on a non-pressure-reducing mattress. Also, maintain the head of the bed ≤ 30 degrees if possible to reduce pressure and shear forces on the sacral area. See Figures 21-1 and 21-2 to better understand how positioning and shear forces lead to the development of pressure ulcers.

FIGURE 21-1. Common sites of pressure ulcer development for patients in supine (left upper figure), seated (right upper figure), and lateral decubitus (lower figure) positions. (From *Preventing Pressure Ulcers: A Patient's Guide*. Washington, DC, US Department of Health and Human Services, USGPO 617-025/68298, 1992.)

Question 21.1.6 Which of the following statements is **NOT** true about the evaluation and treatment of pressure ulcers?

- A) A pressure ulcer covered by eschar cannot be staged until the eschar is removed.
- B) If a pressure ulcer shows no signs of healing over 2 weeks, one should reevaluate wound management strategies and reexamine factors affecting the wound.
- C) One should consider osteomyelitis or deep soft-tissue infection in a wound that is not healing.
- D) Wound cultures should be obtained routinely to target antibiotics toward the organisms found.
- E) In an otherwise clean wound that is not healing as expected, one should consider empiric therapy with topical antibiotics.

FIGURE 21-2. The effects of shear forces on the sacrum and the heel. (From Grey JE, Harding KG, Enoch S: Pressure ulcers. *BMJ* 332:472, 2006, with permission of Blackwell Publishing.)

Answer 21.1.6 The correct answer is “D.” The routine culturing of pressure ulcers is not recommended. Antibiotics are generally not useful since the organisms found are polymicrobial colonizers and not responsible for infection. Obviously, this does not hold true for patients with a true infection, and empiric therapy with topical antibiotics is indicated if a wound shows no improvement with good wound care. Remember that a flap cannot be used to repair the ulcer until infection is resolved.

► **Objectives: Did you learn to ...**

- Manage insomnia in elderly nursing home residents?
- Develop an approach to the problem of falls in nursing home residents?
- Identify nursing home residents at risk for malnutrition?
- Develop a treatment plan for malnutrition in the institutionalized elderly?
- Diagnose, evaluate, and manage pressure ulcers in the nursing home setting?

QUICK QUIZ: VACCINES

A 65-year-old healthy male presents for a routine visit and asks about pneumococcal vaccination. You correctly tell the patient:

- A) “The CDC recommends that you receive Pneumovax (23-valent pneumococcal polysaccharide vaccine) at your age.”
 B) “Pneumococcal vaccines are proven to reduce your risk of all causes of pneumonia.”

- C) “According to the CDC, you are due to receive Prevnar (13-valent pneumococcal protein-conjugate vaccine) at your age.”
 D) “Pneumococcal vaccines have a high rate of serious adverse effects”
 E) “Pneumococcal vaccines basically make you invincible, unless they give you autism”

The correct answer is “A,” the 23-valent vaccine (Pneumovax) is recommended at age 65. This recommendation has changed. The 13-valent vaccine (Prenvar) is now optional; the elderly are protected by herd immunity secondary to the vaccination of children. For those immunosuppressed, give the 13-valent (Prenvar) followed in 23 valent (Pneumovax) in 8 weeks. For others who might want both, give the 23 valent first followed by the 13 valent in one year. While the PPSV has clearly demonstrated efficacy in reducing the risk of invasive pneumococcal disease (e.g., bacteremia, meningitis), PCV has been shown to reduce pneumonia due to the serotypes against which the vaccine is directed in addition to invasive disease. Neither of the vaccines reduce the risk of all-cause pneumonia. The vaccines are well-tolerated.

QUICK QUIZ: VACCINES, AGAIN

A 67-year-old healthy male presents as a new patient and brings his immunization records with him (and you physically stop yourself from slapping your forehead in disbelief at this patient’s foresight). He has received both pneumococcal vaccines (Prenvar and Pneumovax) at age 65 and 66, respectively, following the old guidelines. He had Tdap (tetanus, diphtheria, and pertussis) and Zostavax (shingles) vaccines at age 60. In accordance with CDC recommendations, you tell him he is due for:

- A) Shingrix (recombinant zoster vaccine)
 B) Prenvar (pneumococcal protein conjugate vaccine)
 C) Tenivac (Td or tetanus/diphtheria vaccine)
 D) Zostavax (live, attenuated zoster vaccine)
 E) All of the above

The correct answer is “A.” The recombinant zoster vaccine (Shingrix) is currently recommended for all immunocompetent patients over the age of 50 years, whether or not they have received the attenuated live virus vaccine (Zostavax), had a case of shingles, or recall having chicken pox. Since early 2018, the CDC has recommended Shingrix over Zostavax due to markedly superior efficacy. Studies have shown that Shingrix is 91% effective in preventing shingles in patients age 70 and older who received both doses. It is a two-dose vaccine, and doses should be separated by 2 to 6 months. The other vaccines in the foils are not indicated for the following reasons: the patient already received both recommended doses of pneumococcal vaccines (“B”); the patient received Tdap 7 years ago and tetanus vaccine (“C”) boosters are due every 10 years; and there is no indication for re-dosing Zostavax (“D”).

QUICK QUIZ: HORMONES AND AGING

Noticing advertisements for testosterone treatment to “make you a vital man again,” one of your vivacious older female patients asks about testosterone for her husband wondering if it can make him 50 years old again.

Regarding sex hormone changes associated with aging, which of the following is true?

- A) Leydig cells in the testes increase with aging
- B) Total testosterone levels increase with aging
- C) Sex hormone-binding globulin levels increase with aging
- D) Follicle-stimulating hormone levels are unchanged with aging
- E) Luteinizing hormone levels decrease with aging

The correct answer is “C.” Sex hormones in males over age 40 demonstrate declining total testosterone at a rate of 1% to 2% per year. Simultaneously, sex hormone-binding globulin increases, resulting in a sharper decline in bioavailable testosterone. In response to low testosterone, follicle-stimulating and luteinizing hormone levels increase. Leydig cells (responsible for producing testosterone) decrease in number. Older males with subphysiologic testosterone levels are at increased risk of sexual dysfunction, osteoporosis, diminished lean body mass, depression, and inability to kill a mountain lion with their bare hands. Although controversial, some experts recommend testosterone supplementation in symptomatic males with low-serum testosterone. Testosterone supplementation may (notice the word “may”) improve strength, lean body mass, depressed mood, bone mineral density, and sexual function in aging males with documented low testosterone levels. Side effects of testosterone supplementation in older males include: cardiac disease, liver dysfunction, dyslipidemia, erythrocytosis, prostate tissue growth, acne, gynecomastia, and edema. If your patient is baleful and pushes the request for “T,” point out that testosterone adds nothing to the treatment of erectile dysfunction beyond that benefit which is offered by tadalafil (Cialis), sildenafil (Viagra), etc. You can reassure him that he will be just as virile at age 98 without testosterone and will avoid the risk of worsening heart disease. A consensus statement does recommend testosterone **For Postmenopausal Women** with hypoactive sexual desire disorder (J Clin Endocrinol Metab 2019 Oct 1; 104:4660). This a “disease” probably invented by men.

HELPFUL TIP:

Any time you see the word “may,” think “may not.” They are logical equivalents.

CASE 21.2

A 79-year-old female patient, well known to you from 5 years of treating her hypertension, presents to your office for an “annual examination” and “medication refill.” Her medications are lisinopril, amlodipine, and acetaminophen. She’s

noticed some hearing loss over the last year, and wonders if she should blame her medications and not all those rock concerts she attended as a young adult. Oh, by the way, her gynecologist recently retired and she would now like you to assume that care, which apparently included all of her preventative care (because OB/GYNs are “primary care doctors for women”—sarcasm intended).

Question 21.2.1 Which of the following drugs is NOT associated with sensorineural hearing loss?

- A) Ibuprofen
- B) Aminoglycosides
- C) Furosemide
- D) Magnesium salicylate
- E) Acetaminophen

Answer 21.2.1 The correct answer is “E.” All of these drugs except for acetaminophen can cause hearing loss. Platinum-based chemotherapeutics, aminoglycoside antibiotics, and loop diuretics have been associated with hearing loss, as have salicylates (e.g., aspirin) and some of the other NSAIDs (e.g., ibuprofen and diflunisal) and chloroquine. This list is obviously not exhaustive.

HELPFUL TIP:

Hearing loss, and sensory impairments in general, can be confused with cognitive impairment or an affective disorder. Hearing aids are useful for most cases of presbycusis, but if speech discrimination is <50%, results with hearing aids may be poor.

Your patient then asks, “Do I have to keep getting mammograms and Pap smears?” She relates a history of normal annual mammograms and Pap smears for the last 20 years, as her previous physician hadn’t changed her practice since the Backstreet Boys were popular. She had a hysterectomy for uterine fibromas and has been monogamous with her husband for 55 years. Her sister died of breast cancer. Using your magic crystal ball, you estimate her life expectancy at 10 years or greater.

Question 21.2.2 Consistent with current guidelines, you recommend:

- A) Continue Pap smears and pelvic examinations yearly
- B) Discontinue mammography but perform clinical breast examinations every 2 years
- C) Discontinue pelvic examinations but continue Pap smears
- D) Discontinue Pap smears but offer mammography at 1- to 2-year intervals

Answer 21.2.2 The correct answer is “D.” Tricky question. Screening decisions in the elderly should be individualized, and the patient’s overall health status must be considered. This patient has very little risk of cervical, endometrial, or vaginal cancer (status posthysterectomy for a benign condition, low-risk sexual behavior, and a history of normal examinations);

therefore, she has no indication for continuing Pap smears. Annual pelvic examination is more controversial, with the American Cancer Society (ACS) recommending physicians discuss this ovarian cancer screening measure with patients and reach a shared decision while the US Preventive Services Task Force (USPSTF) recommends against it.

Screening for breast cancer continues to be recommended for women with a 5- to 10-year life expectancy, but the optimal interval in older women is unknown: The American College of Physicians and USPSTF recommend screening of asymptomatic women **aged 50 to 74** years every other year. But our patient is 79. Whether this patient will benefit from mammography is unknown. There is a significant question of the “overdiagnosis” of breast cancer—in other words a cancer diagnosed by mammogram that would not ever have caused a problem for the patient (think of it as the equivalent of the diagnosis of prostate cancer in men ... they may die *with* the cancer and not *of* the cancer). Before ordering a mammogram, we need to have a discussion with our patients about what types of intervention they would want should a positive mammogram be noted.

HELPFUL TIP:

The 2012 consensus guidelines on screening for cervical cancer recommend discontinuing screening at age 65 if the previous three Pap smears prior to age 65 were completely normal and there were no findings of CIN2 or higher in the previous 20 years. Once stopped, screening should not be resumed for any reason, including a new sexual partner. Note that this is consistent with the 2018 USPSTF guidelines.

Your patient is an overweight white female with no history of bone fracture. She has never had a bone mineral density test and asks if she should have one. You are unaware of any risk factors in her other than Caucasian race and postmenopausal status.

Question 21.2.3 What do you tell her?

- A) “You are not at risk for osteoporosis and should not be screened”
- B) “All women over age 65 should be screened for osteoporosis regardless of risk”
- C) “Take 1,000 mg of calcium per day to prevent osteoporosis. You’ll be unbreakable—like Wolverine...in an Iron Man suit... surrounded by marshmallows”
- D) “Due to your risk factors, you should start a bisphosphonate, vitamin D, and calcium supplementation”

Answer 21.2.3 The correct answer is “B.” The USPSTF recommends bone densitometry screening for all women of age 65 years and older. The National Osteoporosis Foundation recommends bone densitometry for postmenopausal females with one or more of the following risk factors: family history of osteoporosis, personal history of low trauma fracture, current smoking, or low body weight (<127 lb). Additional risk

factors for osteoporosis include: female sex, Caucasian or Asian races, alcohol abuse (thus, “E” is wrong), sedentary lifestyle, and poor intake or absorption of calcium and vitamin D. Smoking is associated with osteoporosis. Diabetes, once thought to protect against osteoporosis, may actually increase the risk of falls and fractures in older adults. The preferred method for measuring bone density is dual-energy x-ray absorptiometry (DEXA). All postmenopausal women should consume 1,200 mg of elemental calcium per day in divided doses (either in food or as supplements or both). The optimal amount of vitamin D is 400 to 800 IU/day. Weight-bearing exercises strengthen bone and should be encouraged. Bisphosphonates are indicated for treatment of osteoporosis and should not be used without a diagnosis (so “D” is incorrect).

HELPFUL TIP:

Supplementing vitamin D is probably more important than supplementing calcium. Calcium supplementation has not consistently demonstrated fracture risk reduction. However, many elderly Americans are vitamin D deficient, and correction of the deficiency results in reduced fracture risk. Given the low risk of adverse effects with daily vitamin D (up to 1,000 IU/day), empiric supplementation is justifiable. Finally, 1,000 to 1,200 mg (not 1,500 mg) of calcium is probably plenty. Additional calcium has been linked to an elevated risk of coronary artery disease and no change in fracture risk. Calcium and vitamin D are clearly beneficial in those with osteoporosis, however. These recommendations change frequently. What is clear is that high dose (>4000IU/day reduces bone density and has no benefit on overall mortality (JAMA 2019 Aug 27; 322:736, JAMA 2019 Aug 27; 322:7360).

You could also use the FRAX Fracture Risk Assessment Tool to provide your patient with some idea of her risk of future fracture and to plan preventive strategies accordingly.

Question 21.2.4 All of the following data elements are required to use the FRAX calculator EXCEPT:

- A) Sex
- B) Weight
- C) Age
- D) Bone Mineral Density
- E) Smoking status

Answer 21.2.4 The correct answer is “D.” The FRAX tool is a validated calculator for assessing the 10-year probability of developing a major osteoporotic fracture. The tool requires numerous demographic and medical history elements and can be made more accurate by including the bone mineral density (BMD), but it does not require the use of BMD. Required elements include: age, sex, weight, height, previous fracture, parental hip fracture, smoking status, alcohol use, glucocorticoid use, history of rheumatoid arthritis, and

history of secondary osteoporosis. It can be located free of charge online at <https://www.sheffield.ac.uk/FRAX/>. We are pretty sure that “The FRAX” is also a Dr. Seuss character (or should be).

Next, your patient asks whether any of her medications put her at risk for osteoporosis.

Question 21.2.5 Which of the following is LEAST likely to increase the risk of osteoporosis?

- A) Glucocorticoids
- B) Anticonvulsants
- C) Sulfonylureas
- D) Loop diuretics
- E) Proton-pump inhibitors

Answer 21.2.5 The correct answer is “C.” Sulfonylureas do not have a direct effect on bone mineralization. Glucocorticoids (“A”) and anticonvulsants (“B”) are known to increase bone turnover, resulting in increased risk of osteoporosis. Loop diuretics (“D”) cause renal calcium wasting. There is an association between proton-pump inhibitor (“E”) use and osteoporosis, possibly through reduced calcium absorption or direct effects on bone metabolism. There does not appear to be this same association with H₂-blockers such as famotidine. Additionally, heparin, methotrexate, cyclosporine, and gonadotropin-releasing hormone agonists may increase the risk of osteoporosis. Excessive amounts of levothyroxine can cause increased bone turnover. Thiazide diuretics are protective.

Your patient asks what causes osteoporosis.

Question 21.2.6 Although most osteoporosis in women is primary (idiopathic), which of the following causes secondary osteoporosis?

- A) Hypoparathyroidism
- B) Multiple myeloma
- C) Estrogen use
- D) Hyperlipidemia
- E) Overly ambitious, or perhaps calcium-addicted, Tooth Fairies

Answer 21.2.6 The correct answer is “B.” About 70% of women have no identifiable cause for osteoporosis and therefore are diagnosed with primary (idiopathic) osteoporosis. Common causes of secondary osteoporosis include chronic corticosteroid use, alcoholism, GI disorders, hyperthyroidism, hyperparathyroidism (so, “A” is wrong), multiple myeloma, and primary renal diseases. Estrogen (“C”) increases bone mineral density. Hyperlipidemia (“D”) is not known to be associated with osteoporosis.

You encourage appropriate vitamin D and calcium intake as well as weight-bearing exercises. You plan to obtain a DEXA scan.

Question 21.2.7 Using DEXA scan results, osteoporosis is defined as:

- A) A T-score of 2.5 standard deviations or more below the mean of a healthy young adult ($T\text{-score} \leq -2.5$)
- B) A T-score from 1.0 up to 2.5 standard deviations below the mean of a healthy young adult (-1.0 up to -2.5)
- C) A Z-score of 2.5 standard deviations or more below the mean for same-aged females (≤ -2.5)
- D) A Z-score from 1.0 up to 2.5 standard deviations below the mean for same-aged females (-1.0 up to -2.5)

Answer 21.2.7 The correct answer is “A.” The T-score compares the patient’s bone mineral density to that of young, healthy women (for female patients; male normative data is used for males). Osteoporosis is defined as a T-score of 2.5 standard deviations or more below the mean (≤ -2.5). Osteopenia is defined as a T-score from 1.0 up to 2.5 standard deviations below the mean (-1.0 to -2.5). “C” is incorrect. The Z-score compares bone mineral density to that of age-matched controls. Therefore, it does not reflect the bone loss from baseline in a young healthy female, and it is not used for diagnosis. “D” is incorrect for the same reason.

Question 21.2.8 If you find that your patient has osteoporosis, you may consider using all of the following drugs to treat her osteoporosis EXCEPT:

- A) Bisphosphonates (e.g., alendronate and risedronate)
- B) Estrogens
- C) Progestins (e.g., Provera and Depo-Provera)
- D) Vitamin D and calcium
- E) Calcitonin

Answer 21.2.8 The correct answer is “C.” Progestins are not indicated for the treatment or prevention of osteoporosis. In fact, in young, healthy, premenopausal women, they have been associated with decreased bone mineral density due to suppression of estrogen production (such as with Depo-Provera). All of the other options are acceptable choices in the treatment of osteoporosis although some are better than others (keep reading).

She returns to discuss her test results, and her bone density is very low with her hip T-score 3.2 standard deviations below the mean (-3.2). You diagnose her with osteoporosis. “Are my bones like Swiss cheese?” she asks. No, you think. *Swiss cheese has more calcium.*

Question 21.2.9 Given that she is otherwise relatively healthy, what is the most appropriate initial therapy for her osteoporosis?

- A) Alendronate (Fosamax) 70 mg PO weekly
- B) Estrogen (e.g., Premarin) 0.625 mg PO daily
- C) Teriparatide (Forteo) 20 g SC daily for 5 years
- D) Zoledronic acid (Reclast) 5 mg IV every 3 months
- E) Denosumab (Prolia) 60 mg SC every 6 months

Answer 21.2.9 The correct answer is “A.” Bisphosphonates are the treatment of choice for osteoporosis. Alendronate,

risedronate, and zoledronic acid have all been shown to reduce the risk of vertebral and hip fractures in persons with osteoporosis. Ibandronate only appears to lower vertebral fracture risk; therefore, it should not be the first choice. Side effects of bisphosphonates include hypocalcemia (more likely with IV administration, as with zoledronic acid, and in patients with vitamin D deficiency), nausea, esophagitis, osteonecrosis of the jaw (usually at higher doses, such as those used to treat cancer), and atypical femur fractures. Although you might be tempted to choose “D,” zoledronic acid due to this patient’s more severe osteoporosis, there is no clear evidence that zoledronic acid is more effective than oral bisphosphonates. The IV route should be reserved for when the patient has failed oral bisphosphonate therapy for some reason—usually due to upper gastrointestinal side effects. Zoledronic acid can cause “flu-like” symptoms, with diffuse myalgia and arthralgia for days after the infusion. “B” is incorrect as the safety data for bisphosphonates is superior to that for estrogen. “C” is incorrect. Teriparatide, a recombinant parathyroid hormone carries a risk of osteosarcoma, and its use is limited to 2 years, not 5. Teriparatide is effective at increasing bone density and reducing fracture risk, but the data are not nearly as robust as the data for bisphosphonates. It is not a first-line drug. Similarly, denosumab should be reserved as a second- or third-line agent. Denosumab (Prolia) is a RANKL inhibitor approved by the FDA for treatment of postmenopausal osteoporosis. It is effective in reducing fracture risk (vertebral and hip) and also appears to be well tolerated. However, it inhibits RANKL in the immune system, which acts similar to TNF, and the long-term effects on infection and carcinogenesis risks are uncertain.

HELPFUL (MAYBE) TIP:

It seems as though more than 5 years of a bisphosphonate may increase atypical femur fracture risk (thought to be due to the suppression of osteoclast activity and reduced ability of bone to remodel). Therefore, a drug holiday is likely warranted. Additionally, many patients maintain bone density after stopping a bisphosphonate after 5 years of therapy—at least for a few years. There are no clear guidelines on this yet. Consider getting a DEXA scan a couple of years after stopping the bisphosphonate. If it shows bone loss, consider restarting the bisphosphonate or starting another agent, such as denosumab.

HELPFUL TIP:

Always check serum calcium, 25-hydroxy vitamin D and creatinine levels prior to starting therapy for osteoporosis. All pharmacologic treatments for osteoporosis may cause hypocalcemia, and low-serum calcium and/or vitamin D levels should be corrected prior to initiating therapy. Patients with chronic kidney disease (glomerular filtration rate < 30 mL/min) and osteoporosis present a therapeutic challenge and should be managed in consultation with an endocrinologist and/or nephrologist.

Before she leaves the office, you present your patient with literature on living wills and durable power of attorney for healthcare (DPOA-HC).

Question 21.2.10 Which of the following is CORRECT regarding advance healthcare planning?

- A) The Joint Commission requires that patients be asked about their advance directives on admission to the hospital
- B) A DPOA-HC can override a patient’s decision regarding treatment; this is known as the “gotcha rule”
- C) Once the patient has signed a living will, no further changes can be made regarding treatment decisions
- D) A DPOA-HC must be a family member or blood relative
- E) A DPOA-HC must be prepared by an attorney with a special certification

Answer 21.2.10 The correct answer is “A.” The Joint Commission requires that patients be asked about their advance directives on admission to the hospital. Advance directives can take many forms but are usually manifest in one of two ways: through a living will or a DPOA-HC. The purpose of a living will is to instruct healthcare decision-making in future events when the patient may not be able to communicate his or her wishes. These documents often contain brief clinical scenarios with patient preferences for life-sustaining measures. In contrast, a DPOA-HC is not as limited and can address situations not foreseen in a living will. If the patient becomes unable to participate in healthcare decision-making, then the DPOA-HC is instructed to exercise substituted judgment, using the patient’s previously stated healthcare preferences, to help direct future care. The DPOA-HC is appointed by the patient and can be a family member or another adult. The DPOA-HC cannot override a patient’s decision in healthcare matters, as such an action would violate patient autonomy.

HELPFUL TIP:

Although advance directives should be addressed with all patients, it is of particular importance to discuss them in the setting of chronic illness, life-threatening illness, advancing age, and with any deterioration in health status. A patient can change advance care plans whenever he or she wishes, as these decisions may change over time depending on goals of care. While a living will is often quite general in nature, a physician order for life-sustaining treatment form (which takes slightly different form in each state that has this legislation) may be even more helpful for patients with advanced illness. These forms go into greater detail regarding patient/family wishes for various kinds of treatment, including hospitalization, ICU care, artificial nutrition, etc.

► Objectives: Did you learn to ...

- Identify and implement appropriate preventive health services for older females?
- Discuss issues related to breast and gynecologic cancer screening?

- Define appropriate criteria for osteoporosis screening and identify risk factors?
- Initiate treatment in a patient with osteoporosis?
- Recognize the important and complementary roles of DPOA and advance directives?

QUICK QUIZ: GERIATRIC PREVENTIVE CARE

Which of the following statements is **INCORRECT** regarding preventive health in older adults?

- A) Although the optimal interval for vision screening is undetermined, many professional organizations recommend vision and glaucoma screening every 1 to 2 years in persons over age 65
- B) In women at high risk for breast cancer, prophylactic tamoxifen reduces the relative risk of *estrogen receptor positive* cancer by 35% to 50% (absolute reduction of seven cases in 1,000 women treated for 5 years)
- C) The American Cancer Society (ACS) and American College of Obstetrics and Gynecology (ACOG) recommend screening ultrasound for ovarian cancer in all women over the age of 60
- D) Although Pap smears are not generally recommended for elderly women, in many countries, the distribution of cervical cancer cases is bimodal, with peaks in the thirties and sixties

The correct answer is "C." In fact, ACOG, the USPSTF, and the American College of Physicians specifically recommend against ultrasound screening for ovarian cancer in asymptomatic women. All other statements are correct. In many countries, there are two age peaks for the incidence of cervical cancer ("D"); however, the median age of cervical cancer diagnosis in the United States is 50, and most new cases are diagnosed between women aged 35 and 65 years. As to "B," nothing is free. The reduction in estrogen receptor–positive breast cancer comes at the cost of an increase of 4 in 1,000 having a thromboembolic event and 4 in 1,000 having an endometrial cancer *and* no change in overall or cancer mortality.

HELPFUL (AND ENCOURAGING) TIP:

The incidence of cervical cancer in the United States has declined by more than 50% since 1975. Talk about a screening program that works!

CASE 21.3

An 82-year-old male patient presents to your office for confusion. His wife reports that he was in his usual state of health until 3 days ago. At that time, he developed abdominal pain and felt feverish. He then began to have a dry, hacking cough. On examination, his temperature is 100.3°F and blood pressure is 118/56 mm Hg. He is pale and lethargic but

in no acute distress. He is oriented to person only. Other than mild upper abdominal tenderness, there are no additional findings on examination. This patient appears to have a new onset of confusion. You suspect delirium.

Question 21.3.1 Which of the following is true with regard to delirium and dementia?

- A) In delirium it is rare to find an underlying medical cause
- B) A primary feature of delirium is inattention
- C) Dementia is characterized by an acutely fluctuating course
- D) Delirium only occurs in patients with dementia
- E) They are the same. After all, memory is but an ephemeral light in the long shadow of time

Answer 21.3.1 The correct answer is "B." The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) provides the diagnostic criteria for delirium. A diagnosis of delirium requires the following criteria: disturbance of attention and awareness (previously termed "consciousness" in DSM-IV); disorientation, memory deficit, or another change in cognition that cannot be accounted for by a pre-existing dementia; acute onset with fluctuating course (often changing throughout the day); and evidence that the disturbance is caused by an underlying medical condition or drug use (so "A" is incorrect). Not all signs and symptoms of delirium are present in every patient with delirium, nor will they be present at the same time. Delirium can be confused with dementia, depression, or psychosis. Patients with delirium may present as agitated, psychotic, somnolent, or withdrawn (these are the tough ones to recognize). Dementia is more chronic in nature with an insidious onset (making "C" incorrect). Dementia progresses over time and usually cannot be reversed. Often delirium is treatable or reversible if the underlying medical condition is identified and treated. Patients with dementia usually have intact attention, whereas patients with delirium have markedly impaired attention. Patients with dementia have "poverty of thought," which implies decreased content of their thoughts. Patients with delirium may have a rich content in their thoughts, but the thoughts are disordered. Patients with dementia are at higher risk for developing delirium, but dementia is not a pre-requisite for delirium, and "D" is incorrect.

HELPFUL TIP:

Delirium may be either hypoactive or hyperactive or both, all in the same patient. Many patients with delirium are not even identified due to their hypoactive state (these aren't the ones screaming obscenities and yanking out inflated bladder catheters—ouch!). Elderly patients are more susceptible to delirium, and delirium is sometimes the only identifiable symptom in an elder with an acute illness.

With further history from the patient's wife, you find that he has coronary artery disease, diabetes mellitus type 2, hypertension, and benign prostatic hyperplasia.

Question 21.3.2 Which of the following is the most useful question to elicit risk factors for delirium?

- A) “Does the patient have any drug allergies?”
- B) “Does the patient use tobacco?”
- C) “Does the patient use alcohol?”
- D) “Does the patient have edema?”
- E) “Does the patient use acetaminophen?”

Answer 21.3.2 The correct answer is “C.” Studies have consistently identified the following risk factors for delirium: advancing age, pre-existing dementia, underlying structural brain disease other than dementia, uncorrected impairment in vision or hearing, multiple chronic illnesses, polypharmacy, the use of physical restraints, history of alcohol abuse, male gender, and functional impairment.

While hypoxia (due to myocardial infarction, pulmonary embolus, or any other source) may lead to delirium, tobacco use (“B”) alone does not predispose a patient to develop delirium. In isolation, knowledge about edema (“D”), acetaminophen use (“E”), or drug allergies (“A”) is less helpful. Questioning about alcohol use (“C”) will help to identify patients who have a tendency to overuse alcohol, putting themselves at risk for delirium. Also, delirium may result from alcohol withdrawal.

HELPFUL TIP:

Pre-existing dementia greatly increases the risk of delirium, and simply moving a patient with dementia to a new environment can precipitate delirium.

Question 21.3.3 The appropriate evaluation of the patient with delirium includes which of the following?

- A) Evaluation of metabolic causes such as electrolytes and glucose
- B) Evaluation for infection such as pneumonia
- C) Evaluation of a patient’s medications
- D) Evaluation of oxygen saturation
- E) All of the above

Answer 21.3.3 The correct answer is “E.” There are many causes of delirium, often acting together in a multifactorial manner, and are best considered by a systematic approach. Metabolic causes include electrolyte disturbances (especially disturbances in serum calcium and sodium levels), hypoglycemia, and hypoxia. Numerous infections may lead to delirium. Neurologic causes include head trauma, meningitis, and vasculitis. Many medications cause delirium including anticholinergics, antidepressants, sedative-hypnotics, and steroids. Dehydration and prerenal azotemia may lead to delirium. See Table 21-2.

You reach for the “shotgun” (metaphorically, we hope) and order a bunch of tests. The chest radiograph shows a left lower lobe consolidation. The abdominal film shows a nonspecific bowel gas pattern. The white blood cell (WBC) count is 12,700/mm³, blood urea nitrogen 36 mg/dL, creatinine 1.5 mg/dL, and glucose 150 mg/dL. The remainder of the blood counts and chemistries are normal. With the exception of trace ketones, the urinalysis is within normal limits.

TABLE 21-2 CAUSES OF DELIRIUM, “WHHHHIMP” MNEMONIC

Wernicke encephalopathy
Hypoperfusion
Hypoglycemia and other metabolic abnormalities
Hypertensive encephalopathy
Hypoxia
Infection or intracranial bleed
Meningitis or encephalitis
Poisons or medications

Cultures will not be available for at least 24 hours. The ECG shows normal sinus rhythm. With the available information, you decide to admit this patient for treatment of delirium due to pneumonia and dehydration.

You are called in the middle of the night for agitated behavior and noncompliance with nursing care. The patient has pulled out his IV and struck a nurse.

Question 21.3.4 You appropriately prescribe which of the following interventions?

- A) Haloperidol 0.5 mg PO once
- B) Haloperidol 1 mg IV once
- C) Physical restraints for the next 24 hours
- D) Morphine 5 mg IV every 4 hours as needed
- E) Lorazepam 1 mg PO for the patient, 0.5 mg for the nurse

Answer 21.3.4 The correct answer is “A.” Most of the time, delirium DOES NOT require any pharmacologic treatment. However, this patient is at risk of harming himself and others due to his agitated delirium, so some action must be taken. Agitated delirium causes physiologic and psychologic stress on the patient, results in interference with medical care, and portends a poorer prognosis. The incidence of delirium in hospitalized patients of all ages is 30%, and the incidence in postoperative patients may approach 50%. Agitated delirium with high risk of physical harm to patient or staff should be treated quickly, and haloperidol is the treatment of choice. In older patients, drug clearance decreases, so low doses of antipsychotic medication should be administered initially. As the geriatricians say, “Start low and go slow.” Increasing doses of oral haloperidol can be given every 30 minutes if the patient continues to have agitation. “B” is incorrect because IV haloperidol is associated with a greater degree of QT prolongation; PO or IM haloperidol is preferred. “C” is incorrect; physical restraints may lead to patient injury and may worsen delirium, but they may be needed if other methods fail. Restraints should only be applied when absolutely necessary and for as short a duration as possible. “D” is incorrect because we have no reason to believe the patient is in pain, and administering narcotics could worsen his delirium. However, pain can certainly result in agitation, so keep it in mind. Finally, “E” is wrong for at least two reasons: there is a substantial risk of paradoxical agitation with benzodiazepine administration in demented elders, and you should not prescribe controlled substances to staff nurses or it’s “Good-bye medical license.” The most recent data suggests that treatment of delirium with antipsychotics does NOT reduce the severity of delirium nor cognitive functioning.

About the best you can hope for is sedation, which has its own problems (Ann Intern Med 2019 Sep 3):

You reflect on the fact that primary prevention of delirium is probably more effective than treatment. For this patient, delirium must now be treated, but you try to avoid this complication in your hospitalized older patients.

Question 21.3.5 You know that research has shown a reduction in delirium in hospitalized older patients when which of the following strategies is employed?

- A) Increased sedative medication use for sleep-deprived patients
- B) Early mobilization for immobilized patients
- C) Cholinesterase inhibitor (e.g., donepezil) therapy for cognitively impaired patients
- D) Physical restraints for combative patients
- E) Music therapy for depressed patients

Answer 21.3.5 The correct answer is “B.” Identifying risk factors and targeting interventions to reduce or eliminate risk factors can prevent delirium. Because one patient may have numerous risk factors for delirium and because delirium is usually a multifactorial syndrome, a multicomponent intervention strategy is warranted.

An often-cited study by Inouye et al. (1999) demonstrated the effectiveness of a multicomponent strategy. In the study, sleep-deprived patients received a warm drink, relaxing music, and back massage at bedtime. Unit-wide noise reduction was implemented. Early ambulation and active range-of-motion exercises were employed for bed-bound patients. All patients were encouraged to ambulate. Cognitively impaired patients received orienting stimuli and cognitively stimulating activities. Patients with hearing and visual impairments received portable amplifying devices and visual aids, respectively. Investigators used a protocol for early recognition and treatment of dehydration. There was no specific therapy for depression or combativeness. As you can see, the preventative strategies for delirium must also be broad as no one treatment has been singularly effective.

If not prevention, how about early detection? The Delirium Observation Screening Scale (DOSS) is an evidence-based tool that could have helped you identify delirium sooner in your patient, it has been validated in several populations, and it is freely available online. It takes into account consciousness, attention, thinking, memory/orientation, psychomotor activity, sleep/wake cycle, mood, and perception. Using DOSS takes just a few minutes and is, of course, easier and much safer than waiting to find him walking his imaginary dragon through the hospital ward while carrying a half-filled bedpan. See <https://igec.uiowa.edu/delirium/delirium-resources> for more resources on delirium.

Question 21.3.6 Which of the following statements about delirium is true?

- A) Bed rails and restraints are effective in preventing injury in the patient with delirium
- B) Atypical antipsychotics (e.g., olanzapine and risperidone) can be used to treat delirium

- C) Diphenhydramine is a good choice for a sleep aid in patients who are prone to developing delirium
- D) A feeding tube (e.g., Dobhoff tube) should be used in the patient who is not eating in order to prevent delirium
- E) Shouting, “You don’t have a dragon! They aren’t real!” helps to prevent complications of delirium

Answer 21.3.6 The correct answer is “B.” Atypical antipsychotics can be used in the treatment of delirium, but nonpharmacologic methods (e.g., bedside sitter and redirection) should be used first. “A” is incorrect because bed rails and restraints actually increase the risk and severity of injury in patients with delirium. Repeat after us: *restraints are used as a last resort*. “C” is incorrect. Diphenhydramine (“C”) is a particularly poor choice because of its anticholinergic side effects, which can exacerbate delirium. Melatonin and the melatonin agonist ramelteon have shown some ability to reduce the risk of delirium, but only when started prior to the onset of symptoms and only in small trials. “D” is incorrect, as anyone who has done inpatient work knows: the feeding tube and the Foley are often the first to get yanked! “E” is also no good. Never argue with a patient about his delusion. You will not win. *See note above regarding antipsychotics in delirium in the hospitalized patient.*

HELPFUL TIP:

Ethical dilemmas abound in the treatment of delirium. Atypical antipsychotic use in patients with dementia is associated with increased mortality. Older antipsychotics pose a greater risk for extrapyramidal symptoms when compared with atypicals and also pose the same mortality risk. By definition, agitated patients with delirium cannot provide informed consent, so “implied consent” is usually substituted to use drug therapy for patients with delirium at risk for self-injury.

► Objectives: Did you learn to ...

- Define delirium?
- Describe the signs and symptoms of delirium?
- Distinguish delirium from dementia?
- Identify causes and risk factors for delirium?
- Treat and prevent delirium?

► CASE 21.4

In the early morning hours, a 78-year-old female presents to the emergency department complaining of right buttock and hip pain. Several hours before her arrival, she fell in the bathroom of her daughter’s home. She recalls standing on a floor mat, leaning her head back to drink a glass of water, and then hitting the ground. She denies loss of consciousness. Her daughter was at the scene quickly and found the patient awake, alert, and moving all extremities. Her vital signs are normal. Other than right hip tenderness, her examination is unremarkable.

Question 21.4.1 Which of the following is most likely to assist you in determining the cause of her fall?

- A) CT scan of the head
- B) ECG
- C) Additional history
- D) Serum chemistry profile
- E) CBC

Answer 21.4.1 The correct answer is “C.” If there’s an option for “more history,” it’s usually the right answer. History is one of the most important factors in determining the etiology of a fall. Ten percent of falls in older persons can result in serious injury, such as a hip fracture or subdural hematoma. Falls in elderly patients are typically multifactorial in nature. Randomized clinical trials demonstrate a reduction in the occurrence of falls in community-dwelling elders when healthcare personnel engage in a multifactorial risk assessment with targeted management. Such an approach requires a thorough history.

Question 21.4.2 All of the following are risk factors for falls in elderly EXCEPT:

- A) Use of four or more medications
- B) Orthostatic hypotension
- C) Attempting tai chi, for which good balance is required
- D) Environmental hazards (e.g., poor lighting or uneven walking surfaces)

Answer 21.4.2 The correct answer is “C.” In fact, balance exercises such as tai chi and yoga have been shown to reduce the risk of falls in the elderly. All of the others listed increase the risk of falling. Additional risk factors for falls include history of a fall in the last year, impaired balance and gait, poor vision (acuity <20/60), decreased muscle strength, and syncope or arrhythmia. Still more risk factors: poor lighting, lack of grab bars and handrails, cluttered floor, restraint use, and improper bed height.

Question 21.4.3 During your examination, which of the following physical maneuvers is most likely to assist you in evaluating the risk of future falls?

- A) Get-up-and-go test
- B) Test for pulsus paradoxus
- C) Osler maneuver
- D) Lumbar spine flexibility test
- E) Test for nystagmus

Answer 21.4.3 The correct answer is “A.” The “timed get-up-and-go-test” is a commonly used method of assessing disability and fall risk in geriatric assessment. From a seated position, the patient is instructed to stand up, walk 3 m (approximately 10 ft), turn around, and return to their chair. An adult with no disability should be able to complete this test in <10 seconds. Increasingly longer time to perform the test is associated with increasing fall risk. While performing the test, assess the patient’s sitting balance, transition from sitting to standing,

gait and steadiness, and quickness with turning. While potentially useful in the evaluation, the other tests listed are not directly associated with fall risk. The Osler maneuver may be helpful in finding cases of pseudohypertension and should be checked in patients who are having falls associated with position changes despite normal or even high blood pressures as measure by sphygmomanometer. The Osler maneuver is performed by blowing up the blood pressure cuff until the radial pulse is absent. Then see if you can palpate a sclerotic, non-compressible, radial artery. If so, the Osler test is positive and the patient may have pseudohypertension.

After a thorough history, you perform a complete workup, including ECG, radiology studies, and appropriate laboratory tests. You find that the fall was caused by environmental factors (poor lighting and a loose throw rug) rather than an organic cause intrinsic to the patient. Fortunately, x-ray of her hip is negative for fracture. The patient asks how exercise might help her avoid future falls.

Question 21.4.4 Which of the following is the best answer?

- A) Physical therapist supervision is essential to have an effective fall prevention program
- B) In elderly patients, the effect of exercise on falling is unknown
- C) Strength training has a greater effect than balance training on reducing fall risk
- D) Unsupervised balance and strength training is effective in reducing fall risk
- E) Group exercise is more effective than exercising alone to prevent falls

Answer 21.4.4 The correct answer is “D.” There is no particular type of exercise that seems to prevent falls to a greater degree than any other type of exercise. Strength, balance, and gait training all appear to be important. Exercise programs have been shown to benefit elders at risk for falls. Although initial instruction by a therapist may be helpful, a physical therapist need not supervise all exercises. Patients are able to perform exercises targeted toward fall prevention at home, and they do not need to be part of an exercise group. A meta-analysis of the Frailty and Injuries: Cooperative Studies of Intervention Techniques (FICSIT) trials found that combined balance and strength training reduces the risk of falls in community-dwelling elders.

HELPFUL TIP:

Peripheral sensory disturbance is a common finding in the elderly and increases the risk of falling. A common cause of peripheral neuropathy is vitamin B12 deficiency. Check vitamin B12 levels. If they are low, great; treat with oral B12, 1,000 to 2,000 mcg/day. Alternatively, you can treat with 1,000 mcg/month IM. If the B12 level is borderline and you still have a high suspicion, check serum methylmalonic acid and homocysteine levels. These should both be high in B12 deficiency.

You recommend strength and balance exercises to the patient, but she is worried and says, “My heart’s too old for exercise.”

Question 21.4.5 You assure her that light exercises are safe and then review normal age-related cardiovascular changes, which include:

- A) Reduced ventricular compliance
- B) Reduced maximal heart rate
- C) Reduced response to sympathetic nervous stimulation
- D) Increased atrial filling
- E) All of the above

Answer 21.4.5 The correct answer is “E.” Even in the healthy elderly without signs of vascular disease, there are important changes in the cardiovascular system. Maximum cardiac output is reduced, mostly through reduced maximal heart rate; thus the equation:

$$\text{Estimated maximal heart rate} = 220 - \text{age}.$$

Additionally, there is reduced response to sympathetic stimulation, with less chronotropic and inotropic response to stress. Reduced ventricular compliance results in increased atrial filling volume and pressure, increased left atrial size, and increased dependence on atrial contraction for ventricular filling. However, endurance training may improve cardiac output, and active older adults have a higher cardiac output compared with sedentary persons of the same age.

HELPFUL TIP:

Hip fractures in the elderly are often caused by falls. In general, the sooner that a fractured hip is repaired, the better the outcome. Ideally, a hip should be repaired within the first 24 hours after the injury. Also, don’t just fix the break. Look for the underlying issues, like osteoporosis and the reasons the patient fell in the first place.

Because of her right hip pain, you consider giving the patient an ambulatory device for temporary use. She has good upper extremity strength, can bear some weight on the right, but needs improved stability.

Question 21.4.6 Which of the following devices would be most appropriate in this setting?

- A) Wheeled walker
- B) Forearm crutches
- C) Walk cane (hemi-walker)
- D) Imperial walker
- E) Multiple-legged cane (quad cane)

Answer 21.4.6 The correct answer is “E.” Ambulatory devices are employed with the following goals: improve mobility, decrease the risk of falling, and relieve discomfort associated with acute or chronic musculoskeletal and neurologic conditions. An inappropriately selected device can increase energy expenditure and the risk for falls. Canes widen a patient’s base,

resulting in increased stability. They are typically used for balance, not weight bearing. Multiple-legged canes—called “quad canes” because of the presence of four tips—provide a more stable base and some weight bearing, when compared with standard, single-tipped canes. Walk canes are useful for patients who require full weight bearing on one arm, as in a stroke survivor with loss of lower extremity function. Crutches, either forearm or axillary, are used for patients who cannot bear any weight on one leg.

Walkers can support a patient’s weight, provide lateral stability, and expand a patient’s support base. Standard walkers, those with four rubber tips, provide the greatest support and are helpful in cases of ataxia. Front-wheeled walkers are useful for patients with a fast gait, such as a festinating gait in parkinsonism. Also, a front-wheeled walker is easier to manipulate than a standard walker. Four-wheeled walkers should be used when the patient requires some increased stability but does not need as much weight-bearing as a standard walker would provide. Patients with mild-to-moderate Parkinson disease may benefit from four-wheeled walkers. In this case, the patient requires only improved stability and slight assistance with bearing weight. Of the available choices, the multiple-legged cane is the best option. A single-tipped cane may have been a reasonable choice as well. “D” is incorrect because the Imperial Walkers in *Star Wars* are infamously unstable and can be felled by a simple harpoon cable shot from the back of a snowspeeder.

The nurse brings you a quad cane from your supply closet.

Question 21.4.7 What method do you use to fit the cane?

- A) Allow the patient to fit the cane length to her comfort level
- B) Select a device with a length equal to the distance from the floor to the greater trochanter of the femur
- C) Fit the cane length so that the handle comes to rest at the patient’s waist
- D) Select a device with a length equal to the distance from the floor to the fingertips with the arm relaxed
- E) Extend the cane to its maximum length, giving it the appearance of a shepherd’s crook or wizard’s staff

Answer 21.4.7 The correct answer is “B.” You should fit a cane for a patient by selecting a device that reaches from the floor to the greater trochanter of the femur. Another option is to fit the cane so that it reaches the flexor crease of the wrist when the arm is extended to the side. A properly fitted ambulatory device should be comfortable, allowing the patient to stand erect without excessive forward flexion of the spine. Excessive forward flexion occurs when the device is too short and can result in increased risk of falling. To obtain maximum efficiency from the upper extremities, the device should not be too long. The usual recommendation is to have a device fitted so that the elbow is flexed at 15% to 30% when the cane is in use. This is done by measuring as noted above.

► **Objectives: Did you learn to ...**

- Recognize the morbidity associated with falls in older people?
- Evaluate causes and risks of falls in this population?
- Implement appropriate interventions for falling patients?
- Assess gait abnormalities that may lead to falls?
- Select ambulatory devices for appropriate patients?

QUICK QUIZ: ASSISTIVE DEVICES

If a patient is having difficulty walking due to left-sided hip pain from osteoarthritis of the hip, in which hand should a cane be used?

- A) Left hand
- B) Right hand
- C) Either hand
- D) Both hands simultaneously
- E) No cane should be prescribed; a wheelchair is preferred

The correct answer is “B.” Whenever a cane is used to support lower leg function limited by weakness or pain, the cane should be used in the hand *contralateral* to the affected side (left side weak, right hand gets the cane). This enables the patient to maintain normal arm swing while advancing the cane and the affected leg at the same time to reduce the weight-bearing forces on the affected limb during the step.

► **CASE 21.5**

A 69-year-old female with no complaints presents to your office with her two daughters. Further history from her daughters reveals that the patient was widowed 4 years ago, now lives alone, and has experienced memory loss over the last 2 years. One daughter has taken over the patient’s finances. The daughters report that their mother often wears the same clothes and bathes infrequently—new and unfortunate habits for her. The past medical history includes hypothyroidism and hypertension. Family history is significant for depression and memory problems in the patient’s mother prior to her death from “old age.” The patient takes chlorthalidone, levothyroxine, and acetaminophen as needed.

Physical examination reveals a thin, elderly female in no distress. She is alert but does not correctly identify the year. She describes her mood as “happy” most of the time. The remainder of the examination is unremarkable. You suspect that she has a “major neurocognitive disorder,” previously termed “dementia.” (Note: we don’t make this stuff up.... the name has been changed. However, the term “dementia” is so commonly used and well understood that we will continue to use this term here.)

Question 21.5.1 According to the DSM-V, which of the following is true regarding the diagnosis of major neurocognitive disorder (NCD, formerly dementia)?

- A) The diagnosis is rarely missed in the primary-care setting
- B) To diagnose a major NCD, impairment in executive function *must* be present
- C) To diagnose a major NCD, impairment in cognition *must* be present
- D) Alzheimer disease (AD) is a diagnosis of exclusion
- E) Neuroimaging is essential in the diagnosis of any major NCD

Answer 21.5.1 The correct answer is “C.” The DSM-V has redefined the diagnostic criteria for dementia and in fact renamed it “major neurocognitive disorder.” *In one of the most significant revisions, there is no longer a requirement for memory impairment to diagnose dementia.* Rather, major neurocognitive disorder is a deficit in any of the following six cognitive domains: learning/memory, language, executive function, complex attention, perceptual-motor function, and social cognition. The deficit must be acquired and not be due to other medical conditions, mental health issues, or substance abuse. *Finally, it is referred to as major neurocognitive disorder because it interferes with a patient’s independence.* Mild cognitive disorder, on the other hand, is the term for patients with some cognitive decline but who remain independent. “A” is incorrect. In contrast to delirium and depression, the onset of dementia is insidious. Symptoms often go unrecognized for months to years prior to diagnosis. Although the patient may complain of confusion or memory loss, family members are more likely to provide the chief complaint and history. During the initial phases of a dementing illness, patients and family members may attribute cognitive changes to normal aging. In early cognitive impairment, memory symptoms may wax and wane. However, symptoms of dementia can be differentiated from occasional normal lapses based on their increasing severity. For example, it is normal to forget an acquaintance’s name, but clearly abnormal to forget a spouse’s name. “B” is incorrect. Many patients with dementia have impaired executive functioning (e.g., judgment, reasoning, and planning), but the presence of impaired executive functioning is not a requirement. “D” is incorrect, as AD is diagnosed by a specific set of clinical criteria. DSM-V provides diagnostic criteria for dementia and AD, making AD a diagnosis of inclusion rather than exclusion. “E” is incorrect. Dementia is a clinical diagnosis and does not require neuroimaging for confirmation. Experts and professional medical associations differ in their recommendations regarding the use of neuroimaging in dementia. In general, neuroimaging is recommended if dementia occurs in the following scenarios: onset before age 65, sudden onset, presence of focal neurologic signs, and suspicion of normal pressure hydrocephalus.

You use several office assessment tools to further characterize the memory loss. She scores 23/30 on the Folstein Mini-Mental State Exam, missing orientation and recall items. Clock drawing is grossly abnormal. Her geriatric depression

scale is 3 positive responses out of 15 (positive screen is 5/15 or greater). She performs all basic activities of daily living (ADLs) independently but has voluntarily given up driving and control of her finances.

Question 21.5.2 Regarding assessment tools used in the evaluation of memory loss, which of the following statements is most accurate?

- A) The Mini-Mental State Exam (MMSE) evaluates executive function and visual-spatial skills
- B) Formal neuropsychological testing offers no benefit over the MMSE for detecting dementia
- C) The use of a screening tool for depression is not helpful in the evaluation of memory loss
- D) Clock drawing evaluates executive function and visual-spatial skills
- E) The MoCA evaluates the ability to discern a chocolate coffee beverage from regular coffee

Answer 21.5.2 The correct answer is “D.” Clock drawing can be used to evaluate executive function as well as visual-spatial skills. **Clock drawing is a simple test that takes 1 minute or less to perform.** The patient is asked to draw a clock face and set the hands to 2:50 or 11:10. This test requires planning and visual-spatial ability on the part of the patient—two areas that are incompletely evaluated by the MMSE. A normal clock does not rule out dementia, but an abnormal clock is suggestive of cognitive impairment. There are several scoring systems, and the sensitivity and specificity for dementia are as high as 87% and 82%, respectively. Of course, in 50 years no one alive will have ever seen a clock with hands, and this test will go the way of the dodo bird.

“A” and “B” are incorrect. The MMSE is a 30-point scale, with the cutoff for dementia between 24 and 26. The MMSE can be performed in a few minutes and tests memory, orientation, language, construction, and concentration. The MMSE does not test prosody (expressive and receptive inflection of vocalization) or executive function and, as a result, has poor sensitivity for early cognitive impairment in some individuals. Performance on the MMSE is strongly correlated with education; therefore, there may be false-positives in undereducated patients and false-negatives in highly educated individuals. Compared with the MMSE, formal neuropsychological testing assesses a broader array of cognitive functions, identifies behavioral abnormalities and assesses mood disorders. It can also help to differentiate between types of dementia. In general, neuropsychological testing is the most sensitive and specific cognitive assessment tool, but it is time-consuming and requires a high level of expertise to administer and interpret. “C” is incorrect because depression may cause memory problems, especially in the elderly, and depression screening should be included in the workup of memory concerns. Depression often coexists with dementia, and treatment of depression may improve memory problems. *It is also important to keep in mind that depression commonly is the first presenting sign of memory problems.* “E” is incorrect. See the related Helpful Tip for more on the MoCA.

HELPFUL TIP:

The Montreal Cognitive Assessment (MoCA) is a cognitive assessment tool freely available online, published in multiple languages, and validated in the diagnosis of dementia. Like the MMSE, it is a 30-point scale, but the MoCA tests a wider range of cognitive domains with less emphasis on orientation. Compared to the MMSE for the diagnosis of dementia, the MoCA has greater sensitivity (94% compared to 87% for MMSE), but takes a few minutes longer to administer and has a higher false-positive rate (around 40%).

So far, you have collected the following information on this patient: MMSE score 23/30, inability to properly draw a clock, impairment in driving and managing finances, disorientation to time, but intact abilities to cook, clean, and care for herself.

Question 21.5.3 Using conventional staging for Alzheimer disease (AD), how would you categorize this patient's dementia?

- A) Mild
- B) Moderate
- C) Severe
- D) Terminal
- E) Insufficient information to determine the stage

Answer 21.5.3 The correct answer is “A.”

- Mild AD symptoms include impaired memory, mild personality changes, and mild disorientation (MMSE 19–24)
- Moderate AD symptoms include aphasia, apraxia, insomnia, and increasing confusion (MMSE 10–19)
- Severe AD symptoms include severe memory loss, motor impairment, and loss of some basic ADLs (MMSE <10)
- Symptoms of terminal AD include immobility, dysphagia, weight loss, and increasing susceptibility to infections

Question 21.5.4 Which of the following findings would most likely cause you to search for a diagnosis other than AD in a patient presenting with moderate cognitive impairment?

- A) Paranoid behavior
- B) Apraxia
- C) Poor judgment
- D) Aphasia and personality changes
- E) Bradykinesia and rigidity

Answer 21.5.4 The correct answer is “E.” Bradykinesia and rigidity are features of parkinsonism, which, in the setting of memory loss, should prompt consideration of Lewy body dementia or Parkinson disease. Paranoid behavior, delusions, and hallucinations can all occur with more severe AD. Aphasia, apraxia, and personality changes typically occur later in AD but can be initial complaints in atypical presentations of AD.

Although you strongly suspect AD in this patient, you consider other types of dementia as well. Suppose this patient presented with urinary incontinence and ataxia in addition to her current findings.

Question 21.5.5 Which of the following diagnoses would be most likely?

- A) Creutzfeldt–Jakob disease
- B) Lewy body dementia
- C) Normal pressure hydrocephalus (NPH)
- D) Pick disease
- E) Walking corpse syndrome

Answer 21.5.5 The correct answer is “C.” NPH classically presents with dementia, gait ataxia, and urinary incontinence. When detected early, it responds to ventriculoperitoneal shunting and is thus a reversible cause of dementia. However, the dementia is rarely fully reversible. Gait abnormalities typically occur first and are the most likely to improve with removal of cerebrospinal fluid (CSF). The diagnosis of NPH is supported by findings on brain MRI, and it is confirmed by symptom improvement after CSF removal. Incidentally, NPH is a misnomer since intermittent CSF pressure elevations have a pathophysiologic role in the disease. “E” is a real thing, but not the right answer. Walking corpse syndrome is a rare psychiatric illness in which the patient is under the delusion that he is dead. Keep reading to learn why the other foils are wrong.

In discussing this case with one of your colleagues he wonders if you have missed a diagnosis of frontotemporal dementia (FTD).

Question 21.5.6 You think it is unlikely that your patient has FTD because she does not have:

- A) Depression
- B) Disinhibition
- C) Hemiplegia
- D) Rapidly progressing dementia
- E) Tremors and hallucinations

Answer 21.5.6 The correct answer is “B.” FTDs (including Pick disease) constitute a heterogeneous group of neurodegenerative disorders that have the common pathologic finding of cortical degeneration in frontal and temporal areas of the brain. Typical features of these dementias include an insidious onset and a slowly progressive course. Patients have impairments in judgment and insight. They are disinhibited and socially inappropriate. Patients may present with anxiety, depression, delusions, or emotional indifference. “A” is incorrect. Depression frequently coexists with many types of dementia but does not define one particular type. “C” is incorrect; the presence of hemiplegia in a patient with dementia should bring to mind vascular causes. “D” is incorrect because rapidly progressing dementia is the hallmark of prion disease, such as Creutzfeldt–Jakob disease. “E” is incorrect as tremors, hallucinations, and memory loss are consistent with Lewy body dementia (named

for its characteristic pathological finding—the presence of Lewy bodies in the brain stem and cortex). Clinical features consist of cognitive impairment, detailed visual hallucinations, fluctuation in alertness, and motor symptoms of parkinsonism.

HELPFUL TIP:

Alzheimer disease (AD) is the most common form of dementia, encompassing about 60% of patients with dementia. Vascular and Lewy body dementias account for about 15% to 30%. In many cases, dementia has more than a single cause. AD and vascular dementias frequently coexist—an entity commonly referred to as “mixed dementia.”

The elevator gets stuck on your way back from making your morning rounds and your phone’s battery is dead, giving you more time to contemplate dementia.

Question 21.5.7 Which of the following is NOT consistent with the diagnosis of vascular dementia?

- A) Diabetes
- B) Tobacco use
- C) Diffuse slowing or normal electroencephalogram (EEG)
- D) Normal brain MRI
- E) History of carotid endarterectomy

Answer 21.5.7 The correct answer is “D.” A normal MRI essentially rules out vascular dementia. Features suggestive of vascular dementia include a stepwise deterioration in cognitive function, onset of cognitive impairment with stroke, infarcts and white matter changes on neuroimaging, and focal neurologic findings on examination. There are no well-defined criteria for clinically diagnosing vascular dementia, and available rating scales have poor predictive value when compared with autopsy as the diagnostic standard (of course by then it is too late). Known vascular disease (like carotid artery disease) and vascular risk factors, such as diabetes, hypertension, and smoking, support the diagnosis.

Finally back in your office with coffee in hand, you decide to evaluate for reversible causes for this patient’s dementia, and you consider ordering laboratory tests.

Question 21.5.8 Which of the following laboratory tests is NOT indicated in the initial evaluation for reversible causes of dementia?

- A) Cyanocobalamin (vitamin B12)
- B) Liver enzymes
- C) CBC
- D) CSF analysis
- E) Thyroid function tests

Answer 21.5.8 The correct answer is “D.” When evaluating a newly diagnosed case of dementia, one must consider infectious, metabolic, toxic, and inflammatory etiologies. Therefore, the

TABLE 21-3 LABORATORY EVALUATION OF DEMENTIA**Required Minimum Testing**

- Complete blood count
- Serum glucose and electrolytes
- Vitamin B12
- Renal function tests
- Liver function tests
- Thyroid function tests

Testing Based on Clinical Suspicion

- Neuroimaging (recommended for all patients by some societies)
- Urinalysis
- Urine toxicology screen
- HIV antigen/antibody assay
- CSF analysis
- Syphilis

minimal required laboratory tests should include CBC, serum glucose and electrolytes, vitamin B12, and renal, liver, and thyroid function tests. Further laboratory tests should be obtained as clinical suspicion indicates. In the appropriate patient, one might obtain urinalysis, urine toxicology screen, HIV antibody assay, syphilis serology, and CSF analysis. Because of the extremely low incidence of neurosyphilis in modern times, routine testing for syphilis is no longer required but should be considered in the appropriate setting. Neuroimaging is not a required part of every workup but may be helpful in some patients. See Table 21-3.

Blood chemistries, blood counts, thyroid hormone levels, vitamin B12 level, and liver enzymes are in the normal range. A non-contrast CT scan of the brain shows nonspecific “age-related” changes (that was helpful!). The patient and her family return to discuss the test results. You begin to educate them about AD and dementia in general. The two daughters are concerned that other family members may be at risk for developing AD.

Question 21.5.9 Which of the following is the strongest risk factor for developing AD?

- A) Age
- B) Apolipoprotein E 4 (*APOE* 4) allele
- C) Family history
- D) Head trauma
- E) Low educational level

Answer 21.5.9 The correct answer is “A.” As with many diseases, age is the greatest risk factor for developing AD. Among persons 65 to 69 years old, the incidence of AD is 1%. In persons 85 years and older, the incidence rises to 8%. All of the other answer options are associated with an increased risk of AD but not to the same degree as age.

Family history is another factor strongly associated with developing AD. By age 90, almost half of persons with first-degree relatives with AD develop the disease. There are genetic risk factors as well. Mutations on chromosomes 1, 14, and 21 are known risk factors for AD. Trisomy 21 is a risk factor for developing AD at

an earlier age (often by age 50). *APOE* 4 allele increases risk and decreases age-of-onset of AD in a dose-related fashion, with the greatest risk present in persons homozygous for *APOE* 4.

Other potential risk factors include a history of head trauma, lower educational achievement, female gender, and depression. Postmenopausal estrogens may actually increase the risk of dementia. Hypertension, diabetes, and hyperlipidemia are associated with dementia, and controlling these diseases might reduce the risk of developing dementia in the future, but the evidence is not strong. Increased physical, mental, and social activities may reduce cognitive decline in later years.

Question 21.5.10 The patient and family ask about medications to treat AD. Which of the following statements is TRUE?

- A) Studies show that vitamin E supplementation improves cognition and prevents further neuron loss in AD
- B) Ginkgo biloba and cholinesterase inhibitors have a synergistic effect, improving cognition in AD
- C) Cholinesterase inhibitors do not prevent neuron loss in AD
- D) Cholinesterase inhibitors maintain cognition at baseline levels for 2 years after initiation of therapy; after that time, patients decline slowly
- E) Memantine is considered first-line therapy for mild cognitive impairment and early dementia

Answer 21.5.10 The correct answer is “C.” Cholinesterase inhibitors do not prevent neuron loss. Results with vitamin E have been inconsistent, and some studies have found a slightly **higher** risk of death in those on high-dose vitamin E (≥ 400 IU/day), primarily in those with coronary artery disease. Given the low cost and potential benefits of vitamin E, it may still be reasonable to use in combination with a cholinesterase inhibitor in AD at a dose of <400 IU/day if the patient or family is so inclined. There is no evidence to support the use of ginkgo biloba in AD. As of 2019, there are just two classes of FDA-approved drugs for AD. Cholinesterase inhibitors (e.g., donepezil, rivastigmine, galantamine) represent the larger class of available pharmacotherapy used to treat mild-to-moderate AD. Studies suggest that cognitive decline may stabilize for 3 to 6 months after which there is steady loss of cognition. By 9 to 12 months, there is no difference in the rate of decline between those on therapy and those on placebo. The other class has only one medication, memantine, which is an *N*-methyl *D*-aspartate (NMDA) antagonist used to treat moderate-to-severe AD. NMDA antagonists and cholinesterase inhibitors are often prescribed in combination; however, there seems to be little or no clinical benefit to combining these drugs. Memantine appears to do nothing for mild dementia and has shown very minimal (some might say clinically insignificant) difference in moderate-to-severe dementia.

**HELPFUL TIP:**

All of the cholinesterase inhibitors have similar efficacy. Tacrine is known to cause hepatotoxicity and is rarely used. The choice of cholinesterase inhibitor depends on cost, patient acceptance, and physician experience.

Using your favorite clinical decision aid, the Ouija board, you decide to start the patient on a cholinesterase inhibitor.

Question 21.5.11 In your discussion about the medication, you tell the patient and her family:

- A) “These drugs are indicated for treating all types of dementia”
- B) “These drugs offer no benefit in moderate Alzheimer dementia”
- C) “These drugs are proven to reverse memory loss”
- D) “These drugs are proven to reduce mortality”
- E) “Gastrointestinal intolerance is one of the most common side effects of these drugs”

Answer 21.5.11 The correct answer is “E.” There is no shortage of controversy when it comes to medications for dementia. However, the side effects are indisputable. Gastrointestinal intolerance—with nausea, anorexia, and diarrhea—is the most common. Also, cholinesterase inhibitors have a “vagotonic” action, which can cause bradycardia and syncope and worsen cardiac conduction abnormalities. To minimize adverse events, the dose of cholinesterase inhibitor should be increased only after the patient has been on a stable dose for 4 to 6 weeks.

There are statistical differences in the outcomes measured for AD patients on cholinesterase inhibitors, but are these changes clinically significant? There is no difference in performance of ADLs, time to nursing home placement, etc. “A” is incorrect. Mostly, these drugs are used in AD. Their use in Lewy body and vascular dementia is off-label but may be worth a try; there is some data to support cholinesterase inhibitors for these patients. However, there is no evidence to support their use in FTDs (e.g., Pick disease). “B” is not true. Most studies of cognitive effects of cholinesterase inhibitors have occurred in mild-to-moderate AD (MMSE 10–24). “C” and “D” are incorrect. Compared with placebo, cholinesterase inhibitors delay further cognitive and functional decline but neither reverse dementia nor affect mortality. In cholinesterase inhibitor studies of mild-to-moderate dementia, there is typically a three-point difference on the MMSE between treatment and placebo groups at 6 months. This finding is due to a loss of thinking abilities in the placebo group and a delay in that loss in the treatment group.

HELPFUL TIP:

Not every confused elderly person should be put on a cholinesterase inhibitor. Consider the diagnosis, severity of disease, and the goals for the patient and family. Determine why you are starting the drug and be clear on the goals you hope to achieve. Then be willing to discontinue it if your patient is not reaching those goals. The side effects of cholinesterase inhibitors are symptoms often seen in nursing home patients (e.g., falls due to bradycardia and weight loss from anorexia). If your patient is losing weight and/or falling, consider discontinuing the cholinesterase inhibitor.

One year later, the patient returns with her daughter, with whom she now lives. The daughter reports disturbing symptoms that occur nightly. The patient wakes up in the middle of the night and wanders the house, becoming confused and agitated. With a subtle nod toward her mother, the daughter states, “I just can’t take much more of this.”

Question 21.5.12 After inquiring about pain and any changes in health status and finding none, your initial recommendation is to:

- A) Employ soft restraints only during the night
- B) Consider environmental changes including more daytime structured activities through an adult day care center
- C) Initiate an antipsychotic before bedtime
- D) Initiate a sedative-hypnotic before bedtime

Answer 21.5.12 The correct answer is “B.” Treating behavioral issues in patients with AD can be very challenging. Further history must explore the possibility of pain-related agitation, decline in comorbid conditions or new health conditions, such as occult infection, and any medication changes that may be playing a role. If a treatable cause is not identified, then environmental change is the best initial recommendation. Adding structured daytime activities may facilitate a better sleep–wake cycle. Adult day care can provide structured activities during the day, along with respite for the daughter who is obviously asking for extra support. Although medications are sometimes needed, “C” and “D” are incorrect for initial treatment in this case. Once environmental changes have failed or there are other immediate health risks involved, then medications may be necessary. Antipsychotics currently offer the only drug treatment for behavioral symptoms in **dementia**; as opposed to delirium, which was discussed above however, there are no great choices. Haloperidol, risperidone, and olanzapine are used most often. See Table 21-4 for selected medications used to treat behavioral symptoms in dementia. Sedatives, such as benzodiazepines, often result in paradoxical agitation in elderly patients with dementia. “A” is incorrect. Restraints should be avoided in most cases, even soft restraints. Although they are sometimes required to prevent harm to the patient or caretakers, restraints are known to result in worsened agitation and an increased risk of fall, injury, and rhabdomyolysis.

HELPFUL TIP:

When patients with Lewy body dementia receive antipsychotic medication for hallucinations, parkinsonian features become much more pronounced. If possible, avoid antipsychotics in these patients. If needed, use a second generation (“atypical”) antipsychotic. Zonisimide (an antiepileptic) can improve motor symptoms without worsening cognition (*Neurology*. 2018 Feb;90(8):e664–e672).

Despite the addition of adult day programming, medication becomes necessary. Haloperidol, or “vitamin H,” nightly has resolved the agitation. Although you may have increased your

TABLE 21-4 MEDICATION MANAGEMENT FOR BEHAVIORAL SYMPTOMS OF DEMENTIA

Behavioral Subtype	Acute Management	Long-Term Management
Psychosis	Conventional high potency Antipsychotic (CHAP) ^a	Risperidone, CHAP
Anxiety	Benzodiazepines	Buspirone
Insomnia	Trazodone	Trazodone
Sundowning	Trazodone; consider CHAP, risperidone, olanzapine	Trazodone; consider CHAP, risperidone, olanzapine
Aggression, severe	CHAP, risperidone	Divalproex, risperidone, CHAP
Aggression, mild	Trazodone	Divalproex, SSRIs, trazodone, buspirone

^aCHAP includes haloperidol, perphenazine, and fluphenazine. For elderly patients with dementia, typical doses should be about one-quarter of the usual dose (e.g., risperidone 0.25 mg, olanzapine 2.5 mg, or quetiapine 25 mg, and haloperidol 0.25–0.5 mg).

Note: Recent data suggests that quetiapine is the safest option for an antipsychotic in this group with haloperidol being associated with the greatest increase in stroke and mortality risk (*JAMA Psych* 2015, March 18).

patient's risk of dying (as seems to occur when antipsychotics are used in dementia), her daughter is thrilled with the result. Three months later she returns with concerns about depression. The patient spontaneously cries several times per day, her appetite is poor, and she has no desire to leave the house or even get dressed most days.

Question 21.5.13 Since a pill worked last time, her daughter wants to know what antidepressant is most effective for depression in patients with dementia?

- A) Citalopram
- B) Mirtazapine
- C) Sertraline
- D) None of the above

Answer 21.5.13 The correct answer is "D." There are very few quality studies available to guide treatment of depression in patients with dementia. The available evidence shows no difference between antidepressant therapy and placebo. The diagnosis of depression in a patient with dementia is complicated, since dementia causes apathy, sleep disturbance, appetite loss, and social withdrawal. If depression is suspected in a patient with dementia, a prudent approach would be to employ nonpharmacologic therapy and then provide an empiric trial of an antidepressant.

HELPFUL TIP:

There is some support for using stimulant medication (e.g., methylphenidate) to treat apathy in patients with dementia. The potential benefit must be weighed

against the known adverse effects of stimulants, such as appetite suppression, hypertension, and cardiac arrhythmia.

Over time, as the patient's dementia progresses, you reevaluate end-of-life issues and advance directives. With the support of her family, the patient decides not to have cardiopulmonary resuscitation.

Question 21.5.14 In end-stage AD, which of the following is correct?

- A) Malnutrition is the most common cause of death in patients with severe dementia
- B) Hospitalization for pneumonia in patients with severe dementia improves morbidity and mortality
- C) In severe dementia, gastrostomy tube feeding prevents aspiration
- D) To increase comfort, dehydrated patients with severe dementia should receive IV hydration
- E) In advanced AD, treatment of infections with oral and IV antibiotics is equally efficacious

Answer 21.5.14 The correct answer is "E." Hospitalization for demented patients with pneumonia is a wash. The number of patients saved by the use of IV antibiotics is offset by an increase in death and functional deterioration as a result of the hospitalization. Thus, on balance, oral and IV antibiotics are equally efficacious in the treatment of infections in these patients; therefore, severely homebound patients with dementia or nursing home residents should be treated in their usual environment rather than hospitalized (if consistent with their healthcare goals). "A" is incorrect. The majority of patients with dementia die of infection, not malnutrition. "B" is incorrect as noted above. "C" is incorrect. Even in moderate-to-severe AD, feeding tubes can be useful in the acute setting. But the tube should be removed and natural feeding resumed as soon as the acute event passes. **Permanent gastrostomy tube feeding is not recommended in patients with severe or terminal dementia. Tube feeding does not prolong life, prevent aspiration, or promote weight gain in advanced dementia.** Although many patients with advanced dementia are malnourished and dehydrated, these conditions do not appear to cause discomfort. Hand feeding is as effective as any other means for providing nutrition and can lead to rewarding interactions for both the patient and the caregiver.

HELPFUL TIP:

Remember the caregivers! Ask about their health and mood. Twenty-five percent of caregivers to the elderly are depressed, while older people caring for their disabled spouses have a 63% higher chance of dying than non-caregivers of the same age. Consider screening caregivers using a validated tool like the short form of Zarit Burden Interview.

► **Objectives: Did you learn to ...**

- Identify symptoms, signs, and diagnostic criteria for dementia?
- Describe different types of dementia and how they are diagnosed?
- Evaluate the patient with dementia, considering the potential causes of dementia?
- Describe potential benefits and limitations of current pharmacologic therapy for AD?
- Describe the natural course of AD?
- Manage a patient with end-stage AD?

► **CASE 21.6**

A 71-year-old male whom you have known since starting your practice recently suffered a stroke, resulting in language deficits and right hemiparesis. His medical history is significant for hypertension, hyperlipidemia, ulcer requiring partial gastrectomy (remote), and coronary artery disease. He quit tobacco and alcohol 5 years ago. He is retired and widowed. After a 3-day hospitalization, he appears stable enough for discharge. His medications include aspirin, metoprolol, lisinopril, and atorvastatin. Prior to entering a care center to receive skilled nursing care and therapies, the patient wants to know who will pay for the services. He has Medicare parts A and B.

Question 21.6.1 You are able to assure him:

- A) Medicare will cover all expenses indefinitely regardless of personal financial resources
- B) Medicaid will cover all of the expenses for the first 100 days of skilled care regardless of personal financial resources
- C) Medicare will cover part of the expenses for the first 100 days of skilled care regardless of personal financial resources
- D) Medicare requires a hospital stay of 7 days or longer prior to entering a nursing home for skilled care
- E) Medicaid and Medicare do not cover nursing home expenses under any circumstances

Answer 21.6.1 The correct answer is “C.” Medicare Part A, which provides some healthcare for patients 65 years and older if they qualify for Social Security benefits, will pay all costs for skilled care for the first **20 days** and part of the costs thereafter up to a total of 100 days per calendar year. This Medicare benefit includes rehabilitation (e.g., physical therapy, occupational therapy, and speech therapy) and skilled nursing care (e.g., nursing home, skilled care facility, and rehabilitation hospital) after a hospital stay of at least 3 days. (Note that the 3-day rule is considered antiquated by many providers and, as of 2019, Medicare has begun piloting programs that do not require three nights in a hospital.) The skilled care benefit is contingent upon the patient having an appropriate diagnosis, rehabilitation potential, and continuing to show improvement during the time the benefit is in place. Medicaid will provide extended nursing home care if a person’s assets and income are below a certain threshold, which varies from state to state. Although Medicare Part B will pay for physician visits to nursing home patients,

Medicare does not pay for nursing or other care directly related to permanently living in a nursing home.

Although he received fairly intensive physical, occupational, and speech therapies, your patient does not regain much function. He has only minimal movement in the right arm and complains of pain in the right shoulder. A radiograph of the right shoulder shows degenerative changes. The nursing staff administers acetaminophen 650 mg PO when the pain is severe, yet he continues to complain of shoulder pain. You involve physical therapists in his care to reduce the risk of chronic dislocation of the shoulder.

Question 21.6.2 In order to control his pain, which of the following is the most appropriate to add as a *scheduled*, and presumably chronic, medication?

- A) Acetaminophen
- B) Oxycodone
- C) Gabapentin
- D) Aspirin
- E) Naproxen

Answer 21.6.2 The correct answer is “A.” The point here is that scheduled acetaminophen is more appropriate for around-the-clock pain than PRN dosing. Acetaminophen is the safest analgesic of those listed. It may provide sufficient pain relief—if given scheduled (e.g., 1,000 mg PO TID). If it does not, then another medication may be added. “B” is incorrect as a first step as narcotics can cause confusion, sedation, urinary retention, and falls, and they have been associated with an increased mortality risk in the elderly. However, this patient has a history of an ulcer, and a narcotic analgesic may be a reasonable medication to add after acetaminophen (hydrocodone). Use clinical judgment. We have farmers who have been on the same dose of hydrocodone for years and years. “C” is incorrect. Gabapentin is indicated for postherpetic neuralgia and is more useful for neuropathic pain (although not very useful there either; tricyclics are better). “D” and “E” are incorrect. Aspirin and NSAIDs must be used with caution in the elderly due to increased risks of silent GI bleeding, fatal GI bleeding, and kidney injury. NSAIDs are typically not first-line agents for arthritis pain in this age group and probably offer no greater pain relief than acetaminophen. Also, consider topical therapies for pain, including capsaicin and lidocaine. Nonpharmacologic modalities should be employed as well, including massage, exercises, and physical therapy.

A nurse calls to report that your patient has developed lethargy, decreased appetite, and a temperature of 37.8°C. Your first thought is, “So? That’s not a fever.”

Question 21.6.3 And then you realize that:

- A) An elevated temperature in older persons is most often due to changes in basal body temperature regulation
- B) Oral antibiotics will not be sufficient to treat this infection
- C) Antibiotics will not be necessary to treat this condition
- D) Absence of significant fever in the elderly does not rule out serious bacterial infections

Answer 21.6.3 The correct answer is “D.” Older persons, especially frail elders and nursing home patients, often have lower basal body temperatures compared with younger persons and may not mount as great a febrile reaction to infection. Recall that the “normal” body temperature of 37°C was determined in the 19th century as a mean temperature in a series of children. The mean healthy adult temperature is actually about a quarter degree lower. While a temperature >38.1°C in a frail elder is most likely associated with a serious bacterial or viral infection, absence of significant fever does not rule out serious bacterial infections. In fact, hypothermia is also an important sign of significant illness in older, frail patients. “C” is incorrect. With the available information, it is difficult to say with any certainty if the patient has an infection treatable with antibiotics. If he did, oral antibiotics are often appropriate in the nursing home setting, even when treating pneumonia.

With a decline in his function and a mildly elevated temperature, you plan to evaluate this patient for infection. According to the nursing staff, there are no other residents with apparent infections. Your patient has not developed any focal symptoms (e.g., cough, dysuria, diarrhea, or site-specific pain).

Question 21.6.4 Which of the following tests will be LEAST helpful?

- A) CBC
- B) Urinalysis with microscopic examination
- C) Stool culture
- D) Chest radiograph
- E) Blood oxygen saturation (pulse oximetry)

Answer 21.6.4 The correct answer is “C.” He is not having diarrhea so a stool culture is not likely to be of benefit. This is not a black-or-white area, but there are some principles and expert opinions to follow. Patient and family wishes regarding care must be known prior to initiating an evaluation, therapy, or hospital transfer. While the elderly may have a serious infection with only slight or even no leukocytosis, a normal WBC count on CBC (“A”) will reduce suspicion for serious bacterial infection. Even without specific urinary symptoms, urinalysis (“B”) is recommended because of the high incidence of UTI in this population. Remember, however, that asymptomatic bacteriuria can occur in up to 50% of women and 40% of men living in long-term care facilities and treating this confers no benefit. Blood oxygen saturation (“E”) below the normal range (<90% on room air) may indicate serious respiratory illness; in the setting of hypoxia, a chest radiograph (“D”) is recommended.

Question 21.6.5 Regarding infectious diseases in nursing home settings, which of the following is correct?

- A) If the influenza vaccine is administered within 24 hours of an outbreak, patients require no further prophylaxis
- B) All residents who are carriers of methicillin-resistant *Staphylococcus aureus* (MRSA) must undergo an MRSA eradication program with appropriate antibiotics
- C) Most cases of bacteremia are caused by infected skin ulcers

- D) New residents should receive a two-step tuberculin skin test, unless positive on the first test
- E) All residents who are carriers of *Clostridium difficile* must undergo an eradication program with appropriate antibiotics

Answer 21.6.5 The correct answer is “D.” The incidence of tuberculosis is relatively high in the older population, as is mortality from the disease. Institutionalized elders should be screened for tuberculosis with the two-step tuberculin skin test. A two-step test involves repeating the tuberculin skin test 1 to 3 weeks after an initial negative test (<10 mm induration). Anergy testing is no longer recommended. The test is positive if the induration is 10 mm or more.

“A” is incorrect. In a nursing home, an influenza outbreak can have devastating results, with a mortality rate up to 30%. In the event of an outbreak, even residents who received the vaccine should receive antiviral prophylaxis (see Chapter 8 for more). Only about 30% to 50% of nursing home residents will develop an adequate antibody response to the influenza vaccine, and that response takes up to 2 weeks after administration to develop. “B” and “E” are incorrect. Residents who are carriers of MRSA or *C. difficile* will not benefit from eradication if they are not infected. In addition, they may return to a carrier state quickly after antibiotic treatment; therefore, antibiotic treatment of these carrier states is not recommended. “C” is incorrect because UTIs are the most common cause of bacteremia in nursing home residents.

HELPFUL TIP:

In elderly nursing home residents, a positive response to tuberculin skin testing is most often due to a reaction to latent disease. Risk factors associated with reactivation of tuberculosis include chronic steroid use, diabetes, malignancy, HIV, malnutrition, renal failure, and chronic institutionalization.

HELPFUL TIP:

The high-dose influenza vaccine (e.g., Fluzone-HD) has four times the usual dose of antigen and is approved for adults 65 years of age or older. Seroconversion rates are higher for patients receiving the higher dose vaccine, and influenza-like illness rates are modestly lower in recipients. However, it has not shown a benefit for more serious morbidity or mortality. The cost is higher than that of the other options, side effects are similar, and its role is not well established.

Over the next year, the patient has increasing difficulty with cognition. He begins to experience urinary incontinence several times per day, necessitating the use of a pad. A midstream clean-catch urinalysis shows bacteria and WBCs (2–4 WBC/hpf) but is negative for glucose and nitrites. His postvoid residual bladder volume is 80 cc.

Question 21.6.6 Which of the following is true regarding the potential cause of and therapeutic intervention for urinary incontinence in this patient?

- A) The most likely cause is obstruction from the benign prostate hyperplasia, and an alpha-blocker is indicated
- B) The most likely cause is immobility, and scheduled voiding is indicated
- C) The most likely cause is detrusor hyperactivity, and an indwelling catheter is indicated
- D) The most likely cause is stress incontinence, and pelvic floor muscle strengthening (Kegel exercises) is indicated
- E) The most likely cause is bacteriuria, and antibiotics will improve the incontinence

Answer 21.6.6 The correct answer is “B.” Urinary incontinence is incredibly frequent in nursing home residents, with a rate of up to 50%. As with many other geriatric syndromes, incontinence is often multifactorial or the result of decreased physical and/or cognitive functions. A frequent cause of urinary incontinence in nursing home residents is immobility due to severe physical impairment, dementia, or both. In this setting, the initial treatment of choice is prompted voiding every 2 hours when the patient is awake. Also, fluid and caffeine intake should be monitored and adjusted to reduce urine output without causing dehydration.

“A” is incorrect. Although there is no information about the patient’s prostate size, he has a relatively normal postvoid residual volume, making overflow incontinence from outlet obstruction less likely. A postvoid residual volume greater than 300 mL would be more concerning for urinary retention. “C” is incorrect—or at least the diagnosis of detrusor hyperactivity cannot be made on the basis of current information. The patient has not been fully evaluated with urodynamic tests, so it is difficult to determine whether his incontinence is stress-type or urge-type. If he has urge-type incontinence due to detrusor hyperactivity, an indwelling bladder catheter is not appropriate. Detrusor hyperactivity can often be treated successfully with pharmacotherapy (anticholinergic medications). It is important to be mindful of the anticholinergic side effects, which include falls, confusion, constipation, dry mouth, and urinary retention and could ultimately be more detrimental than the incontinence.

“D” is also not likely. Stress incontinence is less common in men than women, and urine loss is typically associated with increased abdominal pressure (e.g., coughing, sneezing, and lifting). Finally, “E” is incorrect. The presence of bacteria in the urine is a common finding in nursing home patients. In general, bacteriuria without symptoms (the main symptoms of infection being fever, new dysuria, suprapubic pain, CVA tenderness, worsening urgency and frequency, rather than incontinence (JAMA. 2014 Feb;311(8):844–54.)) should not be treated. Studies have demonstrated little or no improvement in incontinence after treating asymptomatic bacteriuria in elderly nursing home patients.

HELPFUL TIP:

When urinary incontinence is due to obstruction or detrusor **hyporeflexia**, intermittent bladder catheterization should be employed and chronic indwelling

catheters avoided. Appropriate indications for chronic indwelling bladder catheters in the nursing home include comfort care of the terminally ill, presence of skin wounds contaminated by incontinent urine, and urine retention not practically managed with intermittent catheterization.

Although his urinary incontinence improves, your patient develops difficulty with loose stools and occasional fecal incontinence. The stools are quite watery with no blood or melena. Aside from occasional abdominal cramping, he feels well. He has no new neurologic symptoms.

Question 21.6.7 Which of the following is the most likely cause of fecal incontinence in this situation?

- A) Infectious diarrhea
- B) Ulcerative colitis
- C) Decreased anal sphincter tone
- D) Fecal impaction

Answer 21.6.7 The correct answer is “D.” In nursing home residents with limited physical mobility, overflow incontinence due to fecal impaction is most likely. Nursing home patients are often taking medications that contribute to constipation as well. Even with a stool softener and/or a laxative, constipation may still result. Fecal impaction can be treated with an enema, stool softeners, laxatives, and dietary changes, but sometimes requires manual disimpaction (where’s a medical student when you need one?). Decreased sphincter tone may occur as a result of neurologic insult, but this patient was previously continent of stool. Although infection might be causing incontinence, there are no other symptoms of infection. The onset of inflammatory bowel disease is usually seen in younger populations, often with blood in the stools, making ulcerative colitis less likely.

As a result of your patient reporting physical abuse of another patient by the nursing staff, an investigation is under way in the nursing home.

Question 21.6.8 Reflecting on elder abuse and neglect, you realize which of the following is true?

- A) Up to 75% of nursing aides in nursing homes have seen or heard of a resident being abused or neglected
- B) A “dependent elder” is defined as anyone living in a nursing home
- C) Approximately 70% of elder abuse and neglect occurs in nursing homes
- D) There is a universally accepted definition of elder abuse and neglect, which is codified in federal law
- E) Elder abuse is widely defined as “purposeful physical harm of anyone over the age of 65 years”

Answer 21.6.8 The correct answer is “A.” In some studies, high rates of mistreatment have been found in nursing homes, with up to 75% of nursing aides witnessing or hearing

about acts of abuse. However, it is not known whether nursing home residents are at greater risk than community-dwelling dependent elders. “B” is incorrect. The definition of “dependent elder” is not consistent, and may apply to elders who are cognitively impaired, physically debilitated, or financially dependent. Nursing home residents are frequently dependent; however, living in a nursing home itself is not sufficient to establish that a person is a dependent elder. “C” and “D” are incorrect. The study of elder abuse and neglect (also referred to as elder mistreatment) suffers from lack of a universally accepted definition, variations in laws between states, and inherent difficulties in obtaining accurate reports of abuse. Therefore, attempts to determine the incidence of elder abuse and neglect have resulted in wide variations. “E” is incorrect. Elder abuse may include physical harm, sexual abuse, psychological abuse, neglect, or financial exploitation. Although all states now have laws addressing elder mistreatment, those laws vary between states, and healthcare providers are encouraged to know the laws in their area.

**HELPFUL TIP:**

Risk factors for elder mistreatment include older age, cognitive impairment, substance abuse, low socioeconomic standing, minority status, and caregiver stress (probably the most important).

As your patient’s cognitive impairment progresses, he becomes more withdrawn and uncooperative with nursing care, such as bathing. A nurse calls to ask, “Shouldn’t he be on risperidone or something to improve his behavior?”

Question 21.6.9 According to the Omnibus Budget Reconciliation Act of 1987 (OBRA ‘87), antipsychotic medication is indicated for demented patients with:

- A) Repetitive, bothersome behavior (e.g., name calling)
- B) Continuous crying out and screaming
- C) Uncooperative behavior (e.g., refusing to eat and bath)
- D) All of the above

Answer 21.6.9 The correct answer is “B.” One goal of OBRA ‘87 was to decrease the inappropriate use of antipsychotic medications in nursing home residents. In patients with dementia, antipsychotic medications may be appropriately administered in the following settings: agitated, belligerent acts that present a danger to the patient or other residents; psychotic symptoms (delusions, hallucinations, paranoia); and continuous crying out and screaming (lasting 24 hours or longer). Attempts to redirect the patient should always be employed first. You should also attempt to uncover occult causes of agitation, such as infection or pain (keep a log). Once behavior control is attained, assess whether the antipsychotic can be reduced in dose or discontinued. According to OBRA ‘87, inappropriate indications for antipsychotic medication include restlessness, uncooperative behavior, poor self-care, or repetitive and bothersome actions.

► **Objectives: Did you learn to ...**

- Describe some common Medicare/Medicaid reimbursement issues for nursing home care?
- Manage chronic pain in the nursing home?
- Describe an appropriate evaluation for the nursing home resident with fever?
- Recognize infectious disease issues commonly presenting in the nursing home?
- Develop an appropriate strategy for the evaluation and management of urinary and fecal incontinence in nursing home residents?
- Recognize the impact of elder abuse and neglect? Implement appropriate measures for agitated behavior in the nursing home?

**QUICK QUIZ: GERIATRIC PHARMACOTHERAPY**

Which of the following is true about drug therapy in the elderly?

- A) GI absorption is substantially decreased in the elderly
- B) Sedative-hypnotic drugs should be given an 8-week trial without interruption for anxiety in the elderly
- C) Mirtazapine (Remeron) causes anorexia and weight loss in the elderly
- D) Compared with young adults, the volume of distribution of fat-soluble drugs is increased in the elderly

The correct answer is “D.” The volume of distribution of fat-soluble drugs is relatively increased in the elderly due to a loss of muscle mass and proportionately more fat mass. Therefore, fat-soluble drugs, like diazepam, have a greater relative volume of distribution, while water-soluble drugs, like alcohols, will have a relatively smaller volume of distribution. “A” is incorrect because drug absorption does not change substantially with aging. “B” is incorrect. Sedative-hypnotic drugs should be used only for short-term therapy of 2 to 4 weeks because of the risk of falls and other adverse effects; this is true for both community-dwelling elders and those in nursing homes. “C” is incorrect because mirtazapine can actually increase appetite and lead to weight gain in the elderly. For this reason, it can be useful in patients who are depressed and not eating well.

**HELPFUL TIP:**

Although hepatic drug metabolism does not change substantially with age, drugs tend to have decreased elimination in the elderly as a result of decreased renal function. For these reasons, the half-life of many sedative-hypnotic drugs is substantially increased in the elderly.

**QUICK QUIZ: ELDER MISTREATMENT**

An elderly patient with moderate dementia presents for routine follow-up with a visibly fatigued spouse who complains,

“He’s always up at night, bumping into things and taking stuff out of drawers.” You notice several scratches and bruises on the patient.

Which of the following physical exam findings would be most concerning for physical abuse?

- A) Ecchymosis on the forearms
- B) Excoriations on the forearms
- C) Ecchymoses on the back of the neck
- D) Excoriations on the face

The correct answer is “C.” Older, frail patients with cognitive impairment simultaneously are at risk of mistreatment from caregivers and are likely to show signs of self-inflicted injuries due to skin fragility and behaviors associated with dementia. For these reasons, bruises and scratches are common in older patients. However, signs of injury in an unusual location for accidental trauma (e.g., back, plantar feet, palmar hands, oral mucosa) may be due to mistreatment and warrant further investigation.

▶ CASE 21.7

Your next patient is an 83-year-old male familiar to your clinic, who presents for routine care. He has hypertension, hyperlipidemia, and osteoarthritis. He has been widowed for 10 years and continues to live independently in an apartment in the same town as his daughter. He stopped smoking 30 years ago, but continues to drink alcohol. He denies any problems related to his drinking, but reports that his routine includes three shots of whiskey per day. He says he likes drinking one shot before his daily walk and the other two shots after he returns. He finds the routine very motivating and keeps him in shape.

Question 21.7.1 In regard to his drinking behavior, you are aware that:

- A) Older adults accumulate significantly lower blood alcohol levels than younger adults due to decreased absorption
- B) Drinking three shots per day should not be any concern as long as his liver function tests are normal
- C) Alcohol consumption can reduce the availability of nutrients such as zinc, vitamins A, B1, B2, B6, B12, and folate
- D) The lifetime prevalence of alcoholism for men age ≥ 65 is less than 5%, but should still be screened for routinely
- E) The standard screening CAGE questionnaire for drinking problem behavior has not been validated in older adults

Answer 21.7.1 The correct answer is “C.” Alcohol consumption can reduce the availability of nutrients such as vitamins A, B1, B2, B6, B12, zinc, and folate. Alcoholic patients often present with malnutrition, poor self-care, and alcohol-related illnesses such as anemia, peptic ulcer disease, diabetes, hypertension, liver disease, neuropathy, and cognitive impairment. Checking for deficiencies may be warranted in this situation

depending on your patient’s other dietary intake. “A” is incorrect. Older adults accumulate significantly **higher** blood alcohol levels than younger adults. A young adult’s blood alcohol level will be approximately 0.03% after “one drink” (1.5 oz of distilled liquor, 5 oz of wine, or 12 oz of beer); whereas in a 75-year-old, the level may rise as high as 0.08%, which is the legal limit for intoxication in many states. “B” is incorrect. **Drinking behavior should be questioned regardless of liver function tests.**

The National Institute on Alcohol Abuse and Alcoholism has identified drinking **more than one** alcoholic beverage per day as potential problem drinking in older adults. “D” is incorrect. The lifetime prevalence of alcoholism for men aged ≥ 65 is higher, at approximately 14%; while women aged ≥ 65 have a prevalence of 1.5%. Denial of the problem is common in older patients, and impairments in functioning related to alcohol use may not be recognized until serious complications arise. “E” is incorrect. Diagnosis of alcohol abuse and dependence in older adults is challenging. Brief screening tools such as the CAGE questionnaire (see Chapter 21) have been validated in the older population and could be used in this situation.

In this case, your patient denies any drinking problems and his CAGE screen is negative. Still, you advise him to cut back to one drink per day or less and plan to follow up. He is independent with all basic ADLs and instrumental activities of daily living (IADLs). He walks daily, eats three small meals per day, and maintains a steady weight around 180 lb ($\text{BMI} = 25 \text{ kg/m}^2$). He manages his own finances, prepares his own meals, but usually has his daughter do the grocery shopping for his convenience. When you ask about transportation, he reports that he mostly drives to get around town to the golf club (not Mar-a-Lago), social events, and the post office when needed. He denies any vision or hearing problems.

Just as a review (this is a review book, after all) ...

Basic activities of daily living (ADLs) include: bathing, dressing, toileting, grooming, feeding, and functional mobility (transferring or ambulating).

Instrumental activities of daily living (IADLs) include: shopping for groceries, driving or using public transport, using the telephone, performing housework, doing home repairs (not climbing on the roof but changing light bulbs and such), preparing meals, doing laundry, taking medications, handling finances.

HELPFUL TIP:

If you are concerned about driving safety, ask direct questions about any recent driving problems, such as minor accidents, traffic violations, or getting lost. The legal requirements about physician reporting of unsafe older drivers vary from state to state, but the AMA has published a useful guide, available online and updated in 2010, called “Physician’s Guide to Assessing and Counseling Older Drivers” (<http://www.nhtsa.gov/people/injury/olddrive/OlderDriversBook/pages/Contents.html>)

One month later, your patient's daughter calls to inform you that he fell and broke his left hip while vacationing with the family in California. He had total hip arthroplasty (THA) and is still in the hospital recovering. Now they are trying to make arrangements to bring him home. The discharge planner has identified a local nursing home that can provide rehabilitation, but some of the family would like for him to return to his apartment.

Question 21.7.2 In regard to recovery after hip surgery, you inform the daughter that:

- A) Rehabilitation after hospital discharge results in better outcomes for patients with hip fracture
- B) Rehabilitation can only be provided inpatient at a hospital or nursing home, not at home
- C) Surgical repair in elderly patients should be delayed if possible (>72 hours after injury) to reduce 1-year mortality and other complications
- D) Early mobilization after hip surgery is recommended in younger patients, but in older patients weight bearing is usually delayed at least 5 days after surgery to allow proper healing

Answer 21.7.2 The correct answer is "A." Studies show that rehabilitation immediately after hospital discharge appears to result in superior outcomes for patients with hip fracture or stroke. "B" is incorrect. Rehabilitation can be provided in either inpatient (i.e., hospital or skilled nursing facility) or outpatient settings (clinic, day hospital, or home). For inpatient care, patients must be able to participate in rehabilitation that includes a minimum of 3 hours of therapy 5 days per week. Care usually involves an interdisciplinary team including nurses and various therapists. Home-based services can provide part-time or intermittent therapy as prescribed by a physician. "C" is incorrect. Early surgical repair (<24 hours after fracture) is ideal and has been shown to reduce 1-year mortality and complications such as pressure ulcers and delirium. Delay for medically unstable patients may be necessary. "D" is incorrect. Early mobilization is the standard of care for both hip and knee arthroplasty in younger and older adults. Weight bearing often begins on the second postoperative day.

Your patient and his daughter agree that rehabilitation locally sounds like the best plan.

Question 21.7.3 The goals of rehabilitation include:

- A) Restore function
- B) Help patients compensate for and adapt to functional losses
- C) Prevent secondary complications
- D) Maximize potential for participation in social, leisure, or work roles
- E) All of the above

Answer 21.7.3 The correct answer is "E." These are all goals of rehabilitation.

The patient returns to the local nursing home for inpatient rehabilitation. Despite wonderful progress with physical therapy, he is unable to ambulate without using a cane. He is frustrated that he cannot walk on his own, and is concerned that all this walking and exercise is going to damage the recently surgically repaired hip joint.

Question 21.7.4 You can tell him that:

- A) He does not need to restrict his activity because the hip prosthesis is well designed for bending, walking, and climbing stairs
- B) His frustration is likely a major depressive disorder and will require medication treatment
- C) He should continue the exercises because the advantages outweigh the low risks of surgical failure
- D) He should not expect full recovery even with exercise, because nearly every patient requires an assistive device to walk after total hip replacement

Answer 21.7.4 The correct answer is "C." Whether correction is with screws, partial repair, or complete joint replacement, early weight bearing is usually tolerable with low rates of surgical failure and helps to counteract the poor outcomes clearly associated with prolonged inactivity. As noted in a previous question, early mobilization and continued exercise are the keys to preventing further decline and loss of function. "A" is incorrect. After total hip replacement, patients should avoid certain motions such as bending over to tie shoes and crossing legs when seated. Oftentimes a raised toilet seat is also recommended to reduce the load placed on the hip prosthesis in extreme flexion. Walking and general range of motion exercises should be encouraged as tolerated. "B" is incorrect. Depression is not uncommon after a disabling injury such as hip fracture. However, this patient's frustration may or may not reflect clinical depression and should be further evaluated before starting medication. "D" is incorrect. Although hip fractures carry approximately 5% in-hospital mortality and a mortality of approximately 25% in the year following fracture, about 75% of survivors recover to prior level of function. Up to 50% of these patients require an assistive device, but certainly not everyone.

HELPFUL (AND REALLY IMPORTANT) TIP:

For hip fractures or replacement, repair using an anterior approach as opposed to the traditional posterior/lateral approach reduces recovery time and is associated with a lower risk of dislocation.

After 2 more weeks, your patient is now functioning well enough to return home. He can transfer independently and ambulates with a cane for support. Prior to discharge, the rehabilitation team would like to assess his home environment.

Question 21.7.5 The occupational therapy practitioner on the team:

- A) Provides a comprehensive assessment wherever the patient is employed based on his/her occupation, which does not typically include the home environment
- B) May provide training for specific adaptive equipment for patients to enhance performance in everyday activities and promote independence
- C) Is a skilled professional who has completed an occupational therapy training program after completion of high school
- D) Is licensed to write prescriptions in most states, primarily for pain control

Answer 21.7.5 The correct answer is “B.” Occupational therapists (OTs) provide training for specific adaptive equipment to enhance performance in everyday activities and promote independence. They also provide guidance to family members and caregivers if needed. “A” is incorrect. OTs provide home or job-site assessment, regardless of employment status or occupation. “C” is incorrect. OTs are skilled professionals whose education includes the study of human growth and development with an emphasis on the social, emotional, and physiological effects of illness and injury. One must have earned a bachelor degree or beyond to enter the field of occupational therapy. There are also occupational therapy assistants who generally earn an associate degree and practice under the supervision of a trained OT. “D” is incorrect since OTs do not have license to prescribe medications.

► Objectives: Did you learn to ...

- Identify and screen for drinking problem in the older patient?
- Promote early rehabilitation after hip fracture repair?
- Describe some aspects of rehabilitative services?

► CASE 21.8

A 68-year-old male arrives at your clinic to establish care. He admits that he does not visit the doctor regularly, but he feels his health has been pretty good since he changed his “bad habits.” He did not bring any records, but he knows he has heart disease and high blood pressure. His bad habits included smoking about 1 pack per day for 40 years, but he proudly states he quit “cold turkey” after a heart attack at age 63. As far as healthcare maintenance, he did have a colonoscopy 5 years ago at his wife’s request, and he remembers his last PSA was normal, but he does not recall any type of screening for abdominal aortic aneurysm (AAA).

Question 21.8.1 The USPSTF recommends one-time AAA screening:

- A) For all men aged 65 to 74 years
- B) For all men aged 65 to 74 years who have smoked >100 cigarettes in their lifetime

- C) For all men aged 55 to 64 years who have smoked ≥ 1 pack of cigarettes per day for 10 years or more
- D) For all men aged ≥ 75 if life expectancy >10 years
- E) All smokers ≥ 55 , regardless of gender

Answer 21.8.1 The correct answer is “B.” The USPSTF recommends one-time AAA screening with abdominal ultrasonography for all men aged 65 to 74 years who have ever smoked (defined as >100 lifetime cigarettes). “A” and “C” are incorrect. The USPSTF currently does NOT recommend screening men who have never smoked (<100 cigarettes in a lifetime). The American College of Cardiology/American Heart Association (ACC/AHA) guidelines advise screening men older than 60 years who have a strong family history (parents or siblings) of AAA, but family history is not explicitly considered in the USPSTF guidelines. “D” and “E” are incorrect. The evidence in men older than age 75 years and in women does not support AAA screening, and neither of the above guidelines recommends routine screening in those groups. One of several imaging modalities can be used for screening, including ultrasound and CT scan.

You recommend a screening ultrasound for AAA, but then he questions why screening for AAA is necessary (guess you need to work on your rapport-building).

Question 21.8.2 You inform him that:

- A) AAA occurs in approximately 1 in 20 older men who have ever smoked
- B) Rupture of an AAA has a morality rate of 50%
- C) AAA ruptures cause approximately 1,000 deaths per year in the United States
- D) Treatment for AAA includes open surgical repair, endovascular repair, or surveillance once the aneurysm reaches 6 cm but not before this

Answer 21.8.2 The correct answer is “A.” AAA is a common condition, occurring in approximately 1 in 20 older men who have ever smoked. “B” is incorrect. Rupture of an AAA is associated with an even higher mortality rate of 80%, hence the importance of screening. “C” is incorrect. Epidemiologic studies indicate that AAA ruptures are responsible for 10,000 to 20,000 deaths per year in the United States. “D” is incorrect. Treatment of AAA is based on the aneurysm size, rate of expansion, and symptoms. Asymptomatic patients with aneurysms ≥ 5.5 cm in diameter should undergo repair, not surveillance. Surveillance for medium-sized aneurysms (4–5.4 cm) is by ultrasound or CT every 6 to 12 months and every 2 to 3 years for aneurysms 3 to 4 cm. Earlier repair in men with AAA ≥ 5 cm or women with AAA ≥ 4.5 cm may be indicated if rate of increase is ≥ 0.5 cm in 6 months. AAA repair options include open surgical repair or endovascular repair. Endovascular repair has lower 30-day mortality rate, but overall mortality is identical after 3 to 4 years. In 2011, the ACC/AHA updated their guidelines regarding AAA repair, recommending either surgical or endovascular repair for most patients.

The ultrasound shows minimal atherosclerotic disease of the abdominal aorta and no aneurysm. Two years later, the patient returns for follow-up at the prompting of his daughter who has been noticing that he complains about his knees hurting all the time. He has never been interested in surgery, but he would like to try something different. When asked about his pain on a scale of 0 to 10 (0 meaning no pain and 10 meaning the worst pain possible), he reports pain around 2/10 most days, and up to 6/10 after moderate activity. He uses acetaminophen sometimes but does not want to get addicted to pain medicine.

Question 21.8.3 In addition to increasing his dose of acetaminophen, you suggest a topical analgesic such as:

- A) The 5% lidocaine patch because it can be applied conveniently anywhere on the body to provide additional knee pain control
- B) The 5% lidocaine patch because it acts locally where applied without achieving clinically significant serum drug levels
- C) Capsaicin cream because it can be applied topically once per day as needed for effective pain control
- D) Capsaicin cream because it only takes 1 to 2 days to achieve a clinical effect
- E) Diclofenac 1% gel because it can provide anti-inflammatory effect with lesser GI toxicity compared with systemic NSAIDs

Answer 21.8.3 The correct answer is “E.” Older adults are less likely to be adequately treated for pain compared with younger adults. Acetaminophen remains the best choice for first-line therapy of mild-to-moderate pain due to its tolerability. Topical agents such as the lidocaine, capsaicin, or diclofenac can also provide localized pain control. Topical agents can be very useful pain therapy because they penetrate the skin to act on peripheral nerves and soft tissue directly underlying the application site. These topical agents have minimal systemic absorption and thus limited potential for any clinically significant systemic effect or drug–drug interactions. Diclofenac 1% gel is a topical NSAID well-suited for treatment of osteoarthritis. Adverse GI events are less common compared to oral NSAID therapy.

“A” is incorrect. The lidocaine patch must be applied directly over the painful area for best results, but it is not effective in arthritis. Topical lidocaine seems to work for neuropathic pain (e.g., post-zoster) or for local, superficial, skin irritation. “B” is wrong for the same reason. “C” and “D” are incorrect. Capsaicin cream is dosed on a regular schedule every 6 hours to achieve maximal effect, which generally takes 2 to 4 weeks.

He tries acetaminophen 1,000 mg TID and capsaicin three to four times per day, and reports improved pain control. You see him 1 month later for a follow-up visit. Today he picked up a coupon at the local drug store for an arthritis pill that contains chondroitin. He wants to know if this might help his knee pain.

Question 21.8.4 You discuss the current evidence and inform him that:

- A) Large-scale trials indicate significant symptomatic benefit in osteoarthritis with the use of chondroitin supplements
- B) For patients with severe osteoarthritis only, a clinically relevant benefit is likely and the use of chondroitin should be encouraged
- C) Chondroitin is a large macromolecule that is poorly digested and is potentially unsafe in older patients with any stomach problems
- D) The combination of chondroitin and glucosamine is no better than placebo for knee arthritis

Answer 21.8.4 The correct answer is “D.” The combination of chondroitin and glucosamine remains an extremely popular supplement sold over-the-counter for joint pain. However, scientific evidence is lacking to support the use of chondroitin to prevent or reduce joint pain associated with osteoarthritis. The largest randomized-controlled trial of chondroitin and glucosamine for osteoarthritis of the knee showed no improvement in pain versus placebo. Most studies are negative or show very modest improvement, although a systematic review in 2015 concluded that chondroitin may have minimal short-term benefits versus placebo. Therefore, “A” is incorrect. Similarly, “B” is incorrect. For patients with advanced osteoarthritis, a clinically relevant benefit is unlikely. “C” is incorrect. Chondroitin is a large macromolecule, and only 12% to 13% of ingested chondroitin is absorbed into the blood stream. However, multiple studies have found no evidence to suggest that chondroitin is unsafe (except to the sharks that provide the cartilage to make the supplement—they are rapidly becoming extinct).

Now that your patient has seen you for a few years, he feels more comfortable in discussing other health concerns ... like constipation (hey, you’ve built some rapport!). He usually has a bowel movement (BM) every 2 to 3 days, but sometimes he gets hard stools that require excessive straining. His wife tells him to eat more fiber, but he wants to know what else he can do to help “keep regular.”

Question 21.8.5 Which of the following statements is true about constipation?

- A) The prevalence of self-reported constipation decreases with aging
- B) Patients should be encouraged to defecate before meals when the colonic activity is the greatest
- C) Fiber is a safe, inexpensive approach to improve stool consistency and accelerate colon transit time
- D) Increased caloric intake correlates well with constipation in the elderly

Answer 21.8.5 The correct answer is “C.” Fiber is a safe, inexpensive approach to improve stool consistency and accelerate colon transit time. Increasing fiber is a good first-line approach and should be encouraged. The daily

TABLE 21-5 ROME CRITERIA FOR FUNCTIONAL CONSTIPATION

Two or more of the following should be present for at least 12 weeks out of the preceding 12 months:

- Straining for greater than 25% of defecations
- Lumpy or hard stools for greater than 25% of defecations
- Sensation of incomplete evacuation for greater than 25% of defecations
- Less than three defecations per week
- Manual evacuation or assistance to facilitate defecation

recommended fiber intake is 20 to 35 grams. “A” is incorrect because the prevalence of self-reported constipation increases with aging—up to 45% of frail elderly individuals report constipation as a health issue. It is not uncommon for patients and physicians to have different clinical definitions of constipation, so further history is helpful to clarify what the patient means by “constipation.” The Rome Criteria offers a consensus definition of constipation used in clinical trials as outlined in Table 21-5 and may be helpful to further characterize constipation. “B” is incorrect. Patients should be encouraged to defecate first thing in the morning or 30 minutes **after** meals when colonic activity is the greatest, and to take advantage of the gastrocolic reflex. “D” is incorrect. Decreased (not increased) caloric intake is more likely to be associated with constipation in the elderly.

You rule out secondary causes of constipation and decide that your patient likely has primary transit constipation. You first provide nonpharmacologic recommendations to promote regular bowel habits, including dietary changes and increased exercise.

Question 21.8.6 Which of the following options would be the best pharmacologic approach to use on a daily basis in order to help this patient with his constipation?

- A) Fiber: psyllium (Metamucil), oat bran, or methylcellulose (Citrucel)
- B) Stool softener: docusate calcium (Surfak) or docusate sodium (Colace)
- C) Stimulant laxative: senna (Senokot), castor oil, or bisacodyl (Dulcolax)
- D) Enema: tap water, sodium biphosphonate, or soap enema
- E) Any of the above would be equally valid choices

Answer 21.8.6 The correct answer is “A.” Primary causes of constipation fall into three categories: (1) normal transit constipation, (2) slow transit constipation, and (3) anorectal dysfunction. There is no evidence-based guideline for the preferred order of using different types of laxatives. Supplemental fiber helps improve stool form and frequency and is a good first step. Psyllium also has the benefit of reducing lipids and improving glucose control in diabetics. Adequate fluid intake is necessary when using psyllium since it may exacerbate constipation when fluid intake is insufficient. “B” is incorrect.

While stool softeners are commonly prescribed and may be helpful, they are less effective than other options including psyllium. “C” is incorrect. Stimulant laxatives, when used in recommended doses, are unlikely to harm the colon. However, stimulant laxatives may cause electrolyte imbalance or abdominal pain and are not the first-line therapy. “D” is incorrect. Enemas should only be used in acute situations and with caution due to the risk of colonic perforation. Large-volume enemas can result in hyponatremia, while enemas containing phosphate can lead to hyperphosphatemia and renal failure, especially in patients with renal insufficiency.

HELPFUL TIP:

There are many causes of secondary constipation, including numerous medications (e.g., anticholinergics, calcium channel blockers, opiates) and coexistent medical conditions such as diabetes, hypothyroidism, scleroderma, and amyloidosis.

► Objectives: Did you learn to ...

- Screen for AAA?
- Provide the safe and effective treatment for osteoarthritis pain?
- Identify and treat constipation in the older patient?

QUICK QUIZ: DIABETES TARGET

A 73-year-old male patient returns to see you for further management of diabetes mellitus type 2. He has had diabetes for decades and he has been generally well controlled on oral medications of metformin and glipizide. He also has hypertension and hypercholesterolemia for which he is treated. He thinks he is in otherwise fair health and is active in his community and lives independently with his wife.

What is his target hemoglobin A_{1c}?

- A) <5.5%
- B) <6.5%
- C) <7.5%
- D) <8.5%

The correct answer is “C.” The American Diabetes Association and the American Geriatrics Society recommend a goal of hemoglobin A_{1c} less than 7.5% for older adult patients who are otherwise healthy and have good functional performance. The benefits versus the risks of intensive diabetic control start to shift as the medical complexity and functional impairments of the patient increase. Therefore, older patients with multiple chronic medical conditions, cognitive impairment, or functional impairments have a less stringent goal A_{1c} between 8.0% and 8.5%. For older patients with limited life expectancy such as these, the goals of diabetes care are to reduce the risks associated with hyperglycemia and hypoglycemia rather than prevent long-term complications of diabetes.

Clinical Pearls

- Avoid antipsychotics in the demented elderly with behavioral and psychological disturbances. First, explore and treat potential underlying causes, modify the environment, and educate caregivers.
- Conduct a complete drug review regularly, looking for drug–drug interactions, drug–disease interactions, ineffective drugs, and symptoms attributable to medications.
- Do not perform cervical cancer screening on women over the age of 65 years if the previous three Pap smears prior to age 65 years were completely normal and there were no findings of CIN2 or higher in the previous 20 years.
- Do not treat asymptomatic bacteriuria in older adults. Cystitis does not cause confusion (J Am Geriatr Soc 2019 Mar; 67:484).
- Do not treat insomnia in older adults with sedative drugs, including diphenhydramine. First, employ good sleep hygiene, cognitive behavioral therapy, and melatonin.
- Do not use medical interventions, such as appetite stimulants and gastric tube feedings, for demented older adults who are losing weight. Provide appealing and calorically dense foods, feeding assistance, and a social context for eating.
- Estimate longevity and determine patient preferences prior to initiating screenings and preventative interventions.
- Older patients who sustain a hip fracture have better clinical outcomes with early repair (within the first 24 hours).
- Periodically reassess cholinesterase inhibitors for dementia; taper and discontinue the drug if there is no perceived benefit or if adverse events occur (e.g., weight loss, bradycardia).
- Pressure ulcers should be treated primarily with pressure relief, good wound care, and good nutrition. Minimal benefit is attributable to dressing type or advanced wound care treatments (e.g., electrical stimulation, ultrasound).

Care of the Surgical Patient

22

Alka Walter, Erin Hayward, and Brigit E. Ray

► CASE 22.1

A 40-year-old male patient with type 2 diabetes, taking a “flozin” (SGLT2 inhibitor), calls your office because he is having difficulty urinating and quite a bit of pain in the perineal area. He has not felt well for several days and was running a low-grade fever. He went to his chiropractor 2 days ago when he only had pain and swelling in the scrotum and the chiropractor adjusted his ... well, we won’t go there... He is now noting that his temperature is higher (he doesn’t have a thermometer and is reading his temperature via his old mood ring from the 1990s). You suggest that he present to your office.

Examination reveals an obese male who is waddling into the office because of pain in his scrotal area. Vitals: blood pressure 150/100 mm Hg, pulse 112 bpm, respirations 20 bpm, and temperature 39.0°C. Other significant findings include a swollen scrotum that is dusky red, exquisitely tender to touch, and without crepitus. You do not have extended laboratory access in your office, but a urine dipstick is negative for blood and leukocyte esterase. His blood sugar, which is usually fairly well controlled, is elevated at 320 mg/dL.

Question 22.1.1 Your next step for this patient will be which of the following?

- A) Start the patient on cephalexin (Keflex) for methicillin-sensitive *Staphylococcus aureus* and *Streptococcus* coverage and follow-up with the patient in the morning
- B) Emergent surgical referral
- C) Begin trimethoprim/sulfamethoxazole (Bactrim) for methicillin-resistant *S. aureus* (MRSA) coverage and follow-up with the patient in the morning
- D) Admit the patient and start him on IV vancomycin, piperacillin/tazobactam, and metronidazole for coverage of MRSA, *Streptococcus*, *Pseudomonas*, anaerobes

Answer 22.1.1 The correct answer is “B.” This presentation likely represents Fournier gangrene (and remember that SGLT2 inhibitors, such as this patient is on, increase the risk of

Fournier). The erythematous, swollen scrotum with pain out of proportion to examination and associated signs of fever, tachycardia, and elevated blood sugar make Fournier gangrene the most likely diagnosis. While crepitus is common with Fournier gangrene due to presence of gas-forming anaerobic bacteria, its absence does not rule out gangrene. Without early surgical debridement and IV antibiotics, infection can progress rapidly to sepsis and multiorgan failure. Therefore, “B,” emergent surgical referral, is the best option for this patient. Antibiotics, particularly oral (options “A” and “B”), are inappropriate as a sole therapy. Broad-spectrum IV antibiotics may be part of initial management, but “D” is incorrect because the patient emergently needs surgical debridement to remove the necrotic tissue.

Question 22.1.2 Fournier gangrene can best be described as:

- A) Necrotizing fasciitis
- B) Necrotizing cellulitis
- C) Caused by aerobic bacteria
- D) Secondary to streptococcus
- E) A mathematical function that can be written as an infinite sum of harmonics

Answer 22.1.2 The correct answer is “A.” Fournier gangrene is a form of necrotizing fasciitis. This is termed “Type I” necrotizing fasciitis and is caused by mixed aerobic and anaerobic bacteria. This subset is typically seen in individuals with a “weakened” immune system such as the elderly or patients with diabetes. There are two other subtypes of necrotizing fasciitis: types II and III. Type II necrotizing fasciitis is caused by hemolytic Group A *Streptococcus* and *staphylococci* (including MRSA) and is frequently referred to in the media as “flesh-eating bacteria.” This subset can occur in *any* individual. Type III necrotizing fasciitis is typically caused by *Clostridia* infection and is typically referred to as “gas gangrene.” This subset typically can occur after significant injury or surgery. “B” is incorrect. Necrotizing cellulitis is isolated to the superficial skin. Fournier gangrene involves deep tissues including the fascia. “C” and “D” are incorrect because, as noted above, Fournier gangrene

is caused by mixed aerobic and anaerobic bacteria. Common pathogens involved include coliforms, *Clostridia*, *Bacteroides*, *Klebsiella*, *Staphylococcus*, and *Streptococcus*. If you used “the-longest-answer-is-always-right” method and chose “E,” you are way off base and possibly a musician; “E” describes Fourier’s transform (look it up).

Question 22.1.3 Which of the following is NOT a risk factor for Fournier gangrene?

- A) Diabetes
- B) Immunosuppression
- C) Varicella infection
- D) End-stage renal disease
- E) Advanced age

Answer 22.1.3 The correct answer is “C.” Varicella infection is a risk factor for Type II necrotizing fasciitis. All the other options are risk factors for Fournier gangrene (Type I necrotizing fasciitis).

The surgeon evaluates the patient and asks for your opinion on the antibiotic regimen. You nearly fall over in shock that your advice was solicited.

Question 22.1.4 What do you recommend for this patient with necrotizing fasciitis?

- A) Penicillin and clindamycin
- B) Clindamycin and metronidazole
- C) Meropenem, vancomycin, and clindamycin
- D) Piperacillin/tazobactam (Zosyn), vancomycin, and metronidazole
- E) C or D

Answer 22.1.4 The correct answer is “E.” As noted above, a mixture of aerobic and anaerobic bacteria causes Fournier gangrene. The first two choices (“A” and “B”) will cover anaerobes and some Gram-positive organisms. However, Gram-negative coverage is lacking. More broad-spectrum antimicrobial coverage is needed in this situation. Most experts and guidelines recommend a broad-spectrum antibiotic with anaerobic and Gram-negative coverage (e.g., piperacillin/tazobactam, ampicillin/sulbactam, or a carbapenem) **plus** MRSA coverage (usually vancomycin) **plus** anaerobic coverage (e.g., clindamycin, metronidazole). Although MRSA is not usually the causative agent, these infections are polymicrobial, and empiric MRSA coverage is required. Clindamycin deserves a special mention. *Clindamycin targets toxin production, so it is especially helpful in invasive Streptococcal disease and Staphylococcal and Streptococcal toxic shock syndromes.*

HELPFUL TIP:

IVIG has been used in necrotizing fasciitis caused by *Clostridium* species as well as in those with streptococcal fasciitis. While there is a suggestion of benefit, the data are incomplete and more study is warranted. Hyperbaric oxygen has also been used, but suffers

from the same lack of data. These treatments are potential adjunct therapies. The definitive treatment is early, aggressive, surgical debridement!

The patient has a wide excision of necrotic tissue. After surgery, he becomes hypotensive and tachycardic (blood pressure 85/50 mm Hg, pulse 128 bpm), and his serum lactate is 8 mg/dL (high).

Question 22.1.5 What is the most appropriate next step in his management?

- A) Start IV dopamine to stabilize his blood pressure
- B) Start IV norepinephrine to stabilize his blood pressure
- C) Start IV 0.9% normal saline (NS) boluses to stabilize his blood pressure (30 mL/kg)
- D) Start IV albumin boluses to stabilize his blood pressure
- E) Read him the hospital charges he has accumulated thus far. The epinephrine release will improve his blood pressure

Answer 22.1.5 The correct answer is “C.” This patient is likely hypovolemic secondary to third spacing and/or is in septic shock and needs volume resuscitation. The lactate of 8 mg/dL suggests that he has hypoperfusion with poor tissue oxygenation (although it could also be secondary to necrotic tissue). Just giving dopamine (or other vasopressors) will not increase peripheral circulation and, in fact, may decrease tissue oxygenation by increasing vascular tone and decreasing perfusion. For patients with sepsis who remain hypotensive in spite of volume resuscitation (0.9% NS boluses at 30 mL/kg), the preferred initial vasopressor is norepinephrine. Albumin has not been shown to have any advantage over crystalloids in almost any circumstance— following large-volume paracentesis (>5 L) and perhaps dengue being the notable exception. Mortality of necrotizing fasciitis approaches 30% even with appropriate management. You may have heard that Lactated Ringers (LR) may be superior to NS in critically ill patients (*N Engl J Med.* 2018 Mar 1;378(9):829–839). This did not appear to be the case in *non-critically ill* patients being cared for outside the ICU setting (*N Engl J Med.* 2018;378(9):819–828). These recommendations are not definitive; either LR or NS is reasonable for fluid resuscitation.

HELPFUL TIP:

The thinking about sepsis has changed in the past few years with the Surviving Sepsis Campaign (*Crit Care Med.* 2017 Mar;45(3):486–552) and several subsequent studies. Successful treatment of sepsis requires early recognition, early aggressive fluid resuscitation (boluses of 30 mL/kg) within the first 3 hours, and broad-spectrum antibiotics within 1 hour of recognition of severe sepsis or septic shock. Monitor closely including ultrasound assessment of IVC pressure, urine output, etc. More recent studies indicate that early goal-directed therapy (e.g., aggressive use of central lines, vasopressors with central venous pressure and hematocrit goals) and

early renal replacement therapy do not result in better outcomes (*N Engl J Med.* 2017 Jun 8;376(23):2223–2234; *N Engl J Med.* 2014;371(16):1496–1506; *N Engl J Med.* 2018 Oct 11; 379:1431–1442).

Take home point: Recognize sepsis, promptly treat with fluids and control infection (antibiotics, surgery if appropriate), and continually re-evaluate your patient.

► **Objectives: Did you learn to ...**

- Diagnose and treat Fournier gangrene?
- Differentiate between types of necrotizing fasciitis?
- Prescribe fluids and vasopressors as appropriate to treat sepsis and septic shock?

QUICK QUIZ: PAIN CONTROL

Which of the following drugs will give you the most rapid pain control when given intravenously?

- A) Fentanyl (Sublimaze)
- B) Hydromorphone (Dilaudid)
- C) Meperidine (Demerol)
- D) Morphine

The correct answer is “A.” Fentanyl has a peak effect at 3 to 5 minutes. This is followed by meperidine at 5 to 7 minutes, morphine at 20 minutes, and hydromorphone at 15 to 30 minutes. For rapid control of pain, fentanyl is the preferred agent. Meperidine is the least preferred agent because of drug interactions (MAO inhibitors, SSRIs) and toxic metabolites (normeperidine, which can cause agitation and seizures).

HELPFUL TIP:

Vancomycin is not a great drug for treating *Staphylococcus*. In fact, inpatient mortality rates are higher in patients with **methicillin-sensitive Staphylococcal (MSSA)** infections treated with vancomycin than with other antibiotics. So, if you are treating MSSA, change antibiotics to something other than vancomycin, such as nafcillin or ampicillin/sulbactam—whatever the susceptibilities indicate.

QUICK QUIZ: ANTIBIOTIC COVERAGE

Which of the following organisms is/are not generally covered by trimethoprim/sulfamethoxazole (TMP/SMX)?

- A) *S. aureus*
- B) Streptococcal species
- C) *Escherichia coli*
- D) *Enterococcus*
- E) B and D

The correct answer is “E.” Neither *Streptococcus* nor *Enterococcus* species are sensitive to TMP/SMX. This has implications for the treatment of MRSA. Cellulitis (one of the manifestations of MRSA) can be from either staphylococcal or streptococcal species. If there is an abscess, treat for MRSA (incision and drainage with TMP/SMX or doxycycline). If there is a superficial cellulitis, treat for *Streptococcus* (cephalexin or amoxicillin/clavulanate). If you are not sure, one option would be clindamycin as long as local resistance rates are only 10% to 15%; clindamycin resistance rates are on the rise.

HELPFUL HINT:

The IDSA 2014 guidelines on skin and soft-tissue infections recommend no additional antibiotic therapy following the incision and drainage of a simple skin abscess. However, two large trials have subsequently shown that treatment failure occurred at a lower rate in patients who were given antibiotics. Antibiotics used in these trials were TMP/SMX and clindamycin (*Ann Emerg Med.* 2019;73:8–16).

► **CASE 22.2**

You are working in a rural ED when you get a call that a 62-year-old farmer has been trapped between a tractor and a silo while loading silage. It seems to have pinned his legs and pelvis, but from the waist up he is fine. The ambulance crew places the patient in a collar and on a backboard, per protocol, and transports him to the ED.

The patient is in significant pain in his lower extremities and pelvis (of course, since he is a stoic farmer, he denies this and insists he wants to go back to and finish his chores). His blood pressure is initially 100/65 mm Hg with a pulse of 118 bpm. Primary survey is unremarkable, although he is still “boarded and collared.”

Question 22.2.1 Which of the following most clearly reflects the best approach to this patient’s pain?

- A) Use IV meperidine (Demerol) for pain control
- B) Use IV morphine for pain control
- C) Use IV fentanyl (Sublimaze) for pain control
- D) Pain medications are contraindicated at this point given the patient’s overall condition
- E) Since he’s so tough, just offer him some useless platitudes like “no pain, no gain”

Answer 22.2.1 The correct answer is “C.” Fentanyl generally has a negligible effect on blood pressure (although one should never say “never”). Both morphine and meperidine tend to drop a patient’s blood pressure, so they are relatively contraindicated in this patient with a marginal blood pressure or hypotension. Those who chose “D” or “E” have been hanging around old-time surgeons too long. It is unconscionable to withhold pain medication in this case.

Further examination, by gentle inward pressure on the anterior superior iliac spines bilaterally, shows that the patient's pelvis is unstable. As you recall, a fractured pelvis can lead to significant blood loss into the retroperitoneal space.

Question 22.2.2 In the short term, what is the best way to temporize the underlying pathology?

- A) Vasopressors (e.g., dopamine) plus fluids
- B) Pelvic binder
- C) Fluids (normal saline)
- D) Activated factor VIIa (NovoSeven)
- E) Embolization by interventional radiology (45-minute delay)

Answer 22.2.2 The correct answer is “B.” A pelvic binder will significantly reduce bleeding in most unstable pelvis fractures. In 2018, ATLS also added the option to treat pelvic hemorrhage from pelvic fractures with preperitoneal packing as this has shown success. This is a more invasive procedure and thus it is reasonable to start with the more conservative pelvic binder before moving to this action; particularly in a relatively stable patient. “A” is incorrect. Dopamine is not indicated when the problem is hypovolemia. In fact, vasopressors increase mortality in hypovolemic shock. “C” is incorrect. While normal saline is a good choice for resuscitation fluids, we want to tamponade the bleeding and not just chase our tails with fluids. “D” is incorrect. Recombinant activated factor VIIa has not been shown to improve outcomes after trauma (*J Trauma*. 2010;69:353–359). Additionally, it has a number of adverse effects including increased thromboembolic phenomenon (pulmonary embolism, deep venous thrombosis, etc.). Finally, interventional radiology will likely play a role in his management. Those folks are quite skillful at stopping bleeding vessels, but you'll have to call them in from home. While you're waiting, a pelvic binder should be placed.

HELPFUL TIP:

Tranexamic acid, a drug that prevents fibrinolysis, has been shown to (marginally) reduce mortality from bleeding in trauma patients and is now recommended in the 2018 ATLS guidelines. The dose is 1 g IV over 10 minutes followed by 1 g over the next 8 hours. It should be started *within the first hour*. If started after 3 hours, it increases mortality (*Lancet*. 2010 Jul 3;376(9734):23–32). Additionally, tourniquets placed above the area of injury are now back in favor and are supported by the 2018 ATLS guidelines to treat uncontrolled hemorrhage. Consider tranexamic acid and placement of tourniquet as temporizing measures if you have an actively bleeding patient.

You appropriately place a pelvic binder to tamponade the bleeding. The patient's blood pressure stabilizes. You now turn to other issues. This patient will clearly need a Foley catheter.

Question 22.2.3 Relative contraindications to placement of a Foley catheter include which of the following?

- A) Blood at the urethral meatus
- B) Gross hematuria
- C) High-riding prostate
- D) Gross blood from the rectum
- E) A and C

Answer 22.2.3 The correct answer is “E.” Both blood at the meatus and a “high-riding prostate” (ever wonder what it is riding on?) signify the possible disruption of the urethra. You don't want to place the catheter in the wrong place, like the peritoneal space, so catheterization is relatively contraindicated with these findings. Of note, a “high riding prostate” has been found to be a relatively unreliable indicator for injury. The 2018 ATLS guidelines no longer recommend routine palpation of the prostate to evaluate for urethral injury. “B,” gross hematuria, can be from the kidney and is not a contraindication to catheterization.

You find blood at the urethral meatus. The patient complains that he really needs to void.

Question 22.2.4 Your options at this point include which of the following?

- A) Urethrogram to document an intact urethra
- B) Suprapubic cystostomy under ultrasound guidance
- C) Use of a Coudé catheter to catheterize the urethra
- D) Placement of a bladder catheter via the urethra
- E) A and B

Answer 22.2.4 The correct answer is “E.” One could perform a urethrogram using a water-soluble dye (e.g., Gastrografin) to document that the urethra is intact and if so place a standard Foley. One could also do a suprapubic cystostomy using ultrasound guidance. “C” and “D” are both incorrect. A Coudé catheter is used to bypass a stricture (prostate or otherwise) and would be no safer than a regular catheter in this patient. Likewise, a wire could end up anywhere and should not be used in this case.

HELPFUL TIP:

If you feel uncomfortable doing a formal cystostomy, a central line with balloon placed into the bladder can be used as a temporizing solution.

► Objectives: Did you learn to ...

- Treat acute traumatic pain?
- Recognize and treat pelvic trauma and intrapelvic hemorrhage?
- Describe contraindications to bladder catheter placement?

► CASE 22.3

A 55-year-old gentleman with history of smoking and type 2 diabetes presents to your office after finding a mass in his right

groin. He works as a night stocker in a local supermarket. He first noticed the mass after lifting a 60 lb box from the floor to the shelf several nights ago. Since then, he notices that the mass is painful and “pulses” when he coughs. He has not been able to work due to the pain. In fact, he wonders if you should just fill out disability papers for him now (never happens, right?). He endorses a history of chronic constipation for which he takes over-the-counter medications. He denies weight loss, nausea, vomiting, and urinary symptoms.

On examination, the patient is afebrile with a blood pressure of 135/86 mm Hg and a pulse of 84 bpm. Abdominal examination demonstrates a mildly obese gentleman with no scars of prior surgeries. Bowel sounds are normal. He denies tenderness with palpation of all four quadrants. There is no guarding. Upon standing, exam of the groin demonstrates an enlarged scrotum on the right side. You have him cough. The mass becomes more prominent and you can feel something protruding from the inguinal canal.

Question 22.3.1 Based on the information above, what is the next step in this patient's overall care?

- A) Get CT scan of the abdomen to evaluate for etiology of the mass
- B) Refer the patient to a surgeon
- C) Have the patient monitor the mass over the next couple of months for changes
- D) Have the patient cut back on his constipation medication
- E) Place the patient in an inguinal binder

Answer 22.3.1 The correct answer is “B.” The patient has an inguinal hernia. “A” and “C” are incorrect. History and physical examination are typically sufficient to make the diagnosis of a hernia. The hernia is relatively large and affecting his ability to work, so surgical repair is recommended rather than watchful waiting. Expectant management is an option for small, asymptomatic, or mildly symptomatic hernias, and surgical repair can be deferred. The patient should be provided with counseling on signs and symptoms of strangulation that would warrant emergent evaluation. “D” is incorrect. Constipation is a risk factor for hernias, so advising him to cut back on his constipation medication is not recommended. Have him eat more fiber, though. Finally, “E” sounds like a medieval torture device rather than a therapeutic intervention.

HELPFUL TIP: STUFF THE GUTS BACK IN OR NOT?

Observation of asymptomatic or minimally symptomatic hernias is acceptable—the “watchful waiting” strategy. However, over 7 to 10 years, two-third will elect to go on to repair, with 2% needing emergency repair (*Ann Surg.* 2018 Jan; 267(1):42–49). Tension-free mesh repair is recommended as first choice (don't listen to those late-night TV lawyers!) either by an open or a laparoscopic repair technique (*Hernia.* 2018 Feb;22(1):1–165). Laparoscopic repair has faster recovery times and results in less groin numbness and pain

in the long term. However, open repair has been shown to have lower rates of hernia recurrence (*Ann Surg.* 2012;255(5):846–853).

You refer the patient to a general surgeon within the month and he undergoes a laparoscopic hernia repair with mesh placement. He is discharged the following day. He is relieved that he doesn't need that disability paperwork filled out after all (Phew! You are too!). On postoperative day 2, he is wondering when he can go back to work. He is unable to reach his surgeon, who is in the OR (or maybe on the golf course), and calls your office asking when he can return to work ... lifting 60 lb boxes.

Question 22.3.2 How do you counsel him about when he can return to work?

- A) He may return to work once he is no longer requiring any pain medications and can drive a car
- B) Return to work is typically permitted within 2 to 4 weeks for laborers and within 1 to 2 weeks for those in sedentary jobs
- C) Return to work at his current job is not recommended, as it requires too much heavy lifting. He should seek another line of work
- D) Return to work is typically permitted within 6 weeks for all professions

Answer 22.3.2 The correct answer is “B.” Hernia repair patients are typically able to return to work within 2 to 4 weeks, primarily based on their surgeon's recommendations. For workers with more sedentary jobs, return may be as early as a few days. “A” is not correct. Being off pain medications is not a condition for returning to work. “C” is not correct. He should be able to resume his prior activities once the surgical wound heals completely. However, the patient should be counseled on safe lifting techniques and the possibility of recurrence of his hernia.

The patient is able to successfully return to work about 4 weeks postoperatively. He is feeling so well that he no-shows his follow-up appointments. Two years later, he returns after starting a running regimen to lose weight. Unfortunately, he is now having groin pain on the left after he runs, and he is worried that he has an inguinal hernia on the left (his prior hernia was on the right). He denies any nausea, vomiting, constipation, urinary symptoms, or masses in the groin area. Pain is an aching sensation and worsened with changing positions from sitting to standing or going up stairs. He denies any injury.

The patient is afebrile with a blood pressure of 120/78 mm Hg and a pulse of 84 bpm. Abdominal examination demonstrates a normal-weight gentleman with well-healed laparoscopic incisions. Bowel sounds are normal. He denies tenderness with palpation of all four quadrants. There is no guarding or rebound. Pain is reproducible with palpation of the inguinal ligament on the left. There is no inguinal lymphadenopathy.

Upon standing, examination of the groin reveals normal symmetric scrotum without any abnormal findings. There is no mass when the patient coughs.

Question 22.3.3 What is the most likely diagnosis for this patient's symptoms?

- A) Osteoarthritis of the left hip
- B) Femoral adenitis
- C) Left direct inguinal hernia
- D) Osteitis pubis
- E) Ligamentous strain

Answer 22.3.3 The correct answer is "E." All of the above should be considered in the differential for groin pain, but the most likely diagnosis for this patient's symptoms with his new running regimen is a ligamentous strain. Without a bulge detected on Valsalva maneuver (coughing) or a palpable abdominal wall defect, a hernia is unlikely ("C"). There are no palpable inguinal lymph nodes and patient does not have clinical signs of a fever, so "B" is unlikely. Hip osteoarthritis ("A") can be a cause of groin pain, particularly in people with good old wear-and-tear. However, the type of pain with hip osteoarthritis tends to be a deep and aching sensation within the groin area that is not reproducible on palpation. Of particular note is "D." Osteitis pubis, an inflammatory process of the symphysis pubis, is a very common overuse syndrome causing groin pain in athletes; it manifests as pain over the pubic symphysis, not the inguinal ligament. Other causes of osteitis pubis include childbirth, urologic or gynecologic surgery, and rheumatologic conditions. Treatment includes rest, NSAIDs, and, in rare cases, injection of the symphysis pubis with a steroid mixture (for athletes). Other causes of groin pain that should be considered within the differential and should be based on your clinical history and findings include epididymitis, referred pain, ectopic testes, stress fractures, and tendinopathies. If the pain had been localized to the right, adhesions and mesh complications from prior hernia repair must also be considered.

You treat your patient conservatively and he goes on to complete his first half-marathon a year later.

► **Objectives: Did you learn to ...**

- Diagnose a hernia based on clinical history and physical examination?
- Appropriately manage treatment for hernias?
- Counsel patients on recommended return to activities postoperatively?
- Identify other potential causes of groin pain?

► **CASE 22.4**

A 60-year-old female presents to your office for abdominal pain ... at 4:45 PM ... on a Friday ... on Christmas eve. Two months prior, she underwent a partial colon resection and primary re-anastomosis following a perforated bowel, most likely secondary to a perforated diverticulum. The pain is crampy and intermittent. Further history reveals a 24-hour

history of vomiting, abdominal bloating, and malaise. She reports her last bowel movement was 2 days ago and denies any flatus over the last 24 hours. On examination, her temperature is 37.1°C, pulse 105 bpm, respirations 12 bpm, and blood pressure 158/60 mm Hg. Her abdomen is slightly distended, diffusely tender to palpation without rebound or guarding, and has hyperactive bowel sounds. On flat plate and upright views of the abdomen, there are dilated loops of small bowel and multiple air fluid levels.

Question 22.4.1 Which of the following is true regarding this patient's current disease process?

- A) She most likely has a closed-loop small bowel obstruction (SBO)
- B) She most likely has an extramural source of obstruction
- C) Dilated loops of small bowel are defined as being >5 cm in diameter on plain film
- D) Both partial and complete bowel obstructions reveal no colonic gas on plain film

Answer 22.4.1 The correct answer is "B." This patient most likely has an external source of obstruction. Bowel obstructions are divided into two classes: mechanical and functional (the latter also known as pseudo-obstruction, ileus, or neurogenic obstruction). Mechanical obstructions are further classified by both their location—small versus large bowel—and etiology. Possible etiologies include intraluminal bodies (e.g., gallstone ileus or foreign body), intramural lesions (e.g., tumor, stricture, or intussusception), and extramural lesions (e.g., adhesions). Obstructions can further be divided into open and closed loop. Open-loop obstructions have an outlet for gas and secretion relief (e.g., vomiting) whereas closed-loop obstructions block both inflow and outflow to an area. Closed-loop obstructions, like bowel torsion or volvulus, cause acute, severe abdominal pain, and generally require urgent surgical intervention.

Bowel obstruction presents with crampy, intermittent abdominal pain, vomiting, distension, and obstipation. History often includes previous abdominal surgery. Depending on the degree of obstruction and its duration, there may be hyperactive bowel sounds, high-pitched bowel sounds, or decreased/absent bowel sounds. An upright abdominal plain film or lateral recumbent abdominal film confirms diagnosis with findings of dilated loops of small bowel (bowel >3 cm in diameter) on the flat plate and air fluid levels on the upright or decubitus film. However, plain radiographs, only have a sensitivity and specificity of 79% to 83% and 67% to 83% respectively. **CT scan is more sensitive and specific (93% and 100%) for obstruction than are plain films and will often reveal the source of the obstruction.** CT abdomen and pelvis has become the primary imaging modality to guide management (American College of Radiology Appropriateness Criteria, 2018). Patients with a complete SBO will lack air in the colon on plain film; but remember that air can be introduced into the rectum during a rectal examination. Of note, ultrasonography performed at the bedside is both less invasive and less expensive and is 75% sensitive and 75% specific in the hands of an experienced operator. It is a safe alternative to CT/x-ray especially in children and pregnant women.

Question 22.4.2 Which of the following cause ileus?

- A) Burns
- B) Spinal cord injury
- C) Hypokalemia
- D) Pneumonia
- E) All of the above can cause an ileus

Answer 22.4.2 The correct answer is “E.” All of the above can cause an ileus. Additional causes include peritonitis, pancreatitis, retroperitoneal inflammation or hematomas, uremia, surgery, and medications like narcotics and anticholinergics.

You diagnose an SBO, which you believe is most likely related to adhesion formation after her hemicolectomy.

Question 22.4.3 Which of the following is INCORRECT regarding the management of bowel obstruction?

- A) Initial treatment orders should include NPO, IV fluid resuscitation, and electrolyte replacement as needed
- B) This patient should undergo emergent surgical intervention
- C) If she has fever or leukocytosis, she should undergo surgical intervention
- D) If she requires surgery, broad-spectrum antibiotics to cover anaerobes and Gram-negative aerobes should be administered perioperatively

Answer 22.4.3 The correct answer is “B.” Uncomplicated small bowel obstruction is not an indication for emergent surgery. Peritoneal adhesions account for more than half of all SBOs, and 80% of these resolve without surgical intervention. Answer “A” is true. Initial treatment includes restricting oral intake, IV fluid resuscitation, and electrolyte correction.

Answers “C” and “D” are also true. Patients can be safely observed if there is no evidence of strangulation. Evidence of strangulation includes rapidly progressing abdominal pain or distension, development of peritoneal findings, fever, diminished urine output, leukocytosis, hyperamylasemia, metabolic acidosis, and persistent obstruction. Closed-loop obstructions should always be treated surgically and *patients with a transition point often go on to have surgery*. Patients with de novo obstruction (e.g., no history of laparotomy) usually require surgical intervention to determine etiology. If surgery is necessary, broad-spectrum antibiotics that cover anaerobes and Gram-negative aerobes should be administered perioperatively to reduce wound infection and abdominal sepsis rates.

**HELPFUL TIP:**

Although an NG tube is traditionally used in the treatment of SBO, its use is optional. An NG tube may help alleviate vomiting and distension but does not hasten the resolution of the SBO.

► **Objectives: Did you learn to ...**

- Assess abdominal pain and recognize an acute abdomen?
- Provide appropriate perioperative management for gastrointestinal (GI) surgery?

- Identify and treat small bowel obstruction after abdominal surgery?

► **CASE 22.5**

Mr. and Mrs. Biggs have always been “big boned.” They have decided that weight reduction surgery is the thing for them. However, they are concerned that, for the first time in their lives, they may not be big enough.

Question 22.5.1 Which of the following is NOT a necessary condition for weight loss surgery?

- A) BMI ≥ 40 kg/m² regardless of the presence of weight-related disease
- B) BMI ≥ 35 kg/m² without the presence of weight-related disease
- C) BMI ≥ 35 kg/m² with at least one serious comorbidity like sleep apnea, diabetes, severe joint disease, nonalcoholic fatty liver disease (NAFLD), or weight-related cardiomyopathy
- D) Failure to control weight with diet and other medical interventions

Answer 22.5.1 The correct answer is “B.” A BMI of ≥ 40 kg/m² (not ≥ 35 kg/m²) alone is considered an appropriate weight for surgical intervention in the absence of other comorbidities. As noted above in “C,” BMI of ≥ 35 kg/m² with weight-related comorbidities is considered an indication for bariatric surgery. “D,” failure of medical therapy, is surgeon dependent. Some won’t consider weight loss surgery until the patient has demonstrated lifestyle changes. Others do not require such a trial.

A BMI between 30 and 34.9 kg/m² and either uncontrollable type 2 diabetes or metabolic syndrome may be an acceptable indication for bariatric surgery, although there is not currently enough evidence to support this in routine practice.

To their delight (and chagrin), Mr. and Mrs. Biggs remain above 40 kg/m². There are several surgeons in town who perform different techniques, including a Roux-en-Y and laparoscopic banding.

Question 22.5.2 Which of the following is NOT true?

- A) Roux-en-Y is associated with greater weight loss at 1 year
- B) Laparoscopic adjustable gastric banding (LAGB) is associated with a greater need for repeat surgery compared with Roux-en-Y
- C) Mortality is higher with Roux-en-Y than LAGB and there are more hospital admissions for complications
- D) Vertical banded gastroplasty leads to sustained weight loss and few complications

Answer 22.5.2 The correct answer is “D.” Vertical banded gastroplasty (“stomach stapling”) does not lead to sustained weight loss and has many complications including disruption of the staple line, GERD, vomiting, and erosion of the band into the

stomach. For this reason, it has (or should have) fallen out of favor. The rest are true. Laparoscopic Roux-en-Y gastric bypass (LRYGB) results in the best long-term weight loss and requires fewer repeat surgeries when compared with LAGB. However, the mortality rate is higher (0.14 vs. 0.09%) for Roux-en-Y and there are more perioperative complications. It also requires longer hospital stays.

**HELPFUL TIP:**

Bariatric surgeries help with weight loss by decreasing the storage capacity of the stomach and/or creating conditions for malabsorption. Often, a combination of techniques is performed in a patient. Restrictive surgeries include sleeve gastrectomy and adjustable gastric bandings (vertical or horizontal gastropasty is not performed these days). Surgeries that promote malabsorption are Roux-en-Y gastric bypass and biliopancreatic diversion with duodenal switch. Most surgeries are performed laparoscopically. Newer procedures include endoscopic bariatric procedures with intragastric balloon placement and vagal nerve blockage device implantation (see “Helpful Tip(s): An Orchestra Conductor for Weight Loss?” for more information) (Fig. 22-1).

Mr. and Mrs. Biggs learn more about the procedures and are wondering if this is worth all the trouble.

Question 22.5.3 You can tell them that:

- A) Although they may lose weight, weight loss surgery does nothing for their underlying diabetes, hypercholesterolemia, and coronary artery disease (CAD)
- B) There is no psychological or quality-of-life benefit to weight loss surgery: they will have the same existential crises before and after the surgery
- C) NSAIDs are relatively contraindicated after weight loss surgery
- D) Dumping syndrome is more common after laparoscopic banding than with Roux-en-Y
- E) There is rarely a need for supplemental vitamins after bariatric surgery

Answer 22.5.3 The correct answer is “C.” The rate of gastric ulcers from NSAIDs is higher after bariatric surgery. The rest are not true. Weight loss does improve lipid profiles, decreases mortality due to cardiovascular events, and promotes glycemic control. Therefore “A” is incorrect. There are well-demonstrated psychological and quality-of-life benefits from bariatric surgery (“B”). Dumping syndrome is commonly seen after a Roux-en-Y but not with laparoscopic banding (“D”). Most patients will need supplemental vitamins (“E”). Vitamin deficiencies, especially folic acid, are common after bariatric surgery. Although deficiencies are more of a concern with malabsorptive procedures, supplementation is recommended for all post-bariatric surgery patients.

**HELPFUL TIP:**

Cholelithiasis is common after bariatric surgery, especially Roux-en-Y, and occurs as a result of rapid weight loss.

After their operations, Mr. and Mrs. Biggs return to see you. Mr. Biggs (who opted for the Roux-en-Y procedure and who is changing his name to Mr. Little) complains of recurrent postprandial colicky abdominal pain, diaphoresis, nausea, diarrhea, and tachycardia. His wife, who went for the laparoscopic banding, has no such symptoms. You make the diagnosis of “dumping syndrome.”

Question 22.5.4 Your advice is to:

- A) Start an anticholinergic to reduce stomach emptying
- B) Increase the content of simple sugars to quickly raise the blood sugar with meals
- C) Increase the size of feedings a bit in order to increase the amount of food available for digestion
- D) Separate solid from liquid intake for at least 30 minutes (no beer with that pizza!)
- E) None of the above

Answer 22.5.4 The correct answer is “D.” Separating liquid from solid intake by 30 minutes may help to reduce dumping syndrome. The others are incorrect. While theoretically plausible, anticholinergics have not been shown to be of benefit in dumping syndrome. However, drug therapy with octreotide may be considered if there is no response to dietary modifications after 3 to 4 weeks. Small and frequent meals **devoid of simple sugars** are the way to go. The symptoms seem to be related to the rapid transit of simple sugars into the bowel. Smaller volume meals without simple sugars are an effective treatment for most patients with mild symptoms.

While we’re on the subject, there is another component of dumping syndrome—“late dumping.” This occurs as a result of hypoglycemia secondary to an insulin surge during a meal and presents a few hours after eating. As you might expect with hypoglycemia, vasomotor symptoms are present with fewer GI symptoms.

**HELPFUL TIP:**

Nutritional deficiencies following bariatric surgery can result from not only decreased absorption, but also low food intake, food intolerances, or excessive vomiting. Consider the following labs at 3, 6, and 12 months, and then annually: CBC, basic metabolic panel with calcium, iron studies, vitamin B1 (thiamine), vitamin B12, folate, liver enzymes, albumin, lipid profile, zinc, and copper.

**HELPFUL TIP(S): AN ORCHESTRA CONDUCTOR FOR WEIGHT LOSS?**

“Maestro” (yes, that is the name) is a surgically implanted vagus nerve stimulator that interrupts the signal of the vagus to the brain, thus reducing hunger. It has the

FIGURE 22-1. Common and newer bariatric surgery procedures to induce weight loss.

From Nguyen NT, et al. Bariatric surgery for obesity and metabolic disorders: state of the art. Figures 1 and 2. *Nat Rev Gastroenterol Hepatol*. 2017 Mar; 14(3): 160–169.

same indications as other surgical techniques and leads to 8% more weight loss than those in the sham group.

Finally, in some instances a gastrostomy tube (“feeding tube” ... e.g., AspireAssist) can be placed. The patient can eat all they want and then empty the stomach via the gastrostomy tube after a meal (really).

► **Objectives: Did you learn to ...**

- Recognize the indications for bariatric surgery?
- Describe some different techniques for bariatric surgery and their pros and cons?
- Provide long-term management of the bariatric surgery patient and dumping syndrome?

► **CASE 22.6**

A 24-year-old male presents to your clinic with a 5-day history of rectal bleeding. For several years, he has had hard stools but has developed rectal bleeding in the last few days. In addition, he has severe, intermittent, and crampy abdominal pain that he thinks is due to constipation. He reports a mild fever.

On examination, temperature is 37.9°C, pulse 95 bpm, respirations 12 bpm, and blood pressure 108/78 mm Hg. His abdomen is nontender and without guarding or rebound tenderness. Anoscopy reveals gross blood and two internal hemorrhoids.

Question 22.6.1 Regarding hemorrhoids in general, which of the following is TRUE?

- Patients with hemorrhoids most commonly present for perianal burning, swelling, and pain
- A grade III hemorrhoid can be reduced manually
- If a patient under the age of 50 with rectal bleeding is found to have hemorrhoid on examination, further studies are not indicated
- Because they are above the dentate line, strangulated internal hemorrhoids are not painful

Answer 22.6.1 The correct answer is “B.” Grade III hemorrhoids can be reduced manually. Hemorrhoids are normal vascular structures in the anal canal; however, “hemorrhoids” (the occurrence our patients complain about) arise when the vessels become engorged. Symptoms such as painless bleeding and itching may result. Two types of hemorrhoids exist: external hemorrhoids, from the inferior hemorrhoidal plexus below the dentate line, and internal hemorrhoids from the anal cushions above the dentate line. Internal hemorrhoids occur on the left lateral, right anterior, and right posterior anal walls and are classified into grades I to IV. Grade I hemorrhoids slide below the dentate with straining but not through the anus. Grade II hemorrhoids protrude the anus but spontaneously reduce, whereas Grade III hemorrhoids must be manually reduced. Grade IV internal hemorrhoids cannot be reduced and are at risk for strangulation. “A” is incorrect because most patients with symptomatic hemorrhoids present with painless rectal bleeding. “C” is incorrect. You should consider further evaluation (e.g., flexible

sigmoidoscopy and colonoscopy) in patients under the age of 50 presenting with rectal bleeding, even if hemorrhoids are present and are the likely source of bleeding. In patients older than 50 with rectal bleeding, a full colonoscopy is routinely recommended to rule out any cancerous process. “D” is incorrect. Although most internal hemorrhoids do not cause pain, **strangulated** internal hemorrhoids are very painful and can become necrotic and gangrenous, requiring emergent surgery. Note that **strangulated** (when blood supply is cut off) is different from **thrombosed** (when clot forms within the hemorrhoid).

Question 22.6.2 Which of the following would you NOT consider as a treatment of this patient’s hemorrhoids?

- A) Psyllium
- B) Dicyclomine
- C) Warm sitz baths
- D) Short course of topical hydrocortisone
- E) Increased water intake

Answer 22.6.2 The correct answer is “B.” Dicyclomine (Bentyl, Antispas) is not indicated. Dicyclomine is an anticholinergic and will contribute to constipation—exactly what you want to avoid in hemorrhoids. “A” and “E” are the primary modes of treatment. Psyllium, as well as a diet high in fiber and water, will reduce straining and thus reduces intra-abdominal pressure. “C,” warm baths or showers (40°C), have been shown to reduce anal canal pressures. “D,” a short course of topical hydrocortisone (e.g., Anusol HC), may be of benefit, although strong evidence is lacking. Long-term topical steroids are contraindicated as they can cause thinning of the anal mucosa. Finally, good hygiene and analgesia should be prescribed as needed.

HELPFUL TIP:

Most symptomatic hemorrhoids respond to conservative measures. Surgery should not be performed unless conservative measures fail or other indications exist (e.g., strangulation).

Question 22.6.3 Which of the following is true about managing hemorrhoids in an office setting?

- A) Irritable bowel syndrome is a relative contraindication to excising hemorrhoids
- B) It is best to ligate all hemorrhoids in a single office visit
- C) Band ligation results in sloughing of hemorrhoid in about 1 to 2 weeks
- D) Following excision, thrombosed external hemorrhoids should be closed to prevent bleeding

Answer 22.6.3 The correct answer is “C.” Rubber-band ligation generally results in the sloughing of the hemorrhoid in 1 to 2 weeks. “A” is incorrect. Inflammatory bowel disease (IBD)—not irritable bowel syndrome (IBS)—is a relative contraindication to the management of hemorrhoids in an office setting. Other contraindications to office-based hemorrhoid procedures include

coagulopathy, pregnancy and postpartum period, anorectal fissures, perirectal abscess, anorectal tumors, immunocompromised states, portal hypertension, and patients on anticoagulant/antiplatelet medications. It is preferable to treat hemorrhoids in the latter three conditions with sclerotherapy. A formal hemorrhoidectomy can be safely performed in pregnancy. Common complications following the excision of internal hemorrhoids are bleeding and urinary retention. Other rare ones include rectal perforation, recto-vaginal fistula, and pelvic abscess. “B” is incorrect. Although evidence is scarce, standard of care dictates that only one hemorrhoid be ligated in a single office visit (due to concerns about excessive tissue necrosis). “D” is incorrect. Patients who present with external hemorrhoids that are painful, tender, swollen, with bluish discoloration have thrombosis. If the patient presents within 48 hours of thrombosis, the thrombosed hemorrhoid should be excised. However, if a surgical evaluation is not available and the provider is not comfortable with excision of the hemorrhoid, an incision and evacuation of the clot can be performed. It is important **not** to close the hemorrhoid once the clot is evacuated. In fact, a small ellipse of the hemorrhoid should be removed to facilitate continued drainage and prevent re-accumulation of clot.

You prescribe conservative treatment for your patient’s hemorrhoids, and since he does not return for his next scheduled appointment, you assume he is doing well. You see him again 6 months later. He reports that he had indeed healed—he is back for a new problem. Although he still takes psyllium, he began having painful bowel movements with blood-streaked stool 2 days ago. Upon examination of the anus, you find a fissure.

Question 22.6.4 All of the following findings would lead you to consider Crohn disease EXCEPT:

- A) Posterior midline fissure
- B) Painless fissure
- C) Multiple fissures
- D) Nonhealing fissure

Answer 22.6.4 The correct answer is “A.” The posterior (dorsal) midline is where solitary fissures, unrelated to IBD, are typically located. Fissures in any other location should raise suspicion for Crohn disease. “B,” “C,” and “D” are also suggestive of Crohn disease. See Chapter 7 for more on Crohn Disease and IBD.

Question 22.6.5 In a patient with an uncomplicated, initial anal fissure, what do you recommend for *first-line* therapy?

- A) Lord dilation
- B) Botulinum toxin injections
- C) Topical nitroglycerin
- D) Oral psyllium
- E) Oral nifedipine

Answer 22.6.5 The correct answer is “D.” All of the options are employed for treating anal fissures. However, in patients with an uncomplicated, initial anal fissure, it is always prudent

to initiate conservative therapy (e.g., psyllium, dietary fiber, water, and warm soaks) prior to proceeding to more invasive measures. Most fissures will respond to conservative measures. Generally, healing takes 2 to 4 weeks. In addition to the treatments listed, topical diltiazem and topical nifedipine are also useful as are various surgical approaches like lateral anal sphincterotomy. Lord dilation (“A”) deserves special mention as a relatively arcane procedure for stretching the anal sphincter muscle (under anesthesia, we hope!). One note about Botulinum toxin injection (“B”) for rectal fissures: It also gets rid of those unsightly wrinkles!

► **Objectives: Did you learn to ...**

- Characterize hemorrhoids based on location?
- Grade internal hemorrhoids based on severity?
- Manage hemorrhoids with conservative and surgical treatments?
- Treat an uncomplicated anal fissure?
- Recognize anal fissures as potential signs of Crohn disease?

► **CASE 22.7**

A 58-year-old female presents to your clinic for a lump found on routine breast self-examination. Her older sister died from breast cancer, and she is very concerned about the possibility of breast cancer in herself. She never misses her monthly breast examination and notes she has never felt this lump before. She first noticed the lump 2 weeks ago, and it has not changed in size or consistency since that time. Consistent with her personal healthcare goals but totally inconsistent with any current guidelines, she has had yearly mammograms since age 40 that have always been normal. She denies any weight loss or fatigue and reports being postmenopausal for the last 5 years. She previously took combination hormone replacement therapy, which she discontinued last year.

On examination, her breasts appear symmetrical with no skin abnormalities. The nipples are symmetric in size, shape, and color without retraction or discharge. You palpate a small, pea-sized thickening in upper outer quadrant of the right breast. This is the lump that she noticed 2 weeks ago. It is fixed to the deep aspect of the chest wall, so you have a hard time delineating whether the borders are smooth.

Question 22.7.1 Regarding breast lumps, which one of the following is FALSE?

- Abnormal screening mammography is the most common presentation of breast carcinoma
- Cysts are more common in premenopausal women than postmenopausal women
- A history of fibroadenoma is associated with an increased risk of breast cancer
- A radiographic oil cyst is pathognomonic for fat necrosis

Answer 22.7.1 The correct answer is “A.” The most common presentation of breast carcinoma is a breast lump felt by the patient, although screening mammography makes up a large

percentage of diagnosed breast cancers as well. Breast masses can be benign—including fibroadenomas (most commonly), lipomas, fat necrosis, soft-tissue inflammation or infection—or malignant. “B” is true. Cysts primarily present when women are premenopausal and are uncommon in the postmenopausal state, unless the woman is taking hormone replacement. Cysts are typically well-demarcated, mobile, and firm. The diagnosis is confirmed with aspiration of non-bloody fluid followed by complete resolution of the mass. Fibroadenomas occur between the ages of 20 and 50 and are described as firm, rubbery, and mobile. They can be confirmed by characteristic findings on ultrasound and tissue biopsy if necessary. “C” is also true. While historically believed to be entirely benign, fibroadenomas are associated with a small but significant increased risk for breast cancer. “D” is true. A radiographic oil cyst (a circumscribed mass of mixed soft-tissue density and fat with a rim that is often calcified) is due to fat necrosis, which occurs in areas of the breast that have been subject to trauma, surgery, infection, or radiation therapy. About half of the time, fat necrosis has no precipitant. Oil cysts are most common in the superficial aspects of pendulous breasts of obese women. When an oil cyst is seen radiographically, no further evaluation is needed.

When making diagnostic decisions regarding breast masses, age matters. In women under 30, if there is low suspicion for cancer based on history and exam, a palpable breast mass can be observed for one to two menstrual cycles, and further evaluation only pursued if the mass persists. For this age group, ultrasound is the imaging modality of choice, but mammogram may be added to workup if there is high clinical suspicion for malignancy. **For women 30–39, observation is not recommended, and you should proceed with mammogram or ultrasound, or both.** Ultrasound is still probably more sensitive in this age range. For women over 40, obtain a diagnostic mammogram and ultrasound.

Your patient is concerned about her family history of breast cancer. She asks about genetic testing.

Question 22.7.2 You are able to tell her that the BRCA genes are associated with which of the following?

- Breast cancer
- Uterine cancer
- Ovarian cancer
- A and B
- A and C

Answer 22.7.2 The correct answer is “E.” Approximately 7% of breast cancers and 15% of ovarian cancers are associated with mutations to the BRCA (BReast CAncer) 1 and 2 tumor suppressor genes. These mutations increase risk of familial breast cancer and ovarian cancer. They are not associated with uterine cancer. Specific criteria from the National Comprehensive Cancer Network (NCCN) exist to determine who should undergo testing for BRCA 1/2 and other gene mutations that put patients at risk for hereditary breast and ovarian cancers.

Patients with a particularly concerning family history may benefit from seeing a genetic counselor.

For your patient, you decide to use one of many risk assessment tools (i.e., Gail score... below for more) and find that this patient's 5-year breast cancer risk, even before she came to you with a concerning lump, is estimated to be higher than that of the average 58-year-old woman. You are suspicious that this patient's mass may be cancer, and you order diagnostic mammography and ultrasound. However, these studies show no mass. When your patient returns to discuss her test results, you examine her again. The mass is still palpable and essentially unchanged.

Question 22.7.3 The next best step in management of this patient is:

- A) Breast examination and mammogram every 6 months
- B) Breast examination and mammogram every 3 months
- C) Referral to a surgeon to consider excisional biopsy
- D) Ultrasound-guided needle biopsy
- E) Return to normal screening

Answer 22.7.3 The correct answer is "C." A palpable mass that is suspicious for cancer cannot be ignored even in the presence of negative radiologic studies. No other option is acceptable, nor would any other option be defensible if this patient were to develop overt breast cancer. "D" would be an option if a mass had been identified on ultrasound (see below).

Question 22.7.4 But let's suppose for a moment that a mass was detected on your patient's imaging. You would now turn to the "Breast Imaging Reporting and Data System" (BI-RADS®) criteria which score radiologic findings and the probability of cancer. These designations should be included on any mammography report. For more information, please go to <https://www.acr.org/-/media/ACR/Files/RADS/BI-RADS/BIRADS-Reference-Card.pdf> or Google "BI-RADS." Which of the following is NOT TRUE about how a diagnostic evaluation should proceed?

- A) In women <30 years of age, lesions that are BI-RADS® 3 (probably benign) on ultrasound may be followed by a repeat examination in 6 to 12 months, then every 1 to 2 years if clinical suspicion for malignancy remains low
- B) In women >40 years of age, lesions that are BI-RADS® 3 (probably benign) on ultrasound need no follow-up
- C) In women >40 years of age who have a palpable mass that is not seen on mammogram or ultrasound, BI-RADS® 1 (negative), excisional biopsy should be performed if clinical suspicion dictates
- D) In women >40 years of age who have breast imaging rated as BI-RADS® 4 or 5 should have a core needle biopsy of the area in question

Answer 22.7.4 The correct (incorrect) answer is "B." Women over the age 40 absolutely need follow-up for anything other than a specific benign finding (e.g., lymph node), and even with

that finding, a correlative ultrasound may be indicated. "A" is true. If this young woman had a "likely benign," BI-RADS® 3 ultrasound, this is an appropriate approach. If the mass were a simple cyst, or BI-RADS® 2 (benign), diagnostic evaluation could stop following the ultrasound. With an ultrasound more concerning than BI-RADS® 3, she should have a mammogram and a core needle biopsy for further diagnosis. "C" is true. If the palpable mass cannot be identified radiographically, and clinical suspicion remains high, the mass should be removed by excision. "D" is also true; core needle biopsy is recommended for BI-RADS® 4 and 5 findings, and should be considered versus short-term follow-up for BI-RADS® 3 findings. The American College of Radiology (ACR) and the NCCN are less directive for women aged 30 to 39, with subsequent workup based on whether initial imaging was mammogram or ultrasound.

A needle biopsy either by core needle biopsy or fine needle aspiration (FNA) is the next step after imaging in evaluation of solid tumor masses requiring further diagnosis. Needle diagnosis offers the advantages of being simple, quick, inexpensive, relatively noninvasive, highly available, and an accurate way of diagnosing atypical cells. **Core needle biopsy is the way to go if you have a choice.**

You perform an FNA because you are practicing in a low resource setting without a surgeon. The cytopathologist reads this as "probable malignancy." You recall from previous visits that the patient's older sister had breast cancer. Additionally, your patient went through menopause at age 56, and used hormone replacement therapy for 5 years. You obtain further history, including a history of menarche at 14 years of age and the fact that the patient has never been pregnant.

Question 22.7.5 Which of these factors DOES NOT contribute to an increased risk of breast cancer in THIS patient?

- A) Her nulliparity
- B) Her age at menarche
- C) Her family history
- D) Her age at menopause
- E) Her history of hormone replacement

Answer 22.7.5 The correct answer is "B." The risk of breast cancer is roughly associated with the lifetime exposure to estrogen. This patient's age at menarche is in the mid-to-late age range and is thus **not** a risk factor for breast cancer. Younger age at menarche (e.g., 10 years old) is associated with an increased risk of breast cancer. Nulliparity and greater age at first pregnancy (over 30 years) are associated with an increased risk, as is older age of menopause. A history of a first-degree relative with breast cancer is a strong risk factor. Modifiable risk factors for breast cancer appear to be increased BMI, sedentary lifestyle, and increased alcohol intake. Exposure to thoracic radiation prior to age 30 is something you should remember to ask your patients about. Women who are identified as having dense breasts on mammogram are at increased risk for breast cancer, at least partially due to difficulty in interpreting their mammograms (an ultrasound or MRI may be recommended for these

women if they are already at increased risk of breast cancer). Finally, as demonstrated in the Women's Health Initiative, estrogen/progesterone replacement therapy (HRT) is associated with an increased risk of breast cancer (an excess of about 8 breast cancers per 10,000 women treated with HRT).

While you wait for definitive pathology results, you consider the different types of breast cancer that this patient might have.

Question 22.7.6 Regarding various types of breast cancer, all of the following are true EXCEPT:

- A) Phyllodes tumors are not always malignant
- B) Infiltrating lobular carcinoma is the most common histological type of invasive breast carcinoma
- C) Paget disease of the breast clinically appears eczematous
- D) Sarcomas, lymphomas, melanomas, and angiosarcomas are all possible causes of cancer in the breast

Answer 22.7.6 The correct answer is "B." Infiltrating **ductal** (not lobular) carcinoma is the most common histological type of invasive breast cancer. Invasive breast carcinoma includes a wide variety of histological diseases. Infiltrating **ductal** carcinoma accounts for 65% to 80% of breast cancers, whereas infiltrating **lobular** carcinoma is the second most frequent, accounting for about 10% of breast cancers. "A" is true. The more rare phyllodes tumors, which often have a clinical presentation similar to fibroadenomas, may be either malignant or benign. The malignant nature of phyllodes tumors is sometimes difficult to determine on FNA or core needle biopsy, and wide local excision may be required. "C," Paget disease of the breast, is a rare form of breast cancer with eczematous changes of the nipple, including itching, erythema, and nipple discharge. "D" is true as well. Many other malignancies may occur in the breast, including sarcomas, lymphomas, melanomas, and angiosarcomas.

The pathology results are final and show infiltrating ductal carcinoma. Your patient will see a breast surgeon next week. As you await the results of surgery, you consider her prognosis.

Question 22.7.7 All of the following are favorable prognostic indicators in breast cancer EXCEPT:

- A) Hormone receptor negative
- B) Absence of axillary nodal involvement
- C) Low-grade tumor
- D) Pure tubular, mucinous, or medullary histological types
- E) Tumor size <1 cm

Answer 22.7.7 The correct answer is "A." Patients whose tumors are hormone receptor negative have worse outcomes than do patients whose tumors are hormone receptor positive. "B," absence of axillary nodal involvement, is obviously a better prognostic factor than the presence of nodal involvement. In fact, axillary lymph node status is the single most important

predictor of overall survival in breast cancer. "C," low tumor grade, is also a good prognostic factor. "D," patients with a single cell type have a better prognosis as well. "E" is true. A very useful predictor of tumor behavior is tumor size, and tumor size <1 cm is a positive prognostic sign.

HELPFUL TIP:

Tumors can be either estrogen or progesterone receptor positive or negative and Her2/neu (tyrosine-protein kinase receptor) positive or negative. Tumors that are positive for estrogen and/or progesterone receptors are the most likely to respond to hormonal therapy (e.g., tamoxifen). Tumors that are positive for Her2/neu are most likely to respond to tyrosine kinase inhibitors (e.g., Herceptin).

HELPFUL (BUT DISTURBING) TIP:

It turns out that approximately 16% to 20% of women who undergo breast-conserving surgery for breast cancer need repeat surgery. Some never go for re-excision (15% in one study). Disturbing with major implications for informed consent (*Ann Surg Oncol.* 2017 Jan;24(1):52–58).

A second issue with breast cancer is the matter of "overdiagnosis." Up to 20% or more of the cancers we diagnose on mammogram would never cause problems (*BMJ.* 2009;339:b2587). We are subjecting women to unnecessary chemotherapy/surgery/radiation. What to do about this is a matter of debate.

► Objectives: Did you learn to ...

- Generate a differential diagnoses for breast masses?
- Evaluate a patient with a breast mass?
- Identify risk factors for breast cancer?
- Describe several types of breast cancers?
- Describe factors that are used to establish prognosis in breast cancer?

QUICK QUIZ: BREAST CANCER RISK

A 50-year-old female presents for a routine physical. She wants to know her risk of developing breast cancer. You want to give her a more accurate picture, and you decide to use the Gail model.

When taking her history, you must ask about all of the following EXCEPT:

- A) Number of first-degree relatives with breast cancer
- B) Age at first menstrual period
- C) Number of breast biopsies
- D) Age at first live birth
- E) Number of live births

The correct answer is “E.” The Gail model is a statistical model that estimates a woman’s chance of developing breast cancer. Factors that affect the score include the number of first-degree relatives with breast cancer, current age, age of first menstrual period, number of breast biopsies, BRCA gene status, age at first live birth, race, and history of atypia in a biopsy. This tool may be useful in determining which patients are high risk or even candidates for hormonal therapy for breast cancer prophylaxis. **However, the Gail score is much better at predicting the likelihood of breast cancer in populations than in any individual.** The National Cancer Institute maintains a website for the Gail model calculation, located at <http://bcra.nci.nih.gov/brc/q1.htm>.

► CASE 22.8

An orthopedic colleague asks you to consult on a 64-year-old male prior to an elective total hip replacement. The surgery is scheduled for 5 weeks from now. The patient is a smoker with hypertension, diabetes mellitus type 2, and coronary artery disease. He is currently asymptomatic and is able to walk stairs without dyspnea or chest pain. The surgeon would like some perioperative recommendations.

Question 22.8.1 You would recommend all of the following EXCEPT:

- A) The patient should stop smoking TODAY
- B) The patient should have preoperative and postoperative β -blockers started on the day of surgery
- C) The patient should have an ECG done
- D) The patient should have his hemoglobin/hematocrit drawn
- E) The patient should have his creatinine measured

Answer 22.8.1 The correct answer is “B.” If a patient has a medical indication for a chronic β -blocker, it should be continued perioperatively as long as the dose has been stable well in advance of the day of surgery. While the β -blocker offers some protection against myocardial infarction, there is also increased risk of stroke, hypotension, and overall mortality. **A β -blocker should NOT be started on the day of surgery.** “A” is true. Nonsmokers have better surgical outcomes than smokers, in addition to longer lives and better breath. A few small studies have raised concerns about quitting smoking too close to the date of surgery. Sooner is definitely better (at least 30 days out), but the quitting at any time is better than continuing. Answers “C,” “D,” and “E” are probably true for this patient who has known cardiac disease and an increased risk of acute kidney injury due to his other medical conditions. Many other “routine” preoperative assessments are not supported in the literature. See Tables 22-1 and 22-2 for the appropriate evaluation of the preoperative patient.

Question 22.8.2 You inform your patient that a hip replacement surgery is among the procedures with the highest rates of deep venous thrombosis. Which of the

following is effective for the prevention of postoperative DVT?

- A) Sequential compression devices for in-hospital recovery
- B) Enoxaparin 30 mg subcutaneously every 12 hours
- C) Therapeutic warfarin
- D) Unfractionated heparin 5,000 Units subcutaneously every 12 hours
- E) All of the above

Answer 22.8.2 The correct answer is “E.” All of the modalities listed above can be used to prevent the development of DVT. The non-warfarin direct oral anticoagulants are also increasingly being used at prophylactic doses if patients refuse injectable medications, but careful—DOACS are not to be used following hip fracture repair, where there is an increased risk of bleeding compared to hip arthroplasty (replacement). Aspirin is also commonly used though the data is poor. Subcutaneous heparin may require TID dosing in larger patients, and don’t forget that enoxaparin requires renal adjustment for creatinine clearance <30 mL/min. The minimum time frame for prophylaxis is 10 to 14 days, but usually should be continued longer—up to 35 days. Early mobility is always a goal, so encourage your patient to make good use of that new hip as soon as possible.

TABLE 22-1 PREOPERATIVE STUDIES AND THEIR INDICATIONS

Tests	Indications
BUN/creatinine	Over 60; history of renal, cardiac, or vascular disease
CBC/H&H	Possible hematologic or infectious process; significant blood loss predicted
Coagulation studies	Stigmata liver disease, history of coagulopathy, possible DIC, anticoagulation, alcohol abuse
ECG/CXR	As indicated by history and physical (e.g., exacerbation of pulmonary disease with cough)
Electrolytes	Diuretic use, history of renal or cardiac disease, possible dehydration by history or physical
Glucose	Diabetics, obese patients, undergoing vascular procedures, other reason for increased glucose (e.g., steroids)
Liver enzymes	History of liver disease or stigmata of liver disease
Urine β -hCG	If indicated by history or female of child-bearing age
Urinalysis	Pregnancy, diabetes, urologic surgery, symptomatic patients

Adapted from Feely MA, Collins CS, et al. Preoperative testing before noncardiac surgery: guidelines and recommendations. *Am Fam Physician*. 2013;87(6): 414–418.

TABLE 22-2 NATIONAL INSTITUTE FOR HEALTHCARE AND CARE EXCELLENCE (NICE) GUIDELINES FOR PERIOPERATIVE TESTING^{a,b}

Surgery Grade	ASA Class		
	1 (Normal Healthy Patient)	2 (Mild Systemic Disease)	3 or 4 (Severe Systemic Disease OR Severe Systemic Disease That is a Constant Threat to Life)
Minor (i.e., excising skin lesion, draining abscess, cataract surgery)	<ul style="list-style-type: none"> No routine perioperative testing 	<ul style="list-style-type: none"> No routine perioperative testing 	<ul style="list-style-type: none"> Creatinine (at risk of acute kidney injury (AKI)) ECG (if none in past 12 months)
Intermediate (i.e., inguinal hernia repair, arthroscopy, tonsillectomy)	<ul style="list-style-type: none"> No routine perioperative testing 	<ul style="list-style-type: none"> Creatinine (at risk of AKI) ECG (CV, DM, Renal disease) 	<ul style="list-style-type: none"> Creatinine CBC (renal or CV disease without test) Coagulation studies (chronic anticoagulation or chronic liver disease) ECG
Complex (i.e., total abdominal hysterectomy, prostatectomy, joint replacement, GI surgery, back surgery, lung surgery)	<ul style="list-style-type: none"> CBC Creatinine (at risk of AKI) ECG (> 65 if none in past 12 months) 	<ul style="list-style-type: none"> CBC Serum creatinine ECG 	<ul style="list-style-type: none"> CBC Creatinine Coagulation studies (chronic anticoagulation or chronic liver disease) ECG

^aDo NOT routinely offer testing for sickle cell disease. Do not obtain a urinalysis in anyone or an A1c in those without diabetes.

^bBe sure to obtain a pregnancy test in *all women of childbearing potential*.

Adapted from National Institute for Healthcare and Care Excellence (NICE). Routine preoperative tests for elective surgery: NICE Guideline [NG45]. London, UK: NICE; 2016 Apr 5. Available at: <https://www.nice.org.uk/guidance/ng45>. Accessed 23 April 2019.

HELPFUL TIP:

Graduated compression stockings are marginally beneficial at best for DVT prevention and lead to increased skin breakdown, etc. For this reason, intermittent pneumatic compression with sequential compression devices (SCDs) is preferred (*Ann Surg.* 2010;251(3):393–396 and *Lancet.* 2009;373:1958–1965).

The patient undergoes his hip replacement, and his postoperative ECG is normal. Four hours after surgery, he develops mild respiratory distress, a fever, and cough. On chest x-ray, there is a right lower lobe infiltrate. There is no evidence of fluid overload.

Question 22.8.3 Which of the following is the most likely cause of this patient's fever and infiltrate?

- A) *Pneumococcus*
- B) Gram-negative organisms
- C) Atelectasis
- D) Chemical pneumonitis
- E) Aspiration pneumonia

Answer 22.8.3 The correct answer is "D." In the hours after surgery, a chemical *pneumonitis* would be the most likely cause of this patient's current findings. This requires aspirating gastric

contents with a pH of less than 2.5 and at least 25 mL of stomach contents. Aspiration pneumonitis develops over a matter of hours after aspiration. In contrast, pneumococcal and Gram-negative pneumonias generally develop **several days** after surgery (unless a subclinical pneumonia was present at the time of surgery). Aspiration *pneumonia* is caused by anaerobes and mixed flora and develops slowly over days to a week. Atelectasis warrants special mention. **Atelectasis does not cause fever.** Both atelectasis and fever occur frequently in the postoperative period, but their occurrence together is most likely due to chance. In the postsurgical patient with fever, look for another cause besides atelectasis.

Question 22.8.4 Of the following, which typically IS NOT a cause of postoperative fever in the first 48 hours?

- A) Malignant hyperthermia
- B) Surgical "trauma" (e.g., cutting through muscle)
- C) Wound infection
- D) Hyperthyroidism
- E) Drug fever

Answer 22.8.4 The correct answer is "C." Wound infections generally are not found in the first 48 hours after surgery, although any fever should prompt a physical exam, including inspection of the surgical site. All of the rest can be found either immediately after surgery (malignant hyperthermia, hyperthyroidism, drug fever, etc.) or soon thereafter (fever from surgical

trauma secondary to the release of cytokines). Table 22-3 summarizes the time course and causes of postoperative fever.

The patient's chest radiograph is consistent with aspiration (for our patient, who was presumably supine in the OR at the time of aspiration, the dependent lobes were probably the superior segments of the lower lobes and the posterior segments of the upper lobes. If he'd been upright, which is not the typical positioning for hip arthroplasty, we would expect him to aspirate exclusively into his lower lobes).

Question 22.8.5 Which of the following is NOT TRUE with regard to chemical pneumonitis?

- A) It can progress to ARDS
- B) Patients with chemical pneumonitis can present with fever, dyspnea, bronchospasm, and hypoxia
- C) It should be treated immediately with antibiotics that cover for anaerobes
- D) It tends to resolve within 2 to 3 days (unless it progresses—see option A!)

Answer 22.8.5 The correct answer is “C.” Chemical *pneumonitis* is a process that is unrelated to infection. Therefore, chemical pneumonitis does not need to be treated with antibiotics at all (although as a practical matter they are often given anyway). The rest of the options are true. Supportive care is the best initial therapy for those poor acid-burned lungs. Chemical pneumonitis can, however, progress to pneumonia via secondary bacterial infection—new fever or worsening symptoms should prompt re-evaluation and re-imaging, and possible ICU transfer.

TABLE 22-3 CAUSES OF POSTOPERATIVE FEVER

Immediate (within first 48 hours following surgery):

- Drug (including malignant hyperthermia) or blood product reactions
- Tissue trauma either intraoperative or preoperative
- Chemical pneumonitis
- Preexisting subclinical infection (consider any infectious cause)
- Thrombophlebitis, DVT, MI, gout, pancreatitis, alcohol withdrawal, hyperthyroidism (these noninfectious causes typically result in fevers <39°C)

Acute (48 hours to 1 week after surgery):

- Pneumonia (aspiration, hospital or ventilator associated, or other)
- Abscess or surgical site infection (typically after 1 week, but Group A *Strep* and *Clostridium* infections may manifest within 1–3 days)
- UTI or GI infections including *C. difficile*
- Also: Pancreatitis, alcohol withdrawal, PE, MI, thrombophlebitis, gout

Subacute (1–4 weeks after surgery):

- IV and central catheter site infections
- Antibiotic associated diarrhea, including *C. difficile* infection
- Drug fever: β -lactams, sulfa, heparin, etc.
- DVT, PE, fat emboli from long bones, acute chest syndrome (SSA)

HELPFUL TIP:

The term “aspiration pneumonia” is used differently in different parts of the literature. This leads to some confusion. Some use the term to include all pneumonias caused by aspiration. Many of the cases included in this definition are caused by many of the same organisms that cause community-acquired pneumonia, including *pneumococcus* and *Haemophilus influenzae*. These patients tend to have a fever and infiltrate, etc., which develop within 2 days of the aspiration. For these patients, the appropriate antibiotics should include agents to cover hospital-acquired organisms, especially Gram-negative organisms, including *Pseudomonas*.

Other groups may define aspiration pneumonia as anaerobic infections that result from aspiration. Predisposing factors include intoxication, poor dentition, stroke with swallowing difficulties, weak cough, etc. These patients have a more indolent course, with onset of symptoms over days to weeks. Generally, these patients have purulent sputum, with lower lobe involvement most common. The upper lobes may be involved if the patient aspirates while recumbent. These patients may have a polymicrobial infection including *Peptostreptococcus*, *Fusobacterium*, *Bacteroides*, and *Prevotella*. These patients should be treated with antibiotics such as clindamycin, ampicillin/sulbactam (Unasyn), or amoxicillin/clavulanate (Augmentin); avoid metronidazole as a single agent due to high failure rate.

So, when you read the literature about aspiration pneumonia, be sure you know which definition the authors are using, because the description of the disease and the treatments vary.

HELPFUL TIP:

Drugs that raise the gastric pH (H_2 -blockers, proton pump inhibitors), commonly used in critically ill patients, can increase the risk of postoperative pneumonia (and *Clostridium difficile*). They don't change mortality but do reduce the risk of GI bleed (*N Engl J Med*. 2018;379:2199–2208). Just make sure to stop them upon discharge.

You treat the patient with fluids and tracheal suction. However, he remains febrile and tachycardic at about 128 bpm; ECG shows a sinus tachycardia. There is no evidence of dehydration at this point and he seems euvoletic, including by IVC ultrasound.

Question 22.8.6 Which of the following would be an appropriate first step in the treatment of tachycardia in this postsurgical patient?

- A) Oral or rectal aspirin
- B) Oral or rectal acetaminophen
- C) IV β -blockers
- D) IV fluids

Answer 22.8.6 The correct answer is “B.” The initial treatment of this patient is acetaminophen. Reducing the fever and metabolic stress should result in a reduction of the heart rate. “A” is not the best choice since this patient is postsurgical. Giving aspirin, an antiplatelet agent, may result in increased postoperative bleeding. “C,” IV β -blockers, might be appropriate if the patient were having ischemic symptoms and needed an immediate reduction in pulse. Beta blockers would not impact the underlying cause of his tachycardia—sinus tachycardia is usually not a problem in the heart. “D,” IV fluid—okay, debatable, but take our word for it that he was euvoletic. IV fluids are appropriate in postoperative tachycardia if the patient is dehydrated.

The patient’s pulmonary status has improved. The surgeon notices that the patient has hyperkalemia and thrombocytopenia. The patient is on a number of meds postoperatively. She is wondering if one of these drugs is to blame.

Question 22.8.7 You let her know that the most likely cause is:

- A) β -Blockers
- B) Albuterol
- C) Aspirin
- D) Morphine
- E) Heparin

Answer 22.8.7 The correct answer is “E.” Heparin can cause both thrombocytopenia and hyperkalemia. Hyperkalemia is caused by heparin’s action against adrenal cells that produce aldosterone—this is typically only clinically important if the patient has renal failure, or is on an ACE-I, ARB, or spironolactone. Thrombocytopenia secondary to heparin use comes in two flavors. The more common, mild form (sometimes called heparin-induced thrombocytopenia (HIT) type 1) is a non-immune-mediated thrombocytopenia that occurs in up to 20% of individuals who receive heparin. This mild thrombocytopenia occurs within the first 4 days of heparin administration, typically has a platelet nadir of greater than 100,000/ μ L and no significant clinical consequences. Continue the heparin for these patients.

The more rare and serious form of heparin-induced thrombocytopenia is immune-mediated (aka HIT type 2), caused by the development of IgG antibodies to the heparin/platelet factor 4 complex. This typically occurs 5 to 10 days after the start of heparin therapy and is associated with a high risk of venous or arterial thrombosis. Stop the heparin if you suspect HIT type 2 (including heparin flushes and low-molecular-weight heparin) and anticoagulate with a nonheparin agent.

“A,” β -blockers, may result in hyperkalemia at high doses (via a β 1-receptor effect inhibiting renin release) but do not cause thrombocytopenia, and remember, we didn’t start these on the day of surgery! “B,” albuterol, can cause *hypokalemia* (as can other catecholamines) by driving potassium into the intracellular space. “D” is incorrect because morphine is not associated with hyperkalemia or thrombocytopenia.

HELPFUL TIP:

Heparin can also cause a postoperative fever, as can β -lactams, sulfa drugs, H2 blockers, phenytoin, procainamide, and others.

You leisurely sip your coffee as you review the labs and notice that your patient’s platelets have dropped from 250,000/ μ L to 100,000/ μ L and is now down to 30,000/ μ L. Your patient has been waiting around in the hospital for placement in a rehabilitation facility, and it is already post-op day 6. You are concerned for the immune-mediated form of HIT, so you go through the 4Ts to assess his risk: Degree of Thrombocytopenia, Timing of the platelet count dropping, Thrombosis, other causes of thrombocytopenia (see MDCalc.com for a calculator).

Question 22.8.8 Which of the following would increase the pretest probability that our patient will test positive for antibodies to the PF4-heparin complex (HIT antibodies)?

- A) A fall of greater than 50 percent in his platelet count to a nadir greater than 20,000 platelets/ μ L
- B) Occurrence of this drop between days 5 and 10 since the start of his heparin dosing
- C) New venous thrombosis, arterial thrombosis, or skin necrosis following heparin use
- D) All of the above

Answer 22.8.8 The correct answer is “D,” all of the above.

All of these factors increase our patient’s likelihood of testing positive for HIT. Other factors that increase our patient’s pretest probability for HIT antibody positivity include the fact that he was a surgical rather than a medical patient, and that he received unfractionated heparin following his surgery rather than low-molecular-weight heparin (HIT can occur secondary to LMW heparin use, but it is less common).

You immediately stop the patient’s heparin, and the thrombocytopenia begins to resolve. As he continues to wait for a rehabilitation bed, you get the results of your antibody testing, which confirm the diagnosis of HIT. Fortunately, you have started him on an alternative anticoagulant (the risk of thrombosis in HIT can be up to 50 percent in patients who are not started on alternative therapy).

Question 22.8.9 Which of the following is TRUE about the use of heparin in patients with a history of heparin-induced thrombocytopenia (HIT)?

- A) A low-molecular-weight heparin (LMWH) should be used in patients with a history of HIT
- B) Warfarin may be started immediately at time of diagnosing HIT
- C) The use of bivalirudin and argatroban is contraindicated in the treatment of HIT

- D) A direct oral anticoagulant (DOAC) such as apixaban or rivaroxaban may be used in patients diagnosed with HIT
- E) None of the above

Answer 22.8.9 The correct answer is “D.” The DOACs are increasingly used to reduce the risk of thrombosis in HIT. “A” is incorrect. LMWH should be avoided in patients with strongly suspected (or confirmed) HIT, as should heparin flushes and heparin-coated catheters. “B” is incorrect—although warfarin may eventually be used in these patients, it should not be used immediately following diagnosis. Remember that there is a transient hypercoagulability at the onset of warfarin use, and combining this effect with florid HIT can have bad outcomes (like tissue necrosis). “C” is incorrect. In fact, these medications are often first-line treatment for patients with HIT who need continued parenteral anticoagulation.

► **Objectives: Did you learn to ...**

- Perform a preoperative medical evaluation?
- Generate a differential diagnosis for postoperative fever?
- Diagnose and treat aspiration pneumonitis?
- Recognize some complications of heparin use?
- Employ appropriate DVT prophylaxis measures?
- Manage a patient with heparin-induced thrombocytopenia?

QUICK QUIZ: GENERAL ANESTHESIA FOR SURGERY

Regarding anesthesia evaluation both preoperatively and intraoperatively, which one of the following is FALSE?

- A) Minimum potassium before proceeding with elective coronary artery bypass graft (CABG) surgery should be 3.5 mEq/L
- B) Patients with obstructive sleep apnea (OSA) have higher rates of pre-, intra-, and postoperative complications than patients without OSA
- C) American Society of Anesthesiologists (ASA) Class IV designation includes patients who have well-controlled major systemic disease
- D) Risks of anesthesia include allergic drug reactions, failure to intubate and provide adequate oxygenation and ventilation, nerve damage, and malignant hyperthermia

The correct answer is “C.” ASA Class IV includes patients who have a systemic disease that is life threatening and NOT well controlled. All the other options are true. “B” is a correct statement. Patients with OSA are more difficult to intubate and are more likely to have pulmonary complications before and during surgery. OSA is also strongly associated with hypertension, pulmonary hypertension, and heart failure. “D” is also a correct statement. Anesthesia risks include allergic drug reactions, failure to intubate and provide adequate oxygenation and ventilation, nerve damage (from unrelieved pressure on the nerve), and malignant hyperthermia, among others. Mortality rate from anesthesia is surmised to be about 1 to 2 per 10,000

patients. The American Society of Anesthesiologists Physical Classification System is outlined in Table 22-4. The higher your class, the higher your risk of perioperative mortality.

QUICK QUIZ: THE RHYTHM IS GONNA GET YOU

A 60-year-old male patient of yours is planning to undergo coronary artery bypass grafting (CABG). After you perform a physical examination and laboratory tests, you discuss his case with the surgeon. He asks if you will help to manage him postoperatively, and you agree. He quizzes you on the risk of arrhythmia during the postoperative period.

You correctly reply:

- A) “His risk for atrial fibrillation is less than it would be if he were undergoing valve replacement simultaneously with CABG”
- B) “Of the potential arrhythmias, he is most likely to experience bradycardia”
- C) “Nonsustained ventricular tachycardia is highly unlikely in this setting”
- D) “Keep his potassium low, around 3 mEq/L, and he will be less likely to experience tachyarrhythmias”

The correct answer is “A.” With CABG, the risk of postoperative atrial flutter or fibrillation is around 30%. That risk almost doubles when valve replacement is accomplished simultaneously with CABG. “B” is incorrect because brady-arrhythmias occur much less frequently than tachyarrhythmias. “C” is incorrect. Nonsustained ventricular tachycardia is extremely common in the immediate postoperative period. “D” is also incorrect. Plasma potassium levels <3.5 mEq/L are strongly associated with an increased risk of tachyarrhythmias.

TABLE 22-4 ASA PHYSICAL STATUS CLASSIFICATION

Class	Description
Class I	Healthy person
Class II	Patient with mild systemic disease
Class III	Patient with severe systemic disease that is controlled
Class IV	Patient with severe systemic disease that is uncontrolled and a threat to life
Class V	Patient who is unlikely to survive for 24 hours, with or without surgery

► **CASE 22.9**

A 15-year-old male presents to your office with a 3-day history of diarrhea and right lower quadrant abdominal pain. He has tenderness in the right lower quadrant with guarding

and rebound. He remains afebrile and has been hungry, scarfing down five bacon-wrapped waffles for breakfast (but less than his usual 6 ...). The patient has no other significant history. You consider that this patient might have appendicitis, so you draw some labs. The white blood cell count is normal ($7,500/\text{mm}^3$), as is the urinalysis.

Question 22.9.1 Which of the following is true about the diagnosis of appendicitis?

- A) A normal white count effectively rules out the diagnosis of appendicitis
- B) The majority of patients with appendicitis present with fever
- C) The absence of anorexia effectively rules out appendicitis
- D) A fecalith is found on radiograph in the majority of patients with appendicitis
- E) None of the above

Answer 22.9.1 The correct answer is “E.” None of the above is true. Taking these in order, 10% of patients with appendicitis have a normal white count, a minority of patients with appendicitis present with fever (15% in one study), only 75% of patients with appendicitis complain of anorexia, and a radiographic fecalith is found in only a minority of patients.

Question 22.9.2 Which of the following is *specific* for appendicitis?

- A) Obturator sign
- B) Psoas sign
- C) Rovsing sign
- D) Tenderness at McBurney’s point
- E) None of the above is specific for appendicitis

Answer 22.9.2 The correct answer is “E.” None of the above is specific for appendicitis. An obturator sign (“A”) is present if there is pain on internal and external rotation of the hip. The obturator sign can be seen with any pelvic abscess that is in contact with the hip area, but is more commonly seen with a retrocecal abscess. The psoas sign (“B”) is pain on use of the psoas muscle (e.g., lifting the leg at the hip), and it can be seen with any inflammatory process that is in contact with the psoas muscle, including a psoas abscess. Rovsing sign (“C”) is when pain increases in an area of peritonitis when the abdomen is palpated elsewhere. For example, in a patient with appendicitis, right lower quadrant pain will be increased with palpation of the *left* lower quadrant. This is indicative of peritonitis in the area that has increased pain, but it is not specific for appendicitis. Tenderness at McBurney’s point (“D”) can be seen in a number of processes including appendicitis, ileitis, any process in the cecum, and urinary tract infection.

Question 22.9.3 Which of the following is true about the treatment of pain in the acute abdomen?

- A) Early treatment with morphine will obscure the proper diagnosis
- B) Treatment with pain medication invalidates informed consent

- C) Codeine can be used in the treatment of pediatric abdominal pain
- D) Ketorolac is preferred for patients who may undergo a surgical procedure
- E) None of the above is true

Answer 22.9.3 The correct answer is “E.” None of the above is correct. Early treatment of pain in the acute abdomen does not affect diagnostic accuracy in children or adults (“A”). “C” is not true. Although codeine was used commonly in the treatment of pediatric pain, it is now contraindicated in children due to highly variable metabolism that can result in dangerous levels of opioids in the system. Ketorolac (“D”) is not a good choice because of its antiplatelet effects, which increase the risk of bleeding intraoperatively, should your patient go to surgery. Pain medication does not necessarily invalidate informed consent (“B”) if your patient remains oriented—but your patient is 15, so he can’t consent for himself anyway.

Although you have thought a lot about the top item on your differential, you have not actually done anything more to evaluate this 15-year-old with abdominal pain.

Question 22.9.4 The test most likely to help you arrive at a diagnosis in this patient is:

- A) Erythrocyte sedimentation rate (ESR)
- B) C-reactive protein (CRP)
- C) Abdominal ultrasound
- D) Abdominal CT scan
- E) Colonoscopy

Answer 22.9.4 The correct answer is “D.” The test most likely to arrive at a diagnosis in this patient is a CT scan of the abdomen looking at the appendix. “A” and “B” are incorrect. Both the CRP and the ESR are nonspecific markers of inflammation and are not helpful in the diagnosis of appendicitis. “C,” an ultrasound, can be used and is *often recommended as the first test in pediatric patients* to avoid the ionizing radiation associated with CT. The specificity for ultrasound is high (95–99%). However, it is not as sensitive as a CT scan (as varied as 60–85% depending on the study) and is very operator dependent. *If you can see the appendix*, sensitivity is 98% with a specificity of 92%. Although “D” is the textbook answer, it would be reasonable to start with an ultrasound, and if equivocal, one can then move on to CT or surgical consultation for serial abdominal examinations depending on institutional preference. Finally, ultrasound can also be useful in the female patient in whom other diagnoses need to be ruled out, such as ovarian pathology. “E,” colonoscopy, is not particularly useful in the diagnosis of appendicitis, but could be used for other purposes such as looking for IBD once appendicitis is ruled out by CT.

HELPFUL TIP:

Not all patients with potential appendicitis need a CT scan. Those with obvious appendicitis may need to go

directly to the OR. CT is best used in patients in whom the clinical diagnosis is equivocal. There are long-term risks from radiation exposure, so CT should not be done without a good indication. Be aware of the standard practice in your location as many surgeons now insist upon a CT scan prior to going to the OR.

Question 22.9.5 If this patient's CT scan is positive for appendicitis, the likelihood that he will have a normal appendix removed at appendectomy is:

- A) 0%
- B) 10%
- C) 20%
- D) 30%
- E) 50%

Answer 22.9.5 The correct answer is "B." With the advent of CT scanning, the false-positive rate (of taking normal patients to the OR) has improved, but perhaps not as much as you would think. The negative laparotomy rate is still about 10% in boys and men and up to 20% in women of reproductive age, where other pathology may mimic appendicitis. Overall, those who did not undergo CT were more than three times more likely to have a negative appendectomy. The negative laparotomy rate has gone down in men and the young but has increased in the elderly and in women. There is evidence that CT scanning changes the treatment plan in more than half cases of suspected appendicitis. The sensitivity of CT for appendicitis is 91% to 98%, but the specificity is as low as 75% depending on the radiologist and the population tested (range 75–93%).

HELPFUL TIP:

There is growing evidence that antibiotic therapy alone may adequately treat **uncomplicated** appendicitis. In a recent large trial, approximately 60% of patients who were randomized to the antibiotics-only arm for treating appendicitis did not have recurrent appendicitis, or require appendectomy, within 5 years of their initial event (which means that 40% still ended up with surgery, most within the first year) (*JAMA*. 2018;320(12):1259–1265 and *JAMA Surg*. 2019;154(2):149). The antibiotic regimen used was: IV ertapenem for 3 days followed by PO levofloxacin and metronidazole for an additional 7 days.

Question 22.9.6 In general, which of the following is TRUE about appendicitis?

- A) Pain is in the right upper quadrant in the majority of pregnant women with appendicitis
- B) Atypical presentations are more common in the elderly than in nonelderly adults
- C) Patients with a retrocecal appendix generally present with well-localized tenderness and signs of peritoneal irritation
- D) An appendicitis episode is great way to postpone your board examination—get one soon!

Answer 22.9.6 The correct answer is "B." Symptoms tend to be atypical in the elderly. In fact, elderly patients may have appendicitis with a normal white count, poorly localized pain, and absence of fever. So, maintain a high index of suspicion. The same is true of children, who may have abdominal pain and vomiting, accompanied by refusal to walk. Neonates also have a hard time describing their symptoms—they are the group most likely to present with perforation. "A" is incorrect. Despite classic teaching, patients who are pregnant tend to have "typical" symptoms with right lower quadrant pain. This is especially true in the first half of pregnancy. Certainly the appendix can be displaced cephalad, but the majority will still have right lower quadrant pain. "C" is incorrect. Patients with retrocecal appendicitis will commonly complain of a dull ache on the right side but peritoneal irritation may be minimal or absent.

HELPFUL TIP:

Some patients have recurrent appendicitis. These patients will present with multiple times with "typical" appendicitis that resolves during observation. When the appendix is finally removed, it is frequently scarred down.

HELPFUL HINT:

Appendicitis can occur at *any* age. Individual lifetime risk is 7% to 14% and it is more common in males than females until the age of 30, when the rates equalize. The younger the patient (especially <5 years), the more likely they are to present with a perforated appendix.

► **Objectives: Did you learn to ...**

- Describe the findings in acute appendicitis?
- Diagnose appendicitis and determine how diagnostic tests are best used in the patient presenting with signs and symptoms of appendicitis?
- Manage a patient with appendicitis?

► **CASE 22.10**

A 72-year-old male presents to your office for a 3-month history of episodic abdominal pain. It is primarily located in the epigastric region and radiates to the back. It occurs both during the night and day and lasts about 1 hour. His past medical history is significant for a 5-year history of diabetes. He takes glyburide, atorvastatin, and aspirin (he clearly isn't your patient ... he is not on metformin, the drug of choice in type 2 diabetes). He has no previous surgical history. You order an ultrasound. The ultrasound reveals a normal aorta, but the technician notes several stones in the gallbladder.

You are concerned that this patient may have symptomatic cholelithiasis.

Question 22.10.1 Which of the following is true of his risk for gallstones?

- A) This patient has an increased risk of cholesterol stones because he is diabetic
- B) This patient's risk of gallstones would have peaked in his fourth decade of life
- C) This patient's risk of gallstones is increased because of his atorvastatin use
- D) This patient's risk of gallstones is increased because he is male

Answer 22.10.1 The correct answer is "A." Patients with diabetes have an increased risk of gallstones when compared with the general population. Other associations include female gender (not male, so "D" is wrong), family history, obesity, and certain medical illnesses including hyperlipidemia, cystic fibrosis, short bowel syndrome, parenteral nutrition, hemolytic anemia (e.g., sickle cell), and history of terminal ileum resection. "B" is incorrect because the risk of gallstones increases linearly with age. "C" is incorrect. Atorvastatin and other statins are not associated with an increased risk of gallstone formation, but clofibrate and other fibrates are. It is good to remember that estrogen therapy also has an association with gallstones and that ceftriaxone can cause biliary sludge as well as cholestasis.

Question 22.10.2 Which of the following statements is FALSE regarding the evaluation of the gallbladder?

- A) Ultrasound will find pericholic fluid in only 50% of patients with cholecystitis
- B) An HIDA scan can be abnormal/positive (e.g., no tracer in the duodenum) in patients with common bile duct obstruction and/or cholecystitis
- C) Endoscopic retrograde cholangiopancreatography (ERCP) has an attendant risk of pancreatitis
- D) The absence of disease on ultrasound effectively rules out gallbladder disease

Answer 22.10.2 The correct answer is "D." While ultrasound is highly sensitive for stones (95% or greater), it might miss some. "A" is a correct statement as are "B" and "C." A HIDA (hepatic iminodiacetic acid) scan can be abnormal (e.g., no tracer in the duodenum) not only in cholecystitis but also in other conditions in which the common bile duct (CBD) is blocked including a CBD stone or tumor. Additionally, false positives may occur if there is liver disease (which may prevent the uptake of HIDA into the liver and subsequent secretion into the CBD), patients on total parenteral nutrition (where the gall bladder has no stimulus to contract and thus gets distended with mucus, preventing tracer entry), spasm of the sphincter of Oddi or biliary sphincterotomy. MRCP (magnetic resonance cholangiopancreatography) can be used to identify stones in the common duct prior to surgery.

HELPFUL TIP:

CT is not a very sensitive study for gallstones. Ultrasound is the study of choice (sensitivity is 25% for CT vs. 96% for ultrasound). However, a CT is useful in detecting complications that arise secondary to acute cholecystitis (e.g., pericholic abscess, perforation, emphysematous gallbladder, gangrene and gallstone ileus).

Question 22.10.3 Regarding different types of gallstones, all of the following are true EXCEPT:

- A) Cholesterol stones are associated with obesity and hyperlipidemia
- B) Black pigment stones are associated with cirrhosis
- C) Brown pigment stones are associated with liver fluke infection
- D) Blue pigment stones are associated with being an avid fan of the St. Louis Blues hockey team and/or the Blue Man Group

Answer 22.10.3 The correct answer is "D." While it may seem like beer-swilling hockey fans might be more prone to developing gallstones, there are no studies to support this. Besides, blue pigment stones do not exist. All the other options are true. Stone types include cholesterol, black pigment, and brown pigment stones. Cholesterol stones ("A") are associated with advancing age (due to decreased synthesis of bile salts from cholesterol), hyperlipidemia, diabetes, obesity, and living in the Western Hemisphere (thank you, fast food industry and corn subsidies!). Black pigment stones ("B") contain calcium bilirubinate, calcium carbonate, and calcium phosphonate. They are associated with hemolytic diseases, Crohn disease, ileal resection, cirrhosis, and total parental nutrition (TPN). Brown stones ("C") are observed more often in East Asia and are associated with liver fluke infection.

You refer the patient to your favorite surgical consultant, Dr. Hugh Jeego (or his partner, I. M. Agodd), for evaluation of cholecystectomy. However, before his surgery appointment, you see him again in the ED. He presents with fever, nausea, vomiting, and anorexia for the last 48 hours. His examination is significant for temperature 38.9°C, mild tachycardia and tachypnea, and a normal blood pressure. He is tender in the right upper quadrant and has a positive Murphy sign. He has no jaundice or palpable right upper quadrant mass. Laboratory values include WBC 14,800/mm³, ALT 58 IU/L, AST 64 IU/L, alkaline phosphatase 45 IU/L, total bilirubin 1.5 mg/dL (mildly elevated liver enzymes and bilirubin), amylase 95 IU/L, and lipase 52 IU/L (normal amylase and lipase).

Question 22.10.4 At this point in time, your working diagnosis is:

- A) Acalculous cholecystitis
- B) Acute calculous cholecystitis
- C) Pancreatitis
- D) Ascending cholangitis
- E) Myocardial infarction

Answer 22.10.4 The correct answer is “B.” The clinical presentation, examination, and laboratory data point toward acute cholecystitis. “A” is incorrect because acalculous cholecystitis occurs more often in critically ill hospitalized patients, and you already know that this patient has stones, so his cholecystitis is by definition *calculous* in nature. There must be no gallstones detected on ultrasound to diagnose acalculous cholecystitis (hence the name). “C” is incorrect. His pancreatic enzymes are normal; and although one can certainly have pancreatitis with a normal amylase and lipase, you have a better explanation with cholecystitis. “D” is incorrect. Patients with ascending cholangitis usually have markedly elevated transaminases and an obstructive laboratory pattern (e.g., elevated bilirubin, alkaline phosphatase, and pancreatic enzymes). “E” is very unlikely in this patient who has findings more consistent with intra-abdominal pathology, but you should always consider cardiac (and other thoracic organ) etiologies in older patients presenting with abdominal complaints.

Question 22.10.5 Regarding the differential diagnosis of complicated cholelithiasis, which of the following is true?

- A) Empyema of the gallbladder is primarily a disease of the elderly and carries a high mortality rate due to associated Gram-positive sepsis
- B) Emphysematous cholecystitis occurs primarily in elderly diabetics as a late complication of miliary tuberculosis (TB)
- C) The most common consequence of gallbladder perforation is generalized peritonitis
- D) Charcot’s triad (jaundice, fever, and right upper quadrant pain) is associated with cholangitis

Answer 22.10.5 The correct answer is “D.” The classic Charcot’s triad (jaundice, fever, and right upper quadrant pain) is associated with cholangitis, but it is **not** seen in the majority of cases, probably due to early detection of cholangitis. Nonetheless, it can be helpful if present. “A” is incorrect because patients generally develop a Gram-negative sepsis. “B” is incorrect because emphysematous cholecystitis is not a complication of miliary TB. Emphysematous cholecystitis occurs primarily in elderly male diabetics; gas-producing bacteria, most commonly *C. perfringens*, result in gas in the gallbladder and can cause a severe sepsis. Miliary TB rarely affects the gallbladder. “C” is incorrect. The most common consequence of gallbladder perforation is a localized, walled-off abscess. Additionally, a cholecystoenteric fistula may form between the gallbladder and the duodenum or jejunum. Stones can then pass into the bowel. Stones larger than 2 cm in diameter are likely to lodge in the terminal ileum giving rise to symptoms of small bowel obstruction—a condition termed “gallstone ileus.”

Generally, patients with symptomatic cholecystitis have a prior history of biliary colic. Pain with acute cholecystitis is similar to that of biliary colic except that it is more often severe, longer lasting (>24 hours), and associated with anorexia, nausea, vomiting, fever, elevated white count (12,000–15,000/mm³), right upper quadrant guarding, and a positive Murphy sign (arresting inspiration when palpating the gallbladder). **However, Murphy sign is only about 65% sensitive (even less in the**

elderly). An ultrasonographic Murphy’s sign has an improved sensitivity and specificity of about 90%. Of note, about 30% of patients will have neither a fever nor an elevated white cell count. An elevated bilirubin or alkaline phosphatase level is not typically seen in acute cholecystitis and, if present, should prompt an evaluation for biliary obstruction. However, mild increases in aminotransferases, amylase, and hyperbilirubinemia may occasionally be found in acute cholecystitis due to the passage of sludge or a stone through the CBD without causing an actual obstruction.

Biliary pancreatitis can occur when there is blockage of the ampulla of Vater, and cholangitis occurs when there is ductal stone obstruction and biliary infection. If you think there is obstruction, the patient may need an ERCP to remove the obstruction. Consider an MRCP to document obstruction before referral for ERCP.

Given our patient’s physical findings, leukocytosis, and mild elevation of transaminases, you conclude that this patient has acute calculous cholecystitis.

Question 22.10.6 Which of the following should NOT be considered in the management of this disease?

- A) Initial treatment includes hospitalization with IV fluid resuscitation
- B) Consider an antibiotic regimen to include a third- or fourth-generation cephalosporin plus metronidazole or ertapenem or ticarcillin/clavulanate
- C) Choose a narrow-spectrum antibiotic to treat *Enterococcus* (e.g., vancomycin)
- D) If early cholecystectomy is not chosen as treatment, it should be performed late (at least 6 weeks after diagnosis)

Answer 22.10.6 The correct answer (and what you don’t want to do) is “C.” This answer is incorrect for two reasons. First, just over 50% of episodes of cholecystitis are sterile; as a matter of course, they are treated with antibiotics because of our inability to initially determine which are infected. Second, while you may encounter *Enterococcus*, it is rarely found in isolation, making “C” incorrect. The initial treatment of cholecystitis includes hospitalization, broad-spectrum IV antibiotics, and IV fluid resuscitation (“A”). In addition to the antibiotics mentioned in “B,” other agents like imipenem, meropenem, or piperacillin/tazobactam may also be used with metronidazole. Definitive therapy for cholecystitis is cholecystectomy. Option “D” is correct. It is generally accepted that early cholecystectomy is associated with better outcomes and lower costs and should be completed during the same hospitalization for acute cholecystitis. If this is not possible, cholecystectomy should be delayed for 6 weeks to allow inflammation to subside.

► **Objectives: Did you learn to ...**

- Identify risk factors for gallstones?
- Recognize complications of gallbladder disease?
- Manage a patient with symptomatic gallstones and cholecystitis?

CASE 22.11

A 68-year-old male who was the restrained front passenger of a vehicle traveling in excess of 60 mph is brought to the ED via ambulance. The driver of the vehicle was found dead at the scene. Ambulance personnel report it took 5 to 10 minutes to extricate the patient. On arrival, he is mumbling incoherently. He is initially able to give his name, but he is slurring his words. He denies any medical problems, medications, or allergies. Vitals signs include temperature 35.5°C, pulse 148 bpm, respirations 35 bpm, blood pressure 65/30 mm Hg, and oxygen saturation 81% on 100% FiO₂ by facemask. On examination, he is in severe respiratory distress. Lung sounds are absent on the right and diminished on the left. Heart sounds are muffled. You determine that this patient needs immediate treatment of a tension pneumothorax.

Question 22.11.1 Which of the following is most appropriate at this time?

- A) Perform needle decompression on the left
- B) Perform needle decompression on the right
- C) Place a chest tube on the left
- D) Place a chest tube on the right
- E) Perform a chest radiograph and act on the basis of the results

Answer 22.11.1 The correct answer is “B.” The combination of hypotension, hypoxia, and absent breath sounds suggests a tension pneumothorax. **Immediate decompression of the affected hemithorax should be performed by placing a large-bore (14- or 16-gauge) needle through the chest wall to relieve intrathoracic pressure.** Most of us were taught to aim our needles at the second intercostal space at the mid-clavicular line. The 2018 Advanced Trauma Life Support (ATLS) recommendations have changed and the preferred placement of the thoracostomy needle is now in the fourth or fifth intercostal space at the mid-axillary line. Either site is acceptable if the pleural space can be reached (it may be more difficult in the mid-axillary line, given increased subcutaneous tissue). Of particular note is “E.” If tension pneumothorax is suspected, you **should never** wait for confirmation of the diagnosis by a chest radiograph. It is a true emergency that requires treatment on the basis of clinical examination.

HELPFUL (AND UNFORTUNATE) TIP:

Given the epidemic of obesity in the United States, a simple needle may not be long enough to reach the pleura (yes, really, it has been studied). Have a backup option, such as a longer, pigtail catheter.

His vital signs and oxygen saturation improve with needle decompression. You place a chest tube and give boluses of normal saline through two peripheral IVs. Then the patient is placed in an external fixation device for his femur fracture. Operating room fixation is deferred secondary to unstable medical status. He is ultimately intubated for increased work of breathing. He is admitted to the intensive care unit

(ICU) on a ventilator with a cervical collar following negative FAST examination (focused assessment with sonography for trauma—a sonographic evaluation to rule out fluid in perihepatic, perisplenic, pelvic, and pericardial spaces).

Repeat chest x-ray in the ICU shows the endotracheal (ET) tube and chest tube in appropriate positions. Several rib fractures are noted. There are “fluffy infiltrates” in the left chest that were not present on initial trauma chest series.

Question 22.11.2 Which of the following is true of pulmonary contusions?

- A) They most commonly occur with penetrating rather than blunt trauma
- B) Treatment includes aggressive IV steroid and fluid administration
- C) The condition can resolve over the course of 1 to 2 weeks
- D) Treatment includes appropriate antibiotics

Answer 22.11.2 The correct answer is “C.” Pulmonary contusions develop over the first 24 to 48 hours following a blunt chest trauma and resolve over the course of weeks if not complicated by pneumonia or ARDS. “A” is incorrect. Pulmonary contusion is the most common injury associated with blunt chest trauma. Seventy percent of these injuries result from motor vehicle collisions. Pulmonary contusions are usually, but not always, associated with fractured ribs or flail chest. Chest x-ray changes are usually evident within 1 hour post-trauma but may not appear for up to 24 hours as hemorrhage and edema develop. Pulmonary contusions result in a ventilation-perfusion mismatch, hypoxia, and an increased A-a gradient. If a patient is able to maintain oxygenation and ventilation, intubation is not always required. “B” and “D” are incorrect. Treatment consists of respiratory support as needed, pain control, and pulmonary hygiene (suction and incentive spirometry).

You elect to proceed with pulmonary artery catheter (Swan-Ganz catheter) placement due to the severity of this patient’s condition. Overnight, he begins to decompensate. The nurse pages you with his vital signs and Swan-Ganz readings: temperature 37°C, pulse 100 bpm, respirations 20 bpm (ventilator set at 14 bpm), blood pressure 82/30 mm Hg, PCWP 24 mm Hg (normal 5–15), cardiac index 2 L/min/m² (normal 2.5–3.5), systemic vascular resistance 2,000 dyne-sec/cm² (normal 1,000–1,500), and decreased mixed venous oxygen saturation (about 60%).

Question 22.11.3 What is the cause of shock at this time?

- A) Hypovolemic shock
- B) Neurogenic shock
- C) Cardiogenic shock
- D) Septic shock

Answer 22.11.3 The correct answer is “C.” Based on these numbers and the choices above, this patient appears to be in cardiogenic shock (elevated pulmonary capillary wedge pressure, decreased cardiac output). **Cardiogenic shock** may be

caused by myocardial infarction, valve failure, or malignant dysrhythmias. Similar physiology may occur with another class of shock, **obstructive shock**, which affects the heart function but etiology is extracardiac (pulmonary embolism, tamponade, or tension pneumothorax). Hypovolemic shock, answer “A,” is caused by hemorrhage or other fluid losses. Answer “B,” neurogenic shock, is a type of distributive shock, where classic features are hypotension and relative bradycardia. Answer “D,” septic shock, is also a type of distributive shock. Treatment is directed at the underlying disorder. See Table 22-5 for more on the categories of shock.

HELPFUL TIP ... OR NOTE OF CAUTION:

The routine use of Swan–Ganz catheters in seriously ill patients is no longer recommended and may worsen outcomes. Resist your reflexive urge to “float a Swan.” Bedside echocardiography is a noninvasive way to assess cardiac function and volume status.

A passenger from a second car involved in this accident is brought to the ED with burns to the abdomen and back.

Question 22.11.4 Which of the following is FALSE regarding burn wound management in general?

- A) The Modified Brooke formula for fluid resuscitation in burns calls for 2 mL/kg to be given for each percent of total body surface area (TBSA) burned ($2 \text{ mL/kg} \times \text{weight (kg)} \times \text{TBSA burned}$)
- B) Escharotomy should be performed on all partial-thickness burns
- C) Patients with chemical burns should be treated first with tap water irrigation
- D) A nonadherent gauze should be applied to most burns following gentle cleansing and application of a topical antimicrobial agent

Answer 22.11.4 The correct answer is “B.” Remember that any time you see “all,” it is probably the wrong answer because medicine is never that easy. Escharotomy is usually not necessary unless there is a *full-thickness* wound. However, escharotomy is often done early in chest and abdomen burns even if non-circumferential; these burns often compromise respiration. It *should be done* if it is circumferential and compromising vascular supply to a limb or the trunk (e.g., abdominal compartment syndrome). Regarding answer “A,” some clinicians prefer the modified Brooke formula to the more familiar Parkland formula ($4 \text{ mL/kg} \times \text{weight (kg)} \times \% \text{ TBSA burned}$, with the first half of the volume given in the first 8 hours, second half over the next 16 hours) because Parkland has frequently resulted in over-resuscitation. **Any resuscitation strategy should rely heavily on hourly reassessment of fluid status including urine output (0.5 mL/kg/hr for adults).** “C” is also correct with the addendum that any particulate matter should be brushed off prior to irrigation. Water may activate some substances such as sodium hydroxide. “D” is also a correct statement. **There is broad consensus that patients with extensive burns should be transferred to a specialty burn center.**

HELPFUL TIP:

Fluids are required for adults with $>15\%$ TBSA burns (second degree or higher) and $>10\%$ for children aged 10 years and younger. For **adults** the “Rule of 9’s” is used to determine TBSA affected. Body surface area is estimated as follows: 9% TBSA to each of the following body parts: the head, each arm, front of each leg, and back of each leg; 18% TBSA for the anterior trunk, 18% TBSA for the posterior trunk; the remaining 1% TBSA is accounted for by the genitalia. TBSA affected in children and adolescents should be based on age-specific charts. Both affected and unaffected BSA should be calculated to assure accurate estimation.

TABLE 22-5 SHOCK CATEGORIZED BY HEMODYNAMIC PARAMETERS

Type of Shock	Pulmonary Capillary Wedge Pressure (Preload)	Cardiac Output	Systemic Vascular Resistance (Afterload)	Central Venous Oxygen Saturation
Hypovolemic (Late)	Decreased	Normal, then Decreased	Increased	Normal, then Decreased
Cardiogenic	Increased	Decreased	Increased	Decreased
Distributive (sepsis, neurogenic)	Normal, then Decreased	Increased	Decreased	Normal
Obstructive (PE, tension pneumothorax)	Normal, then Decreased	Normal, then Decreased	Increased	Normal or Decreased

The cutoff for mixed venous oxygen saturation on PAC is 65%.

Adapted from “Hemodynamics in shock.” In: Gaieski DF and Mikkelsen ME. Definition, Classification, Etiology, and Pathophysiology of Shock in Adults. Uptodate.com. Accessed 2 May 2019.

Question 22.11.5 Which of the following is TRUE regarding fluid resuscitation?

- A) A peripheral line will deliver fluid more rapidly than a central line of an equivalent gauge
- B) Albumin is the fluid of choice in the treatment of burns and should be considered for all patients with significant fluid deficits
- C) D5W-½ NS (D5W-0.45%NS) is the preferred fluid for resuscitation in all nonburn patients
- D) All of the above are true

Answer 22.11.5 The correct answer is “A.” A peripheral line will deliver fluid more rapidly than a central line of an equivalent gauge, according to Poiseuille’s law (flow is directly proportional to tube radius and inversely proportional to tube length). The **shorter** the catheter, the more quickly fluid is delivered. The largest port on a traditional triple lumen catheter will give the same flow rates as a 20 gauge peripheral IV. Consider a larger diameter, shorter central line if placing a central line in a patient who may require rapid fluid resuscitation. **You can also consider an intraosseus line for rapid volume resuscitation, especially in children.** “B” is incorrect. Albumin is not helpful and may be harmful in the initial management of burns and trauma. “C” is also incorrect. Normal saline (0.9% NS), or Lactated Ringer’s are the fluids of choice for resuscitation. In the age-old battle of NS versus LR, the jury is still out. Remember, though, that LR cannot be given in the same IV as blood.

► Objectives: Did you learn to ...

- Identify and manage a patient with a tension pneumothorax?
- Describe various types of shock and how they are differentiated?
- Treat a patient in shock?
- Manage a patient with significant burns?

**QUICK QUIZ: INHALATION INJURY****Carbonized particles in the nasal cavity and/or posterior pharynx in a burn patient should suggest:**

- A) The need for excision of the perichondrium in the nose to prevent underlying cartilage injury from avascular necrosis
- B) Inhalational injury to the lungs
- C) Ingestion of a large amount of particulate matter
- D) The need to check carboxyhemoglobin levels
- E) B and D

The correct answer is “E.” Carbonaceous material or blistering in the nares or oropharynx should suggest the possibility of an inhalation injury. Consider intubating these patients early, especially if there will be prolonged transfer time to a burn center. A carboxyhemoglobin level and CXR should be obtained in all patients with moderate-to-severe burns from an appropriate source (not so much with scald burns). Monitor frequently and have a low threshold for intubation.

► CASE 22.12

A 48-year-old female arrives at the ED via ambulance after witnesses saw her vomiting large volumes of blood in a local convenience store before collapsing to the floor—obviously, not her best day. She is barely communicating and cannot provide any history. Ambulance personnel placed two large-bore IVs and started fluid boluses. Just as you start your initial evaluation, she has another episode of large volume hematemesis. You are concerned about her depressed mental status and the severity of her illness and decide to intubate her. After intubation, the chest wall rises symmetrically and the lungs sound clear. Her heart sounds are distant, and she is tachycardic (pulse 120 bpm). Her blood pressure is 80/40 mm Hg. Her oxygen saturation is 78%.

Question 22.12.1 The standard of care in detecting esophageal intubation is:

- A) Auscultation
- B) Radiograph
- C) End-tidal CO₂
- D) Oxygen saturation
- E) Direct laryngoscopy

Answer 22.12.1 The correct answer is “C.” The standard of care is the end-tidal CO₂. All of the others are notoriously unreliable. However, they all should be done. If you think you hear breath sounds but the oxygen saturation is not rising and end-tidal CO₂ is low, the ET tube is probably in the esophagus.

Question 22.12.2 The end-tidal CO₂ can be falsely negative (detecting no CO₂) in which of the following situations?

- A) Ingestion of carbonated soft drinks (“pop” as we call it in the Midwest)
- B) Intubation in the posterior pharynx above the cords
- C) Nasotracheal intubation
- D) During cardiac arrest

Answer 22.12.2 The correct answer is “D.” The end-tidal CO₂ requires that there is gas exchange in the lungs. If there is no gas exchange, the CO₂ will be low. This may be the case during cardiac arrest. “A” can actually cause a **false positive**. Carbon dioxide in the stomach will give a positive end-tidal CO₂ with an esophageal intubation. The same is true of “B.” If the patient is breathing spontaneously, the CO₂ will be elevated even when the ET tube is above the cords. “C,” nasotracheal intubation, should have no effect on end-tidal CO₂.

You order laboratory studies that include a CBC, basic metabolic profile, liver chemistries, amylase, lipase, and coagulation studies. In addition, you type and cross for six units of packed red blood cells. The nurses have already contacted the gastroenterologist on call, and she is on her way. You consider whether or not to perform nasogastric (NG) lavage.

Question 22.12.3 Which of the following is FALSE regarding NG lavage?

- A) NG lavage may be negative even in the presence of an upper GI bleed
- B) NG lavage should not be attempted in obtunded patients until they are intubated
- C) Iced fluid is best for lavage in patients with an upper GI bleed
- D) The placement of an NG tube is contraindicated in patients who may have variceal bleeding

Answer 22.12.3 The correct answer is “C.” Iced lavage fluid should NOT be used in patients with a GI bleed. The cooler temperature inhibits hemostasis and can increase bleeding. Both “A” and “B” are true statements, and “D” is controversial. False-negative NG aspirates occur with intermittent bleeding and bleeding beyond the ligament of Treitz. Lavage **should not** be done in patients who are obtunded or otherwise unable to protect their own airway unless they are intubated. It isn’t helpful in treatment/stopping bleeding anyway. Regarding answer “D,” varices are typically considered a contraindication to the use of an NG tube due to theoretical increased risk of bleeding. If the patient has obvious blood in the vomitus, **NG lavage does not contribute to the diagnosis or management except to maybe clear the stomach before endoscopy.**

**HELPFUL TIP:**

Other contraindications to gastric lavage include known ingestion of hydrocarbons and caustic agents, such as alkalis and acids.

One of the other ED workers recognizes her as a chronic alcoholic who has a history of liver disease. You now notice her marked jaundice, previously missed as you were so focused on your “ABCs.” Other pertinent findings include a 6-cm scalp laceration, which continues to actively bleed, moderate ascites, and lower extremity edema. After lavage with nearly 5 L of isotonic fluid, the patient’s aspirate continues to be bloody. At this point, her vitals are somewhat stable but have shown no sign of improvement. Initial emergent labs have returned: Na 142 mEq/L, K 3.2 mEq/L, Cl 106 mEq/L, CO₂ 18 mEq/L, BUN 40 mg/dL, Cr 0.8 mg/dL, glucose 110 mg/dL, WBC 7,000/mm³, Hgb 9.8 g/dL, Hct 29%, Plt 62,000/mm³, INR 3, PTT 48, albumin 2.4 g/dL, AST 76 IU/L, ALT 39 IU/L, Bili 6.2 mg/dL, amylase 210 IU/L, and lipase 24 IU/dL. The gastroenterologist is still 5 to 10 minutes away.

Question 22.12.4 Which of the following would be the most appropriate next step?

- A) Address the presence of platelet dysfunction by transfusing with a 6-pack of platelets
- B) Central line placement should be priority at this time because fluid resuscitation is the primary concern
- C) Emergent gastric tamponade should be attempted with a Foley catheter
- D) None of the above

Answer 22.12.4 The correct answer is “D.” None of the above is a particularly good idea at this juncture. “A” is not necessary since a platelet count of 62,000 is adequate for hemostasis. A platelet count of <50,000 is considered an indication for platelet transfusion in an actively bleeding patient. Hold off on “B”—coagulopathy (INR 3) is a **relative** contraindication to central line placement but if you have to use a central line, remember that the femoral vein can be compressed in the event of bleeding and infection rates are comparable to other central line sites (*Crit Care Med.* 2012 Aug; 40(8):2479–2485). Recall too that peripheral catheters will deliver more fluid more rapidly when compared with central catheters. “C” is incorrect because gastric tamponade with a Foley is just silly. A Blakemore tube (or its variants) require that the patient is intubated and are temporizing measures *only* until you can get endoscopy. What you could do while you’re waiting for your GI colleague to park her Jaguar is start the patient on octreotide (50 mcg IV bolus followed by an infusion) to decrease the portal blood flow. *Note that octreotide does not change outcomes in and of itself (see below) and is very short-acting.* Vitamin K should also be given, as well as fresh frozen plasma or cryoprecipitate if she continues to bleed. See chapter 7 for more on treating an elevated INR in the face of cirrhosis.

Question 22.12.5 Effective methods for controlling upper GI variceal bleeding that improve outcomes include all of the following EXCEPT:

- A) Variceal ligation
- B) Sclerotherapy
- C) Transjugular intrahepatic portosystemic shunt (TIPS) procedure
- D) Vasopressin

Answer 22.12.5 The correct answer is “D.” Vasopressin, while achieving initial control of bleeding in up to 60% of patients, has essentially **no effect on rebleeding and may cause ischemia elsewhere due to vasoconstriction.** Octreotide has fewer adverse effects and has utility *when combined with variceal ligation.* Octreotide *does not* by itself reduce rebleeding or mortality. Variceal ligation and sclerotherapy both reduce mortality. The TIPS procedure has been shown to effectively stop bleeding by reducing portal pressures. It also reduces **acute** mortality. New data makes a strong case for placing a TIPS to improve mortality *even before a first* variceal bleed (*Hepatology.* 2019 Jan;69(1):282–293) though it is not yet standard of care. *Antibiotics (ceftriaxone or a fluoroquinolone) should be given and reduce rebleeding* (*Hepatology.* 2004 Mar; 39(3):746–753). See Chapter 7 for more on variceal bleeding.

**HELPFUL TIP:**

Indirect evidence of a GI bleed in patients with liver disease includes an elevated BUN, which results from the digestion of blood.

Despite Dr. Graber’s warning to the contrary, you consider placing a central line.

Question 22.12.6 Which of the following locations of central line placement is associated with the lowest rate of infection?

- A) Internal jugular
- B) Femoral vein
- C) Subclavian vein
- D) They all have similar infection rates

Answer 22.12.6 The correct answer is “D.” With new infection control techniques, infection rates are pretty much the same for all central line locations (*Crit Care Med.* 2012 Aug; 40(8):2479–2485). Subclavian lines have higher risks of complications such as arterial injury, hemothorax, pneumothorax, and lung injury. **Note that ultrasound-guided central line insertion is the standard of care.**

The gastroenterologist arrives and you explain the situation. Vitals at this time include a temperature of 36.8°C, pulse 105 bpm, respirations 14 (ventilator dependent), blood pressure 85/40 mm Hg, and oxygen saturation of 92%. The gastroenterologist plans to attempt endoscopy with sclerotherapy, but would like to have the general surgeons available for backup in case emergent operative intervention becomes necessary.

As you prepare to contact the surgeon, you consider the patient’s surgical risk. You quickly recall that there are several prognostic scoring systems including, among others, the Model for End-stage Liver Disease (MELD) scoring system and the Child–Pugh score.

Question 22.12.7 Which of the following is TRUE regarding the MELD scoring system?

- A) The MELD score can be used to predict 3-month survival following TIPS
- B) The three components of the MELD score are bilirubin, INR, and creatinine
- C) The MELD score assesses mortality risk for prioritizing patients on the waitlist for liver transplant
- D) All of the above

Answer 22.12.7 The correct answer is “D.” The MELD score was originally used to predict the 3-month mortality after TIPS (“A”). However, the MELD score has also been validated as a tool to estimate overall mortality related to liver disease and to prioritize patients on the transplant wait list (“C”). The MELD score is computed using creatinine, INR, and bilirubin levels. There are handy online calculators readily available (MDCalc... no we don’t have any commercial interest).

The MELD score is interpreted as follows: **score ≥ 40** , 71.3% mortality in 3 months; **30–39**, 52.6% mortality in 3 months; **20–29**, 19.6% mortality in 3 months; **10–19**, 6% mortality in 3 months; **< 9** , 1.9% mortality in 3 months.

The Child–Pugh classification also assesses prognosis in liver disease, need for transplant (minimum score of 7), predicted

TABLE 22-6 CHILD–PUGH CLASSIFICATION

Points assigned	1	2	3
Encephalopathy	None	Low grade	High grade
Ascites	None	Slight	Moderate-large
Bilirubin	1–2 mg/dL	2–3 mg/dL	> 3 mg/dL
Albumin	> 3.5 g/dL	2.8–3.5 g/dL	< 2.8 g/dL
INR	< 1.7	1.8–2.3	> 2.3

mortality rate from variceal bleed, and outcomes after surgery or TIPS (Table 22-6).

Child–Pugh Class A is defined as having **5 to 6 points** (well-compensated cirrhosis, operative mortality for abdominal surgery 10%), Class B is **7 to 9 points** (significant functional compromise, operative mortality 30%), and Class C is **10 to 15 points** (decompensated cirrhosis, operative mortality 82%).

► **Objectives: Did you learn to ...**

- Manage a patient with a massive upper GI bleed?
- Determine if an ET tube has been placed correctly?
- Recognize the uses and limitations of gastric lavage?
- Recognize the uses and limitations of central line placement and Swan–Ganz catheter placement?
- Evaluate a patient with liver disease, using the Child–Pugh and MELD classification systems?

QUICK QUIZ: INTUBATION

Which of the following IS NOT a contraindication to a blind nasotracheal intubation?

- A) Patient is not breathing
- B) Patient is anticoagulated or has had TPA
- C) Midface trauma
- D) History of a septoplasty

The correct answer is “D.” All of the rest are contraindications to a blind nasotracheal intubation. Specifically, it is not possible to do a blind nasotracheal intubation in a nonbreathing patient. Patients who are anticoagulated may bleed profusely after a nasotracheal intubation, and midface trauma suggests the possibility that the tube could end up in the brain, never a good idea. Avoid nasotracheal intubation in midface trauma, except as a last resort.

► **CASE 22.13**

You are seeing a 33-year-old resident at a large university hospital setting where medical care is provided freely to him. He is about to complete his Internal Medicine residency and

wants to “get his money’s worth” of free procedures before he leaves. He has scheduled a full afternoon of procedures with you, including toenail removal, excision of a mole on his neck, and a stylish new cartilage ear piercing for his new job as a cruise ship doctor.

He has had trouble with recurrent pain and inflammation on the lateral side of his left great toe. On examination you identify onychocryptosis (ingrown nail). He has tried soaks, growing the nail plate past the skin, and regular paring—all without success.

Question 22.13.1 Regarding nail removal in this patient, which one of the following is FALSE?

- A) The great toe is the most commonly affected toe for onychocryptosis
- B) If the patient chooses partial nail removal, about 25% of the nail should be removed on the affected side
- C) Phenol should be placed for no longer than 10 seconds to the germinal tissue to prevent necrosis
- D) When removing the nail, an upward twist of the hand to the medial side should be performed

Answer 22.13.1 The correct answer is “C.” Phenol can be left in place for 3 minutes. Options “A,” “B,” and “D” are all true. Ingrown toenails almost exclusively affect the great toe on the lateral side, occasionally on the medial side. Partial or full nail removal should be implemented when conservative measures have failed. Besides ingrown nails (onychocryptosis), onychomycosis (fungal infection of the nail), recurrent paronychia (nail fold inflammation), and onychogryphosis (deformed, curved nail) are all indications for partial or full nail removal. If recurrent ingrown nails have occurred, germinal tissue can be ablated with phenol on a cotton swab held in place for 3 minutes, and afterward the phenol should be neutralized with alcohol. Other approaches to matrixectomy include electrosurgical and laser techniques and application of sodium hydroxide.

Next, he complains about a small regular mole on his neck that he repeatedly cuts while shaving. He would like to have it removed in whatever way you deem best. The lesion is raised above the skin. Although it is mildly irregular in appearance from the repeated trauma of shaving, there is no other worrying feature of malignancy.

Question 22.13.2 Which of the following is NOT a correct statement regarding removal of this lesion?

- A) Curettage with cautery or shave biopsy would be ideal for this sort of lesion
- B) If sutures are required, 6-0 nylon would be ideal in this location
- C) If a punch biopsy is performed, skin should be held taut perpendicular to the angle of the mandible (the natural skin lines of the neck)

- D) In this location, both shave and punch techniques require closure by suture approximation

Answer 22.13.2 The correct answer is “D.” Various types of skin lesion removal exist: punch biopsy, shave biopsy, curettage, and elliptical excisional biopsy. Punch biopsy involves taking a full-thickness sample in skin areas (except for the eyelids, lips, or penis). Skin should be held taught perpendicular to the natural skin tension lines, and punch instrument is rotated through the skin. The site is closed with either a single interrupted or vertical mattress suture. Shave biopsy is indicated for removal of elevated skin lesions where complete thickness removal is unnecessary. Shave should be made from both lateral edges into center to avoid cutting too deep. No suturing is necessary. Curettage entails a method of removing lesions that also does not require full-thickness sampling. A Fox dermal curettage is used to scrape away unwanted tissue followed by electrical or chemical cautery for hemostasis. Finally, elliptical excision is used when full dermal thickness excision is necessary. Contraindications to skin biopsy include infection at the site and coagulopathy.

Finally, your patient is a little embarrassed to be seen at the mall getting his ear pierced, and asks if you could pierce it for him. He is considering a standard lobe pierce versus an auricular cartilage piercing.

Question 22.13.3 Which of the following is true in regard to counseling and technique?

- A) Eczema at the site is a contraindication to piercing
- B) Auricular cartilage piercing should only be performed by a trained physician
- C) Ears should be pierced from the posterior to anterior site
- D) Ear piercing involves boring a 20-gauge needle into the marked site
- E) Ear piercing is contraindicated in nerds

Answer 22.13.3 The correct answer is “A.” Eczema in the area is a contraindication to piercing. Other contraindications include: infection, previous keloid formation, immunodeficiency, and coagulopathy. All of the other options are incorrect. Auricular cartilage piercing is prone to infection and destruction of the cartilage. *Pseudomonas* is a common pathogen and oral fluoroquinolones are indicated as treatment. “E” deserves special mention, as “nerds” can be converted to “hipsters” simply by piercing their ears. However, there is a corollary to this axiom: any aging male with a gray ponytail should avoid piercings; a pony tail and piercing don’t make you young and attractive and mostly look silly.

► **Objectives: Did you learn to ...**

- Describe techniques and indications for toenail removal?
- Describe various skin biopsy techniques?
- Identify contraindications to ear piercing?

QUICK QUIZ: DOC, IS THAT A HOSE IN MY CHEST?

What statement represents correct chest tube management?

- A) A tube that shows no water fluctuations when placed on “water seal” should have wall suction increased in an attempt to re-open
- B) Initial postoperative setting of a chest tube is most often -100 cm H_2O
- C) Unless there is major injury to the lung, continuous bubbling of the water seal chamber most likely represents an apparatus leakage
- D) If a purse string was placed during initial placement of the chest tube, tightly tying the purse string when pulling the chest tube is enough to prevent pneumothorax

The correct answer is “C.” Continued bubbling in the water seal chamber suggests that there is a leak in the system. Theoretically, once the pleural space is drained of air, there should be no further bubbling. Air leakage is seen as air bubbles that increase with increased intrathoracic pressure (e.g., cough, Valsalva maneuver, and positive pressure ventilation). Continuous air leakage may be due to a large tear in the lung parenchyma, bronchopleural fistula, or an apparatus leak. “A” is incorrect. A tube that is nonfunctional should first be evaluated by a clinician familiar with the management of chest tubes—preferably by the person who placed it. An attempt to clear debris or clot can be made by various maneuvers, e.g., stripping the tube. If this is not successful, the tube should be replaced. Increasing the suction will not reopen it. “B” is incorrect as well. Initial suction should be -20 cm H_2O . “D” is incorrect because an occlusive dressing, such as petrolatum gauze, should be placed over the former chest tube site once the tube is removed. **Note that “purse string” sutures are passé. They increase pain and have no advantage over placement of appropriate anchoring sutures.**

A chest tube can be removed when the following criteria are met: fluid drainage is less than 150 cc/day, the lung is fully expanded on chest x-ray, and no air leak is present. Many clinicians perform a “clamping trial” of 4 to 6 hours followed by a chest x-ray to ensure lung expansion prior to removing a chest tube.

Clinical Pearls

- An elevated lactate can indicate tissue ischemia from hypoperfusion (shock, vascular compromise—the so-called “type A” lactic acidosis). Be aware that other causes of a lactic acidosis include ingestions such as methanol or ethanol, liver disease, diabetes, metformin, diabetes, etc. (“type B” lactic acidosis).
- Consider use of tranexamic acid and tourniquet above the injury to help stabilize uncontrolled bleeding.
- An NG tube is not necessary in the treatment of a small bowel obstruction. However, it can be helpful in preventing vomiting. The trade-off is that an NG tube is uncomfortable.

- Compression stockings do nothing to prevent postoperative DVTs and may cause skin breakdown: don’t use them. Use subcutaneous heparins or intermittent pneumatic compression along with early mobilization.
- Do not get “baseline” labs such as a CBC, PT/PTT/INR, or electrolytes preoperatively without an indication in patients who do not have significant systemic disease. They are not helpful. Target your preoperative workup based on the patient’s comorbidities.
- Do not use colloids for fluid resuscitation unless there is a specific indication (e.g., albumin after large volume paracentesis). The outcomes are generally worse than with crystalloid and the colloids are more expensive.
- Only about 65% of patients with cholecystitis will have a positive Murphy’s sign and 30% will have neither a fever nor an elevated white count.
- Patients who have had bariatric surgery can be vitamin-deficient including vitamins D, thiamine, B12, and folate. A multivitamin should be suggested in these patients.
- Prophylactic antibiotics should be given *before* surgery and *not* continued after surgery.
- Ten percent of patients with appendicitis will have a normal white count. Only 75% will have anorexia.
- When categorizing liver disease, the MELD score is less subjective than the Child–Pugh score and requires only creatinine, INR, and bilirubin.

Psychiatry

Monika Jindal

► CASE 23.1

You are seeing a 48-year-old female who presents with a 3-month history of low mood, low energy, poor concentration, and irritability. She has lost interest in most things she had enjoyed and has also noticed a 20-lb weight gain. She has been having frequent headaches, has been short-tempered, and has noticed that it is hard to wake up in the morning. She reports no thoughts of suicide but has wondered if death would be a relief. She says she has felt restless for a while and feels that she is a bad person. Her mother suffered from depression. She does not consume alcohol or any other substances. She is divorced and has no children.

You think that this patient may meet criteria for a depressive disorder.

Question 23.1.1 Which of the following is NOT a criterion for the diagnosis of major depressive disorder (MDD)?

- A) Low mood
- B) Presence of suicidal ideation
- C) Decreased appetite
- D) Anhedonia or loss of interest
- E) Mood fluctuations

Answer 23.1.1 The correct answer is “E.” While low mood is a criterion, the presence of mood fluctuation is not used to make the diagnosis of depression. The other options listed are part of the criteria set forth in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. (DSM-5). Special emphasis is placed on the presence of depressed mood and decreased interest, **one of which must be present** in order to diagnose MDD. Instead of depressed mood, patients may report somatic complaints or irritability.

Per DSM-5, in order to diagnose MDD, five or more of the following nine criteria must be present for at least two weeks or more. At least ONE must be depressed mood OR loss of interest/anhedonia:

- Depressed mood
- Loss of interest/anhedonia

- Significant change in weight or appetite
- Insomnia or hypersomnia
- Psychomotor agitation or retardation
- Fatigue or loss of energy
- Feeling worthless or excessive guilt
- Poor concentration
- Recurrent thoughts of death, suicidal ideation, attempt, or plan

HELPFUL TIP:

Several mnemonics have been developed to help clinicians remember the DSM-5 criteria and two of these are “SIG E CAPS” (Sleep, Interest, Guilt, Energy, Concentration, Appetite, Psychomotor changes, Suicidality) and “SPACE DIGS” (same but add Depression).

Question 23.1.2 Which one of this patient’s symptoms is considered a symptom of “atypical depression” or major depressive disorder (MDD) with atypical features?

- A) Hypersomnia
- B) Low mood
- C) Anhedonia
- D) Psychomotor retardation
- E) Irritability

Answer 23.1.2 The correct answer is “A.” The typical somatic symptoms of depression include poor sleep or insomnia, decreased appetite, and decreased libido. Patients with **atypical depression** may have hyperphagia, hypersomnolence, leaden paralysis, and mood reactivity.

You begin to explain the nature of depression to this patient.

Question 23.1.3 Which of the following epidemiological statements is NOT true?

- A) The average American has about a 16% chance of developing depression over his or her lifetime
- B) About 7% of Americans suffer depression each year
- C) Women are five times as likely to suffer depression as are men
- D) The incidence of depression is higher in younger cohorts than the elderly
- E) Divorced people are more likely to be depressed

Answer 23.1.3 The correct answer is “C.” The lifetime prevalence of MDD is 16% with 6.9% of adults suffering from MDD in any given year. Depression may be recurrent throughout one’s lifetime. Women are **twice** (not five times) as likely to experience depression as are men. Rates of depression are similar across all age groups, though elderly men are at a higher risk of suicide than elderly women. Being divorced is a risk factor for depression.

**HELPFUL TIP:**

Anxiety, not meeting the level of an anxiety disorder, frequently accompanies depression (70%). However, 60% of people with a lifetime diagnosis of MDD have had a diagnosable anxiety disorder.

This patient’s situation is not unusual for your practice.

Question 23.1.4 What is the prevalence of MDD in primary care patients?

- A) 1% to 2%
- B) 5% to 15%
- C) 30% to 35%
- D) 45% to 50%
- E) 100% (seems like everyone ... even the clinic staff)

Answer 23.1.4 The correct answer is “B.” About 5% to 10% of primary care patients meet criteria for MDD and about twice of that (10–20%) many have “minor” depression. If you answered “E,” you work in a sad, sad place. Hire a clown to work the front desk—but not one of those scary, murderous clowns.

**HELPFUL TIP:**

One reason for lack of diagnosis of depression in primary care is that depression often presents with a wide variety of somatic complaints. Another is that the spectrum of disease in primary care offices is less severe, leading to fewer diagnoses.

Question 23.1.5 Which of these epidemiological statements about depression in primary care is true?

- A) Most depressed patients (about 80%) seek mental health care from primary care physicians
- B) About 50% of patients suffering from depression are clinically recognized by their primary care physician

- C) Only about 50% of the patients diagnosed with MDD receive adequate treatment
- D) The 2015 United States Preventive Services Task Force (USPSTF) recommends screening for depression and having adequate systems for treatment, follow-up, and/or referral
- E) All of the above

Answer 23.1.5 The correct answer is “E.” All are correct. “D” requires special mention. The previous (2009) recommendation suggested screening *contingent* upon having adequate services for patients diagnosed with depression.

**HELPFUL TIP:**

There are several brief self-rating depression scales that can be used for screening (e.g., Beck Depression Inventory, Primary Care Evaluation of Mental Disorders, Patient Health Questionnaire, and Zung Depression Scale). A two-question screen (PHQ-2) may be as effective for screening as these more extensive scales. Simply ask:

- Over the past 2 weeks, have you often felt down, blue, or in the dumps?
- Over the past 2 weeks, have you lost interest in most activities or things that used to bring you pleasure?

A positive answer to **either** of those two questions should prompt a more thorough evaluation of depression with one of the more extensive self-rating depression scales. A negative answer to both questions likely rules out depression in most patients.

You realize that it is also important to focus on the social history in patients with depression.

Question 23.1.6 Which of the following is associated with a DECREASED risk of depression?

- A) Unemployment
- B) Poverty
- C) Being unmarried
- D) Family history of depression
- E) Asian race

Answer 23.1.6 The correct answer is “E.” Factors associated with an increased risk of depression include having a family history of depression, being unmarried (single, divorced, or widowed), a recent childbirth or pregnancy, medical comorbidities, lack of social support, female gender, unemployment, poverty, and substance use. There is a lower prevalence of depression among people of Asian ancestry when compared to the Caucasian populations. Protective factors include: marriage, having children, and being retired (so, retirement is when we are supposed to have fun?).

You believe that your patient is suffering from an episode of major depression, and you decide to initiate treatment with an antidepressant.

Question 23.1.7 Following the first episode of depression, what is her risk of relapse?

- A) <1%
- B) 25%
- C) 50%
- D) 75%
- E) >99%

Answer 23.1.7 The correct answer is “C.” About 50% of patients relapse following the first episode of depression. Following the second episode, the risk of relapse is roughly 75%, and climbs to about 90% after the third episode. In order to reduce the risk of relapse, most authorities recommend antidepressant therapy for 6 to 12 months after remission in patients with their first episode of depression. Approximately two-thirds of relapses can be prevented by continuation of antidepressant medications indefinitely. Patients who might benefit from indefinite medical therapy include: those with a severe first episode (e.g., significant suicide attempt), patients diagnosed with MDD with psychotic features, patients with three or more episodes of MDD, elderly patients with their first episode of depression, and possibly those with a strong family history of depression.

You choose to treat your patient with a serotonin reuptake inhibitor (SSRI) and tell your patient to contact you if she suffers from adverse effects.

Question 23.1.8 Which of the following is NOT a typical adverse effect of SSRIs?

- A) Nausea
- B) Headaches
- C) Restlessness
- D) Insomnia
- E) Urinary retention

Answer 23.1.8 The correct answer is “E.” Urinary retention is not seen with SSRIs, but the other four options are typical SSRI side effects. The anticholinergic effect of urinary retention is typical of the tricyclic antidepressants (TCAs). Sexual and GI problems are commonly seen with SSRIs including loss of libido. Akathisia and dystonic reactions can (rarely) be seen with SSRIs as well. To be complete, paroxetine (Paxil) does have anticholinergic effects and can cause urinary retention.

Your patient returns to see you 2 weeks after starting her SSRI and reports that she has not noticed any benefit from the medication.

Question 23.1.9 Which of the following statements is most accurate?

- A) The antidepressant is not going to work, so she should switch to another antidepressant of the same class
- B) The antidepressant is not going to work, so she should switch to another antidepressant from a different class
- C) It is too early to judge the efficacy of the antidepressant at this point

- D) She’s probably suffering a paradoxical reaction of increased depression with her medication
- E) Going up on the dose is not an option at this time

Answer 23.1.9 The correct answer is “C.” The benefit of antidepressant medication usually takes about 3–4 weeks (although side effects may occur upon initiation). Thus, it is premature to abandon this medication. Most authorities recommend trying an antidepressant for 6 weeks at an adequate dose before considering that medication a “treatment failure.” Increasing the dose or giving it at least 4 to 6 weeks total at the current dose would both be valid options.

You increase the medication dose, and the patient returns to see you in another 2 weeks. This time, she is feeling better and more energetic. People at work are beginning to notice her improved attitude, and her sleep has become more refreshing. She wants to know how long she should stay on the medication.

Question 23.1.10 The correct answer is:

- A) At least 1 month
- B) At least 2 months
- C) At least 4 to 6 months
- D) At least 2 years
- E) Forever

Answer 23.1.10 The correct answer is “C.” Different organizations recommend different durations of treatment, but the shortest recommended course is 4 to 6 months, with most authorities recommending treatment for 6 to 12 months after remission.

► **Objectives: Did you learn to ...**

- Diagnose MDD?
- Describe the epidemiology and natural history of depression?
- Recognize features of depression with atypical features?
- Initiate treatment of depression?
- Identify adverse effects of SSRIs?

► **CASE 23.2**

You are assessing a 45-year-old professional male who has a history of MDD in his early twenties but has fully recovered since. He recently suffered an uncomplicated anterior wall myocardial infarction (MI). His wife mentions that she thinks he is depressed. He is tired all the time, has poor sleep, a poor appetite, and he has been irritable. He has also been tearful and blames himself for his MI (too many “pounder” burgers ... with cheese ... and bacon). He is willing to consider the diagnosis of depression because he remembers having suffered from it before. He also knows a history of MDD puts him at risk for medical illnesses.

Question 23.2.1 Which of the following illnesses is more prevalent in patients with MDD?

- A) Coronary heart disease
- B) Cerebrovascular disease
- C) Diabetes mellitus
- D) Osteoporosis
- E) All of the above

Answer 23.2.1 The correct answer is “E.” It is unclear if patients with depression are more likely to have these illnesses as a result of the depression or the reverse: patients with these illnesses are more likely to be depressed. Depressed patients have an average of 3.4 more chronic medical conditions than nondepressed patients. At least two studies have now linked a lifetime history of MDD to an increased risk (1.2–3 times) of early menopause (of course that would be a bit strange in this patient, a male).

You know that some of this patient’s symptoms could be secondary to his medical illness.

Question 23.2.2 Which one of the following symptoms, if present, is the *most specific* for depression?

- A) Sleep problems
- B) Appetite difficulties
- C) Psychomotor agitation
- D) Low energy
- E) Excessive preoccupation with death

Answer 23.2.2 The correct answer is “E.” In the mnemonic “SPACE DIGS,” the last four letters stand for symptoms that are more specific for depression and more independent of somatic illnesses. These symptoms are Depressed mood, loss of Interests, inappropriate Guilt, and thoughts of Suicide (“DIGS”). The presence of any of these symptoms should lead you to suspect depression.

HELPFUL TIP:

While a stressor can often precipitate onset of depression, depression can also arise with no precipitating factor, and the response to treatment is independent of whether it is “reactive” (identifiable stressor present) or “endogenous” (no identifiable stressor).

Question 23.2.3 Which of the following statements is NOT true about depression post-MI?

- A) Major depression is an independent risk factor for post-MI mortality
- B) Minor depression is an independent risk factor for post-MI mortality
- C) Minor depression is more prevalent than major depression post-MI
- D) Treating depression improves cardiac outcomes in post-MI patients
- E) Approximately half of the people who sustain an MI have symptoms of depression afterward

Answer 23.2.3 The correct answer is “D.” In the post-MI period, major depression occurs in almost 20%, and minor depression in another 27%. Concurrent major depression elevates mortality risk after MI by a factor of 3.5, which is the same degree of risk as heart failure. Patients with a mood disturbance (e.g., minor depression) also have a higher mortality rate. While treatment of depression has been shown to improve some medical outcomes (e.g., HbA1C levels in diabetics), this is not the case in cardiovascular disease. Treatment of depression does not change mortality or morbidity after an MI (but may improve quality of life).

HELPFUL TIP:

Patients suffering strokes also have an elevated risk of depression with approximately one-third of post-stroke patients meeting criteria for MDD; there is a similar correlation of depressive symptoms with stroke mortality.

You decide to recommend treatment to this patient.

Question 23.2.4 Which of the following therapies is the LEAST desirable choice for treating his depression?

- A) Bupropion (Wellbutrin)
- B) Cognitive behavioral therapy
- C) Nortriptyline (Pamelor)
- D) Fluoxetine (Prozac)
- E) Sertraline (Zoloft)

Answer 23.2.4 The correct answer is “C.” TCAs should be avoided in patients with cardiovascular disease because of their arrhythmogenic potential (e.g., torsades de pointes). Remember that the SNRIs as well as some SSRIs (citalopram [Celexa] and escitalopram [Lexapro]) can also prolong the QT interval. Generally, SSRI therapy (“D” and “E”) would be the preferred drug for the majority of patients who are candidates for pharmacotherapy. Bupropion (“A”) and cognitive behavioral therapy (“B”) are also reasonable choices.

HELPFUL TIP:

Consider a baseline ECG in all patients for whom you are initiating TCAs and citalopram to evaluate the QT interval, particularly if the patient is on other medications that prolong the QT interval. If the QT is prolonged at baseline, it predisposes patients to arrhythmias.

► **Objectives: Did you learn to ...**

- Diagnose depression occurring with an acute medical illness?
- Recognize the impact of depression on other medical conditions?
- Treat a post-MI patient with depression?

QUICK QUIZ: SAD ALL THE TIME

A 44-year-old patient of yours has come to see you multiple times for low mood. She does not have trouble with energy or sleep, but with prompting reports occasional problems with concentration and appetite. Basically, she tells you, “I’ve been depressed for as long as I can remember.” You have tried treating her with two different SSRIs, but she had trouble with side effects and did not notice much improvement in her mood.

Which of the following is the best diagnosis for this patient?

- A) Adjustment disorder
- B) Bipolar affective disorder
- C) Persistent depressive disorder (previously called dysthymia)
- D) MDD
- E) Premenstrual dysphoric disorder

The correct answer is “C.” Persistent depressive disorder (formerly dysthymia in DSM-IV) is best thought of as long-term, low-level depressive symptoms that do not meet criteria for MDD. Symptoms include depressed mood most days for at least 2 years and two or more of the following: low energy, hopelessness, concentration difficulties, sleep disturbance, appetite change, fatigue, and low self-esteem. In order to diagnose persistent depressive disorder, the person cannot be free of the symptoms for more than 2 months during the first 2 years. The treatment is the same as for depression—SSRIs and psychotherapy. Many people with persistent depressive disorder may also experience one or more episodes of MDD in their lifetime.

CASE 23.3

A 34-year-old female presents to your clinic for treatment of depression. She reports a lifelong history of low-level depressive symptoms that have worsened over the past 6 months since she lost her job (don’t worry—this is a different case than the previous one). She also suffers from inadequately controlled diabetes mellitus (HbA1c 9%) and has been diagnosed with a personality disorder in the past. She drinks three to four beers everyday (hmm . . . multiply by 2 just to be safe) and has been arrested for driving while intoxicated twice. On questioning, you realize she has a moderately severe level of depression. She is not suicidal, so you decide to initiate treatment as an outpatient with close follow-up.

Question 23.3.1 Which of these factors does NOT contribute to a poor outcome when treating depression?

- A) Chronic depressive symptoms
- B) Female gender
- C) Personality disorder
- D) Comorbid medical conditions
- E) Alcoholism

Answer 23.3.1 The correct answer is “B.” Even though females are twice as likely to be diagnosed with MDD as males, gender does not seem to influence treatment response. The presence of any of the other factors listed reduces the chance of a successful response to treatment.

In choosing an antidepressant for this patient, you would like to use one with a high success rate (whereas, sometimes you choose the least efficacious drug—what?!). However, you know that the success rates for most antidepressants are fairly similar.

Question 23.3.2 What are the chances of this patient failing to respond to the first antidepressant chosen?

- A) <1%
- B) 10% to 20%
- C) 30% to 40%
- D) 60% to 70%
- E) 90% to 95%

Answer 23.3.2 The correct answer is “C.” Studies have consistently shown an antidepressant response rate of somewhere between 60% and 70% with 30% to 40% failing to respond, regardless of what antidepressant is tried. When unpublished studies are included, the failure rate for SSRIs approaches 50%. Despite this, SSRIs are still the first-line recommended therapy for treatment of depression.

HELPFUL TIP:

Fifty percent of patients who do not respond to an initial SSRI will respond to another drug in the same class. So, changing to another SSRI is reasonable in a patient who has failed one SSRI. Is this observed effect due to differences between drugs, pharmacodynamics, pharmacogenetics, or longer treatment? No one knows.

When you spin your Random Depression Therapy Wheel that your occultist friend gave you during the last blue moon, it lands on escitalopram (Lexapro). So, you start your patient on that drug. Ten days later, she calls you just to say that the new medicine seems no better and her sleep is even worse. She started taking the medication in the morning because she thought it might be interfering with her sleep. She tends to lie in bed for 2 hours before falling asleep.

Question 23.3.3 In addition to recommending good sleep hygiene and increased exercise, you prescribe:

- A) Trazodone
- B) Zolpidem
- C) Lorazepam
- D) Phenobarbital
- E) Two shots of whiskey QHS, preferably a classic like Basil Hayden

Answer 23.3.3 The correct answer is “A.” Trazodone may be helpful with insomnia and can boost serotonergic activity. For depression with disordered sleep, it is preferred to benzodiazepines unless anxiety is a significant issue. Additionally, given this patient’s daily alcohol use, neither benzodiazepines (nor more alcohol) are advised. Phenobarbital should be avoided. Zolpidem might be a consideration but is often associated with considerable side effects (Gee, Doc, I don’t remember driving the car in my underwear and baking two pans of lasagna last night, but oh well) particularly in women who tend to be slower metabolizers. Due to this, the FDA recommended maximum dosage of zolpidem be lower in women, 5 mg compared to 10 mg in men. Obviously avoid alcohol for treatment of insomnia in this and other patients as it can actually disrupt sleep cycles.

HELPFUL TIP:

Indications for psychiatric referral for depression include:

- Failure of medical treatment
- Imminent suicidality
- Severe depression for which hospitalization is thought to be necessary
- Diagnostic clarification or treatment recommendation
- Comorbidities that make treatment response less likely
- Patient requests referral

You add trazodone 50 mg HS PRN and titrate up to the maximum dose of escitalopram, and your patient’s symptoms are now coming under control. When you see her next, she describes a 20-minute episode of chest tightness, dyspnea, diaphoresis, and extreme anxiety. You believe that she suffered a panic attack. You wonder if you should alter your diagnosis.

Question 23.3.4 In which of the following disorders might panic attacks occur?

- A) Panic disorder
- B) MDD
- C) Generalized anxiety disorder
- D) Social phobia
- E) All of the above

Answer 23.3.4 The correct answer is “E.” Panic attacks consist of a cluster of symptoms signifying anxiety and are not a disorder by themselves. As such, they can be part of any affective syndrome including depression, social phobia, generalized anxiety disorder, and panic disorder. The presence of a single panic attack in a person with a depressive disorder should not necessarily lead to a new diagnosis.

► Objectives: Did you learn to ...

- Identify risk factors for a poor outcome when treating depression?
- Assess the likelihood of a successful outcome in a patient with depression?
- Generate alternative methods for treating resistant depression?

► CASE 23.4

A 41-year-old female comes to your office complaining of difficulty trusting people, irritability, low mood, and recurrent nightmares. Her symptoms started when she was a teenager following the death of her parents in one of the mass shootings in _____ (insert your state here). She has never been able to forgive herself for surviving while her parents died. She has not been able to form close relationships, and she is seeking help because of renewed nightmares. They were common in the first 2 years following the incident but had faded away until recently. Now, when she hears news stories of gun violence and school shootings, the memories come flooding back in a very real and visceral manner. She sometimes wakes up in a fright after dreaming that her own house is on fire. She avoids going near any bright lights or fireworks displays. When she is forced to be in the presence of fires, she frequently notices palpitations, dyspnea, and a sense of doom.

Question 23.4.1 What is the patient’s primary diagnosis?

- A) MDD
- B) Generalized anxiety disorder
- C) Panic disorder
- D) Post-traumatic stress disorder (PTSD)
- E) Acute stress disorder

Answer 23.4.1 The correct answer is “D.” The patient’s symptoms are characteristic of PTSD. This may occur after being exposed to a situation in which one’s life or “physical integrity” (or that of another person) is in danger. Some such events are cancer, combat, rape, or other sexual or nonsexual assault; an intensive care unit stay (or, one could hypothesize, taking the boards, perhaps?) may also result in PTSD. Keep reading for further explanation of why this is the best choice.

HELPFUL TIP:

A mass shooting is defined either as at least four victims killed in a single shooting event or at least four victims injured. Hundreds of these incidents occur each year in the United States—only the really big ones make national headlines.

Question 23.4.2 Which of the following is NOT necessary for a diagnosis of PTSD?

- A) The patient needs to experience, witness, or be confronted by a potentially life-threatening event, or an event threatening the physical integrity of self or others
- B) The patient must respond with intense fear, horror, or helplessness
- C) Symptoms have to be present for more than a month
- D) The patient must be involved in combat
- E) The patient must meet a specified number of symptoms

Answer 23.4.2 The correct answer is “D.” Although PTSD is common among military veterans (and was previously known by terms like “shell shock” and “battle fatigue”), there is no requirement that the patient has been in combat. To meet criteria for PTSD, the patient must have been exposed to an event that is threatening to the integrity or life of self or others. The patient then must have symptoms of recurrent intense fear, helplessness, or horror that lasts for >1 month. Symptoms occurring within 4 weeks of the event and lasting for at least 2 days but less than a month are characteristic of acute stress disorder.

Question 23.4.3 Which of the following is **NOT** a part of PTSD?

- A) Nightmares
- B) Flashbacks
- C) Hypervigilance
- D) Fear of death
- E) Difficulty maintaining relationships

Answer 23.4.3 The correct answer is “D.” Fear of death is not a criterion. Symptoms of PTSD are divided into four clusters. To meet the symptom criteria for PTSD, the patient needs at least one symptom from the first cluster, one from the second, two or more from the third, and two or more from the fourth.

The **first cluster (one required)** involves intrusive symptoms regarding the traumatic experience. Examples of symptoms include: flashbacks, nightmares, intrusive memories, and psychological distress in response to triggers that evoke the experience.

The **second cluster (one required)** involves avoidance of stimuli associated with the trauma (people, places, events) and avoidance of distressing memories, thoughts, or feelings related to the trauma.

The **third cluster (two or more required)** relates to negative mood and negative changes in cognition after the traumatic event. Patients may report a numbing of general responsiveness such as markedly diminished interest or participation in significant activities, feeling of detachment or estrangement from others, inability to experience positive emotions, or being in a negative emotional state. They may have negative thoughts distortions toward themselves (negative beliefs about themselves or the causes of the traumatic event).

The **fourth cluster (two or more required)** involves persistent symptoms of increased arousal, such as difficulty falling or staying asleep, irritability or outbursts of anger, difficulty concentrating, hypervigilance, or an exaggerated startle response.

Question 23.4.4 Which of the following is true of treatment for PTSD?

- A) There is no effective treatment
- B) There are no FDA-approved medications
- C) Most patients experience spontaneous remission
- D) Although treatment is often effective, most patients do not achieve cure
- E) Atypical antipsychotics have no role in treatment

Answer 23.4.4 The correct answer is “D.” Symptom improvement, but not cure, is the norm. Cognitive behavioral therapy (if available) is the first-line therapy followed by SSRIs, then SNRIs, particularly venlafaxine. Meditation (specifically transcendental meditation) is effective and can be easily taught (*Lancet Psych.* 2018 Dec; 5:975). Interestingly, “critical incident debriefing” (essentially talking through the incident or reliving the event to try to minimize symptoms, such as with emotive journaling) actually seems to make things worse. CBT and “objective, non-emotive” journaling seem to help (*Soc Sci Med.* 2011;7: 316–326; *Ann Behav Med.* 2002;24:244–250). There is lack of good efficacy data for TCAs, atypical antipsychotics, monoamine oxidase inhibitors (MAOIs), or other drugs. Prazosin may help with sleep and nightmares, but the studies are small and results are mixed. Still, it may be worth a trial added to other pharmacotherapy if the patient is not responding in an adequate manner. Psychotherapy can be helpful and benzodiazepine use should be limited because of the high risk of dependency in this population and the lack of efficacy as monotherapy.

► **Objectives: Did you learn to ...**

- Recognize risk factors for PTSD?
- Diagnose PTSD?
- Treat PTSD?

► CASE 23.5

A 29-year-old female presents to you for a second opinion, bringing a large stack of medical records with her. In fact, she says that this is more like a “fourth or fifth opinion” (lucky you). She heard from a friend of a friend that you are the smartest doctor around and could determine what is wrong with her. In fact, she notes, “None of those other doctors understand my symptoms at all. But you will. They say you’re the best.”

Although you find many negative diagnostic studies in her record, she is sure that her many symptoms must have some physical cause. Over the past few years, she has had chronic headaches, multiple joint pains, diarrhea, fatigue, and intermittent abdominal and chest pains. Her symptoms have prevented her from working. Upper endoscopy, colonoscopy, CT scans, and numerous other studies have not revealed an etiology. Nothing she does improves any of these symptoms. She has spent hours each day researching her symptoms and would like yet another referral to a number of specialists.

Question 23.5.1 Which of the following is the most likely primary diagnosis?

- A) Illness anxiety disorder (formerly hypochondriasis)
- B) Somatic symptom disorder (formerly somatization disorder)
- C) Generalized anxiety disorder
- D) Factitious disorder
- E) Conversion disorder

Answer 23.5.1 The correct answer is “B.” Typically, patients with unexplained symptoms see many doctors, have numerous tests, and often undergo a variety of procedures. Though it is

important to consider a primary psychiatric disorder, a thorough and appropriate evaluation into possible organic causes should be completed before a psychiatric diagnosis is decided upon. Many times, patients with unexplained symptoms will ultimately be diagnosed with a somatic symptom disorder as well as a related disorder (of which “A,” “D,” and “E” are all types).

This patient presents with probable somatic symptom disorder, which by definition must have:

- One or more somatic symptoms that is distressing or disruptive of daily life;
- Excessive thoughts, behaviors, or feelings associated with the somatic symptoms which are exhibited by disproportionate thoughts about the seriousness of symptoms, high anxiety about symptoms, or large amounts of time and energy spent on the health concerns;
- Symptoms are persistent, generally at least 6 months.

“A” is incorrect. **Illness anxiety disorder** is characterized by a preoccupation that one has some sort of serious disease, but somatic symptoms are absent or less pronounced. “C” is incorrect because anxiety is present but totally overshadowed by the somatic complaints. “D,” **factitious disorder**, is diagnosed in patients who intentionally produce symptoms (e.g., overdosing on insulin or injecting feces into the bloodstream) to assume the “sick role.” “E” is incorrect. With **conversion disorder**, patients present with sudden onset of anatomically implausible neurological symptoms (e.g., whole-body numbness and bilateral deafness). **Conversion disorder** is, by definition, not under conscious control. Remember that conversion disorder is a diagnosis of exclusion. You need to make sure there is not an organic basis for the patient’s symptoms. If the symptoms are under conscious control, the diagnosis is “malingering” (really ... that is a diagnosis).

You believe that this patient has somatic symptom disorder.

Question 23.5.2 You begin by saying:

- “Relax. This is all in your head”
- “Your pain isn’t real. But your psychiatric illness is. It’s called somatic symptom disorder”
- “You have a number of symptoms that are very real but cannot be explained by our investigations. The evidence suggests that you do not have any life-threatening illnesses. You have a well-defined disorder, and other patients have similar problems”
- “You have a lot of very serious symptoms. But my physical exam is inconsistent with your complaints. Basically, I don’t believe a word your saying. The sooner that you admit to falsifying these symptoms, the sooner I can start helping you”
- “I have a specialist to refer you to in Outer Mongolia ... take your time getting back”

Answer 23.5.2 The correct answer is “C.” In patients with somatic symptom disorder, it is best to use an honest but gentle approach. Most patients feel better if they have a name for an illness, but using the term “somatic symptom disorder” may

actually be detrimental. It is important to affirm the patient’s symptoms (these are real problems causing real distress) and to try to find some common language to use to describe what he or she is feeling. Patients may not be receptive to your interpretation initially, but repeating the discussion at subsequent visits and focusing on normal diagnostic tests may help them accept the diagnosis.

Next, you discuss a plan of action with this patient.

Question 23.5.3 You initially recommend:

- A multidisciplinary approach, utilizing many different specialty services
- Starting an SSRI
- Starting electroconvulsive therapy (ECT)
- Monthly visits with you and limited diagnostic testing and specialty consultation
- Referral for exploratory laparotomy

Answer 23.5.3 The correct answer is “D.” It is best to have patients with somatic symptom disorder establish regular clinic visits, ideally with one provider. Unscheduled visits to the emergency department should be discouraged unless first discussed with the primary provider. Patients should be allowed to discuss all of their complaints, and a physical examination should be performed at every office visit. These measures will let the patients know that their concerns are being taken seriously. Laboratory tests, radiographs, and consultations should be limited; use your best judgment as to when such diagnostic tests are indicated. “B” and “C” are incorrect as SSRIs and ECT are not primary therapy for somatic symptom disorder, though an SSRI may help with related anxiety symptoms.

HELPFUL TIP:

In patients with somatic symptom disorder who are willing to be referred to mental health providers, individual psychotherapy, CBT, and group therapy may be beneficial.

► **Objectives: Did you learn to ...**

- Recognize and describe somatic symptom disorder?
- Generate an appropriate plan for a patient with somatic symptom disorder?

► **CASE 23.6**

A 21-year-old college student presents to your office for evaluation. She is complaining of feeling stressed out. She is taking classes full-time and is also in one of the military reserve units at the college. One weekend a month, she must attend drill that involves handling weapons. Although she did not have problems handling the weapons initially, she now gets very emotional and upset when she

thinks about having to use them at the next drill weekend. She is nervous and is afraid that she might accidentally fire a weapon. She knows that her fears are silly, and she has been telling herself to “just get over it.” Last weekend, while in class, she suddenly felt that she was going to have a heart attack. She developed tightness in her chest, her heart was racing, and she felt unable to breathe. Although the symptoms eventually abated, the episode made her even more alarmed, and now she is worried that it will happen again, and she will have a heart attack. She comes to see if you can help.

Question 23.6.1 Which of the following is **UNNECESSARY** for the initial workup?

- A) Take more medical, psychiatric, and family history
- B) Order an echocardiogram
- C) Perform a physical examination
- D) Order thyroid function tests
- E) Perform a mental status examination

Answer 23.6.1 The correct answer is “B.” Given the information you have so far, an echocardiogram is not indicated and is rarely used as part of a primary workup. When it comes to test questions, never say no to more history (unless you are supposed to be managing a patient’s airway). A complete history and physical examination, including mental status examination, is essential in the evaluation of this new patient. Thyroid abnormalities can be a cause of some of these symptoms, including palpitations and chest tightness.

She has no prior psychiatric history, but her mother is taking medication for depression. While taking her social history, you ask questions regarding substance abuse.

Question 23.6.2 Use of which of the following substances might explain her symptoms?

- A) Nicotine
- B) Alcohol
- C) Caffeine
- D) Herbal weight loss medication
- E) Any of the above

Answer 23.6.2 The correct answer is “E.” Potential causes of this patient’s symptoms include stimulants, such as caffeine, nicotine (including cigarettes and vaping), amphetamines, ADHD stimulant drugs, pseudoephedrine, some herbal weight loss products containing ephedra (*Ma Huang*), etc. Marijuana can also cause similar symptoms, as can withdrawal from sedatives such as alcohol and benzodiazepines.

She does not smoke, doesn’t use recreational drugs, and doesn’t drink alcohol; she drinks 1 cup of coffee on weekday mornings before class. Her physical examination is normal. Her mental status examination is remarkable for a neutral mood, a restricted and anxious affect, but no suicidal thoughts, and no psychotic symptoms. The

laboratory tests you order are normal. You are leaning toward a psychiatric diagnosis at this point, specifically an anxiety disorder.

Question 23.6.3 Which of the following is **NOT** an anxiety disorder?

- A) Panic disorder
- B) Social anxiety disorder
- C) Agoraphobia
- D) Generalized anxiety disorder
- E) Delirium

Answer 23.6.3 The correct answer is “E.” Delirium, while it may present with features similar to an anxiety disorder, is a cognitive disorder. Anxiety disorders are the most common form of mental illness in the United States, with a lifetime prevalence of approximately 30%. They include options “A” through “D” as well as separation anxiety disorder, specific phobias, selective mutism, unspecified anxiety disorder, and anxiety disorders that are judged to be secondary to a medical condition or a substance.

Of the listed anxiety disorders, you think she has developed panic disorder and that she has been having panic attacks.

Question 23.6.4 Which of the following is **NOT** a typical symptom of a panic attack?

- A) Palpitations
- B) Diaphoresis
- C) Syncope
- D) Dyspnea
- E) Dizziness

Answer 23.6.4 The correct answer is “C.” The symptoms of a panic attack are those associated with an activation of the “fight-or-flight” response referable to the sympathetic nervous system. Typical symptoms include chest pain, fear of dying, paresthesias, dyspnea, a sense of smothering or “impending doom,” nausea, dizziness, numbness, palpitations, sweating, trembling, and derealization or depersonalization. (At this point, we’d like to ask Mother Nature how chest pain helps us when facing a saber-toothed tiger.) It would be rare for a patient to actually lose consciousness from a panic attack (though they may feel they might); and if the patient has true syncope, other diagnoses should be entertained.

HELPFUL TIP:

Hyperventilation can cause cerebral vasoconstriction and secondary cerebral hypoxia resulting in syncope. This *can* occur with panic disorder. However, this is pretty unusual. Syncope should still prompt one to rule out alternative diagnoses.

To make your diagnosis of panic disorder, the patient needs to meet certain criteria.

Question 23.6.5 Which of these is NOT a criterion for panic disorder?

- A) Recurrent and unexpected panic attacks
- B) At least 1 month of worry about having more attacks
- C) Worry about the implication of the attack or its consequences (dying, “going crazy,” etc.)
- D) Change in behavior related to the attacks
- E) Predictable panic attacks that occur in response to cues

Answer 23.6.5 The correct answer is “E.” The criteria for panic disorder do not include predictable panic attacks in response to cues. After patients have had repeated panic attacks, they often develop phobic avoidance of places, objects, or events associated with their symptoms (e.g., agoraphobia). Agoraphobia is a separate diagnosis in DSM-5. Patients often scout out routes of escape before going to places that might provoke a panic attack.

HELPFUL TIP:

The vast majority of patients with panic disorder present with somatic complaints rather than cognitive or mood symptoms. Patients are often misdiagnosed initially. Consider panic attacks in patients presenting with the appropriate somatic symptoms. But never rule out a physical diagnosis (e.g., PSVT, MI) without an appropriate workup.

Your patient is worried that these attacks will keep occurring.

Question 23.6.6 How would you best describe the prognosis for panic disorder?

- A) It is easily curable in most patients
- B) There is no effective drug treatment beyond benzodiazepines, especially alprazolam (Xanax)—lots of alprazolam
- C) Most patients do not improve over time
- D) It is a recurrent or chronic illness
- E) It almost always progresses to total disability

Answer 23.6.6 The correct answer is “D.” Panic disorder is a recurrent or chronic disease in most patients. “A,” “C,” and “E” are incorrect. Although panic disorder is not easily curable, almost all patients will improve over time. However, very few attain complete remission even with medical treatment. Relapse is common (see more about treatment below).

The patient is, of course, very concerned about future panic attacks. She asks what to do when another occurs.

Question 23.6.7 You advise her to do all of the following EXCEPT:

- A) Move to a quiet area
- B) Slow down her breathing
- C) Reassure herself that she is not dying
- D) Breathe into a brown paper bag
- E) Avoid stimulants like caffeine or nicotine

Answer 23.6.7 The correct answer is “D.” All of the other options are reasonable recommendations for a patient suffering from panic attacks. Although commonly observed in popular lore, breathing into a paper bag is not recommended. Breathing into a brown paper bag can have the opposite effect of that intended—the patient may continue hyperventilating with CO₂ building up, which may contribute to more panic symptoms. Hyperventilating (blowing off CO₂) does not produce a panic attack nor relieve it. It’s just a symptom of one. However, educating the patient on consciously slowing her breathing—using slow, deep breaths—may help abort the panic attack. In fact, there’s an app for that. Refer patients to Breathe2Relax (or similar apps). Quiet rooms and reassurance can also help.

You begin to discuss treatment options with this patient.

Question 23.6.8 Which of the following is NOT an effective treatment of panic disorder?

- A) Benzodiazepines such as clonazepam (Klonopin)
- B) Bupropion (Wellbutrin)
- C) Psychotherapy such as CBT
- D) SSRIs such as fluoxetine (Prozac)
- E) TCAs such as imipramine

Answer 23.6.8 The correct answer is “B.” Bupropion is not the best choice for anxiety disorders as it can exacerbate anxiety in many patients. More effective medications include SSRIs, SNRIs, and TCAs; no class has proven superior, and medication choice is based on safety, comorbid illnesses, tolerability, adverse effect profile, history of substance use, cost, etc. SSRIs are frequently considered first line. Psychotherapy has been found to be as effective as medications for the treatment of mild-to-moderate panic disorder and can be used in combination with medications for more severe cases.

As you decide on the medication and dosage, you remember an article you just read in a journal on common mistakes made by physicians treating panic disorder in the community.

Question 23.6.9 Which of these is NOT one of the common mistakes made in the treatment of panic disorder?

- A) Starting the SSRI too high
- B) Not achieving a high-enough target dose
- C) Underutilization of benzodiazepines
- D) Too slow a titration
- E) Often using medications not proven to work with panic disorder

Answer 23.6.9 The correct answer is “C.” Far from being underutilized, benzodiazepines are often overprescribed. While effective for panic disorder, problems with tolerance, dependence, and abuse limit benzodiazepines as long-term agents for panic disorder. Patients with panic disorder are extremely sensitive to medication side effects and are likely to suffer from jitteriness and restlessness if started at a high dose of an SSRI. In order to reduce the chances of precipitating jitteriness and

restlessness, a lower dose of SSRI (about half the starting dose used to treat depression) is usually recommended. The same problems can occur with rapidly increasing doses of SSRIs, so “start low and go slow,” increasing the dose every 2 to 4 weeks to reach the maximum allowable dose. Benzodiazepines are at least third line (after CBT and SSRIs). *A plea: avoid alprazolam (Xanax) like the plague.* It is addictive, short-acting, and has a rebound effect which may be indistinguishable from a panic attack/anxiety disorder even after missing or being late for one dose. Short-acting drugs such as alprazolam often lead to withdrawal symptoms and subsequent abuse. If you are going to choose a benzodiazepine, choose one that is longer acting such as clonazepam or diazepam. Taper benzodiazepines as soon as possible. Avoid them in patients with severe personality disorders and substance abuse.

Your patient says, “I know another female in the reserve who has something similar, but I’ve never noticed the guys to have a problem. Is this just something that happens to women?” You tell her a bit about gender differences in anxiety disorders.

Question 23.6.10 Which of these is NOT true about the gender ratio of the following disorders?

- A) Generalized anxiety disorder affects more women than men in a 2:1 ratio
- B) Panic disorder affects more women than men in a 2:1 ratio
- C) PTSD affects more men than women in a 2:1 ratio
- D) Social anxiety disorder affects slightly more women than men

Answer 23.6.10 The correct answer is “C.” Many affective illnesses (mood and anxiety disorders) including depression and some anxiety disorders are socially determined sexist: women are more likely to be affected than men. All of the options listed are correct except “C,” which inverts the true ratio.

► **Objectives: Did you learn to ...**

- Evaluate patients with anxiety symptoms?
- Recognize panic attacks and diagnose panic disorder?
- Initiate treatment of panic disorder?
- Describe some epidemiologic issues with anxiety disorders?

► **CASE 23.7**

You have a 34-year-old male patient who has started sustained-release bupropion (Wellbutrin SR) 150 mg BID for depression. He reports partial but not total resolution in his symptoms. He also thinks that the medication is causing some side effects.

Question 23.7.1 Which of the following is the most likely adverse effect attributable to this medication?

- A) Insomnia
- B) Sexual dysfunction

- C) Weight gain
- D) QT prolongation
- E) Nicotine cravings

Answer 23.7.1 The correct answer is “A.” Bupropion is associated with vivid dreams and insomnia. Taking the second dose no later than 4 PM can help reduce this of this side effect (or use a long-acting bupropion preparation). Unlike most other antidepressants, bupropion is not associated with sexual dysfunction or weight gain. In fact, it has been associated with weight loss in the short term, and patients who quit smoking are less likely to gain weight if they are taking it. Bupropion can cause dry mouth and nausea, which are usually self-limited. It does not cause QT prolongation, unlike TCAs, some SNRIs, and citalopram/escitalopram. Bupropion appears to curb the cravings for nicotine. It lowers the seizure threshold and should be avoided in patients with epilepsy.

This patient is relatively healthy and takes no other medications, giving you a wide number of options for treatment. In other words, you did not have to think too hard before starting bupropion. However, sometimes you have to use your brain, so let’s think about when not to use bupropion.

Question 23.7.2 In which of the following disease states would bupropion be contraindicated?

- A) Hypertension
- B) Severe depression
- C) Bulimia nervosa (BN)
- D) Bipolar depression
- E) Borderline personality disorder

Answer 23.7.2 The correct answer is “C.” Bupropion is contraindicated in patients with anorexia nervosa (AN) or BN (an increased risk of seizures is found in both diseases) or a current or past seizure disorder. Don’t use bupropion in patients taking an MAOI because of the risk of hypertension. Bupropion is as effective as the other antidepressants, and it can be used in bipolar depression (with extreme caution) and severe depression.

He makes a change in his dosing to move the second daily dose earlier and works on some sleep hygiene and meditation, but his insomnia persists. You decide to switch his medication from bupropion to citalopram (Celexa).

Question 23.7.3 Which is the best way to accomplish this switch?

- A) Stop the bupropion immediately and then wait for 2 weeks before starting citalopram
- B) Taper the bupropion over 2 weeks to avoid a discontinuation syndrome, and then start the citalopram
- C) Start citalopram immediately, and then taper the bupropion over several days
- D) Start citalopram now, then taper off the bupropion a couple of weeks later if he is doing well

Answer 23.7.3 The correct answer is “C.” Unlike SSRIs, which can cause a serotonin withdrawal syndrome (see below), bupropion can be discontinued with a minimal (if any) taper. A brief taper may avoid a sudden rebound of depressive symptoms, while the new agent is started. “A” is incorrect. Bupropion can be taken with an SSRI. However, “D” is less desirable, as it is preferable to stop the bupropion rather than continuing it indefinitely while taking another medication, especially since the patient is experiencing side effects. A single effective agent is generally preferred if possible.

► **Objectives: Did you learn to ...**

- Use bupropion appropriately?
- Identify adverse effects of bupropion?
- Recommend strategies to transition from bupropion to another antidepressant?

QUICK QUIZ: HOMESICK

A 22-year-old college student who moved to your town from Lagos, Nigeria, last month is referred to you by his academic advisor for concerns that he may be depressed. Although he speaks English well, he does not know anyone in town. His family is still in Lagos, and he does not anticipate returning to see them anytime soon. He has not made many friends yet. He enjoys watching soccer in his spare time (which, of course, nobody in the United States appreciates, but that is another matter and it is still more interesting than Cricket). He is not sleeping well and he feels quite homesick.

Which of the following is the most appropriate diagnosis at this time?

- A) MDD
- B) Adjustment disorder
- C) Bipolar affective disorder
- D) Dysthymia
- E) Footballer's withdrawal syndrome

The correct answer is “B.” Adjustment disorder describes a cluster of symptoms that may include emotional or behavioral symptoms that occur in response to identifiable stressor(s). Symptoms must start within 3 months of the onset of the stressor(s) and there should be no other psychological diagnosis that accounts for the symptoms, such as MDD. The patient's distress should be above and beyond that which would be expected from exposure to the stressor. There should be impairment in social or occupational/academic functioning. The patient's symptoms cannot be due to bereavement (a separate diagnosis). Once the stressor is eliminated, the symptoms should resolve within 6 months. Treatment depends on the level of distress and can range from supportive care to active intervention with medications, therapy, or hospitalization. There are several subtypes of adjustment disorder including: with depressed mood, with anxiety, with disturbance of conduct, and mixed episodes.

► **CASE 23.8**

An 85-year-old woman is brought to the emergency department by her daughters because she has been acting strangely lately. Her house is a mess, even though for most of her life she has been quite fastidious. She has been calling her daughters at odd hours of the night, upset and insisting that her youngest daughter is stealing her money. During the day, she goes outside of her house in her nightgown and housecoat, again quite unlike her usual customs. Four months ago, her husband of 58 years was diagnosed with a brain tumor. His condition has deteriorated quite rapidly, and he is now in a nursing home and does not recognize his wife or daughters. The daughters have attributed the patient's odd behavior to the stress she is under. But as her symptoms have continued to worsen, they have become quite concerned and decided to bring her in for evaluation.

In the emergency department, the patient is dressed in her housecoat and slippers and appears disheveled. She is lying on a cart, but she keeps trying to get up and leave. She is angry at her two daughters who are with her, and she is uncooperative with the physical examination. When you ask her about what has been happening, she appears distrusting, and her answers do not make sense.

Question 23.8.1 Which of the following diagnoses is LEAST likely at this point in time?

- A) Delirium
- B) Dementia
- C) Bereavement
- D) Psychotic depression
- E) Alcohol abuse

Answer 23.8.1 The correct answer is “C.” Although your patient's husband is gravely ill and she is grieving, her symptoms are more severe than what is expected for bereavement. Bereavement is a normal process, but it does not include severe impairment in social or occupational functioning, nor does it include paranoid delusions or other psychotic symptoms. All of the other diagnoses listed could result in the severity of symptoms described in this case.

Question 23.8.2 Which of the following tests is indicated in the evaluation of this patient's behavior changes?

- A) Chest x-ray
- B) Urinalysis
- C) CBC
- D) Vitamin B12 levels
- E) All of the above

Answer 23.8.2 The correct answer is “E.” A thorough medical workup is warranted in the patient with “mental status changes” (e.g., delirium and new-onset psychotic symptoms). Several medical problems—infection, hypoxia, MI, to name a few—can cause the symptoms the patient is experiencing and must be ruled out.

Her workup does not reveal an organic cause for her altered mental state. You are now suspecting that she has psychotic depression.

Question 23.8.3 All of the following are appropriate management options at this time EXCEPT:

- A) Discharge with referral for outpatient psychotherapy
- B) Admission to a psychiatric unit
- C) ECT (electroconvulsive therapy)
- D) Psychiatric consultation

Answer 23.8.3 The correct answer is “A.” Psychotherapy is not an appropriate single therapy for psychotic depression—especially in this patient, whose symptoms are so severe. “B” is appropriate, as the patient may benefit from hospitalization. “C” is appropriate as well. ECT is effective in treating psychotic depression and is often indicated if safety is of immediate concern or an early response is needed. “D” is appropriate. In general, patients with psychotic depression should be referred to a psychiatrist.

HELPFUL TIP: A STIMULATING THOUGHT

In recent years, there have been some advancements in brain stimulation therapies for mental health disorders. Repetitive Transcranial Magnetic Stimulation (rTMS) was approved by the FDA in 2008, but didn't gain popularity until 2010 when a study by the National Institute for Mental Health found a fourfold greater rate of remission in patients with resistant depression compared to sham therapy (*Arch Gen Psych.* 2010 May;67(5): 507–516). Benefits of rTMS are that it only takes 30 to 60 minutes, does not require anesthesia, and is more targeted than ECT. Subsequent data is less compelling, but it is still a viable alternative.

Vagus nerve stimulation (VNS) was initially improved for treatment of resistant epilepsy, but was found to have beneficial effects in resistant depression. It was approved by the FDA in 2005 to treat resistant depression if the following conditions are met: patients > 18 years old, depressive illness x 2 years or more, severe or recurrent depression, and depression has not eased after trial of four different treatments. The most rigorous data suggests vagus nerve stimulation is not effective for depression.

Stay tuned as Deep Brain Stimulation (DBS) (yes, the one initially developed for treatment of Parkinson's) and Magnetic Seizure Therapy (MST) are also being developed and studied as possible treatments for mental health disorders.

You determine that your patient's symptoms are severe enough for hospitalization. Her daughters agree, but the patient is adamantly opposed and insists on returning to her home. She's sick of you “NSA-types pushing her around (the one government agency that actually listens to you!),” and

“if you don't let her go, she's going call her friend, Donald Trump.”

Question 23.8.4 How would you proceed?

- A) Call hospital security and make plans to hospitalize her; after all, she appears quite ill and cannot care for herself; when she is well, she will understand that it was the right plan
- B) Discharge her home, asking her daughters to take turns staying with her until she is better
- C) Follow state-dictated protocol to attempt to obtain a legal order for hospitalization against her will
- D) Follow national protocol (New World Order Directive 55.12.A) to attempt to obtain a legal order for hospitalization against her will
- E) Make a medical determination that she is not competent, allowing you to hospitalize her despite her objection

Answer 23.8.4 The correct answer is “C.” Each state has its own laws that govern how an involuntary hospitalization process is conducted. If the patient poses an imminent threat to herself or others, the law generally allows involuntary hospitalization for a brief period of time until a court hearing is held. Involuntary hospitalization is also allowed if the patient is unable to care for herself and she is suffering from a mental illness that renders her incapable of making healthcare decisions (of course if there are surrogates/durable power of attorney for healthcare, they can help with the decision). “D” is incorrect. There are no national laws governing involuntary hospitalization (and the New World Order is a paranoid delusion of some extremists ... or maybe we just want you to believe that). “B” is incorrect. Because of the severity of this patient's symptoms, it would be inappropriate and unsafe to simply discharge her to the care of her daughters.

You have admitted the patient under a 72-hour hold, and you are discussing treatment options with the psychiatrist, who thinks that ECT might be appropriate. You are concerned about cognitive problems in this patient.

Question 23.8.5 All of the following are associated with an increased risk of memory loss with ECT EXCEPT:

- A) Bilateral electrode placement
- B) High stimulus doses
- C) History of seizure disorder
- D) Baseline cognitive functioning
- E) Type of anesthesia

Answer 23.8.5 The correct answer is “C.” A history of seizure disorder is not associated with an increased risk of memory loss with ECT. ECT is known to cause transient problems with memory loss. This usually manifests with the patient having trouble remembering events that occur around the time of the ECT. Most of the memory complaints completely resolve within a few months of completing ECT. However, some situations may increase the risk of memory loss, including bilateral electrode placement (unilateral is safer) and a higher stimulus dose.

In further discussions with the patient and her family, you try to explain ECT and dispel some myths.

Question 23.8.6 All of the following are potential complications or adverse effects of ECT EXCEPT:

- A) Delirium
- B) Nonsustained ventricular tachycardia
- C) Headache
- D) Dementia
- E) Fatigue

Answer 23.8.6 The correct answer is “D.” Although transient memory loss and even delirium can occur after ECT, it does not cause dementia. A number of cardiac rhythm disturbances can occur and are more likely in patients with cardiac disease. However, these are self-limited and generally minor (e.g., premature ventricular contractions, atrial premature complexes, and nonsustained ventricular tachycardia). Headache and fatigue are common after ECT.

► **Objectives: Did you learn to ...**

- Recognize abnormal behavior and generate an appropriate differential diagnosis?
- Evaluate a patient with new cognitive and behavioral problems?
- Determine when involuntary hospitalization is appropriate and how it might be undertaken?
- Discuss potential adverse effects of ECT?

QUICK QUIZ: A REALLY BAD WEEK

A 47-year-old female presents to your clinic in tears, requesting your help. She cannot stop crying, her sleep is poor, and she feels terribly lonely. However, she is able to carry out all life functions with little decrement in ability. She tells you that last week her mother had a stroke. Her mother survived, but is now in a nursing home and suffering from Broca’s aphasia. Your patient describes her mother as her “best friend.” She has not had trouble with depression or other mental illness in the past.

Which of the following is the most likely diagnosis?

- A) Bereavement
- B) Adjustment disorder
- C) MDD
- D) Bipolar affective disorder
- E) Dysthymia

The correct answer is “A.” Bereavement is a natural reaction to a significant loss. Some of the symptoms may mimic those of depression or adjustment disorder, which can throw you off the track of making the proper diagnosis. Unlike bereavement, both depression and adjustment disorder must, by definition, cause *significant impairment*. In bereavement, feelings of emptiness or loss tend to predominate while MDD is associated

with more persistent depression. Additionally, in bereavement self-esteem tends to remain intact, while in MDD people often have feelings of worthlessness. Our patient has only a minor decrement in her level of functioning. The duration and expression of bereavement differs among different cultural groups and subgroups, further complicating the diagnostic process.

► **CASE 23.9**

You get a call from a patient complaining of “not feeling well and getting worse” over the past 3 days. She has had electrical shock sensations in her upper extremities and head and also complains of dizziness and malaise. She takes no medications since she self-discontinued her paroxetine (Paxil) and bupropion (Wellbutrin) a few days ago.

Question 23.9.1 Which of the following is the most likely diagnosis?

- A) Influenza
- B) Bupropion discontinuation syndrome
- C) SSRI discontinuation syndrome
- D) Serotonin syndrome
- E) Hypertensive crisis

Answer 23.9.1 The correct answer is “C.” OK, so this was a soft pitch. We already told you above that bupropion does not have a discontinuation syndrome. A discontinuation syndrome (also known as withdrawal syndrome) has been associated with SSRIs when they are suddenly stopped or doses are missed or reduced. This is especially common with paroxetine (Paxil) because of its short half-life. The symptoms described above are typical of the discontinuation syndrome, particularly the paresthesias that patients often describe as an “electric shock” (Table 23-1).

TABLE 23-1 SYMPTOMS OF SSRI DISCONTINUATION SYNDROME

Somatic Symptoms

- Disequilibrium (e.g., dizziness, vertigo, ataxia, and tremor)
- Gastrointestinal symptoms (e.g., nausea, vomiting, and anorexia)
- Flu-like symptoms (e.g., fatigue, lethargy, myalgias, chills, and headache)
- Sensory disturbances (e.g., paresthesias and sensations of electric shock)
- Sleep disturbances (e.g., insomnia and vivid dreams)

Psychological Problems

- Anxiety/agitation
- Crying spells
- Irritability
- Overactivity
- Depersonalization
- Decreased concentration/slowed thinking
- Confusion and memory problems

Question 23.9.2 Which of the options below is **INCORRECT** information to give the patient over the telephone?

- A) Symptoms usually begin within a few days of stopping the SSRI
- B) The symptoms rarely last longer for 2 weeks and are self-limited
- C) Restarting the medication takes about 2 weeks to relieve symptoms
- D) The longer the patient has been on the medication, the more likely the risk of a discontinuation syndrome

Answer 23.9.2 The correct answer (or **INCORRECT** answer) is **"C."** Symptoms can be noticeable in some patients with just one missed dose (especially with paroxetine [Paxil]), but typically develop within 2 days of medication discontinuation. The syndrome is uncomfortable but usually self-limited, lasting <2 weeks. Restarting the medication will lead to cessation of symptoms within 24 hours in virtually all cases. The risk of discontinuation increases with length of therapy, particularly when the patient has been on an SSRI longer than 7 weeks.

Question 23.9.3 Which SSRI is **LEAST** likely to cause a discontinuation syndrome?

- A) Fluoxetine (Prozac)
- B) Sertraline (Zoloft)
- C) Paroxetine (Paxil)
- D) Citalopram (Celexa)
- E) Fluvoxamine (Luvox)

Answer 23.9.3 The correct answer is **"A."** The risk of withdrawal increases with **shorter** half-lives. The half-life of fluoxetine (Prozac) is about 4 to 6 days, while its active metabolite nor-fluoxetine has a half-life up to 16 days, making it highly unlikely that fluoxetine would cause a discontinuation syndrome in most patients, as it effectively acts as its own taper. Fluvoxamine (Luvox) (with a half-life of 15 hours) and paroxetine (Paxil) (21 hours) have the shortest half-lives and are most likely to cause the discontinuation syndrome. To minimize the risk of withdrawal syndrome, taper off SSRIs when stopping them.

HELPFUL TIP:

Discontinuation syndrome is likely a hyposerotonergic state; therefore, all serotonergic agents can cause a withdrawal syndrome. These agents include SSRIs, MAOIs, TCAs, serotonin–norepinephrine reuptake inhibitors (SNRIs), and mirtazapine (Remeron) ... but not bupropion (is that horse dead or should we beat it some more?).

Your patient restarts her SSRI and feels better. She has questions about antidepressants in general, wondering if she is taking the right one. As you start to discuss benefits and risks of different medications, you remind yourself about some important issues. For example, all SSRIs are not the same.

Question 23.9.4 Which SSRI has the most anticholinergic activity?

- A) Fluoxetine (Prozac)
- B) Paroxetine (Paxil)
- C) Sertraline (Zoloft)
- D) Citalopram (Celexa)
- E) Escitalopram (Lexapro)

Answer 23.9.4 The correct answer is **"B."** With the exception of paroxetine (Paxil), SSRIs do not possess appreciable anticholinergic activity. Do you get the idea we don't like paroxetine?

Question 23.9.5 Which of the following SSRIs is **LEAST** likely to have drug–drug interactions via cytochrome P450 enzymes?

- A) Fluoxetine (Prozac)
- B) Paroxetine (Paxil)
- C) Citalopram (Celexa)
- D) Sertraline (Zoloft)
- E) Fluvoxamine (Luvox)

Answer 23.9.5 The correct answer is **"C."** Citalopram (Celexa) and its stereoisomer, escitalopram (Lexapro), have relatively clean profiles with no major interactions with any of the cytochrome P450 enzymes. Of course, this benefit of citalopram (Celexa) is tempered by its known problems with QT prolongation, which can be exacerbated by other QT prolonging drugs. Sertraline (Zoloft) is also an attractive option if drug–drug interactions are a concern. The other three have significant inhibition of CYP enzymatic pathways and drug–drug interactions that have clinical importance. Paroxetine and fluoxetine are potent inhibitors of the CYP2D6 enzymatic pathway, while fluvoxamine is a potent inhibitor of the CYP1A2 pathway.

Question 23.9.6 Mirtazapine (Remeron) is commonly associated with all of the following side effects **EXCEPT**:

- A) Sedation
- B) Weight gain
- C) Dizziness
- D) Lycanthropy
- E) Increased triglycerides

Answer 23.9.6 The correct answer is **"D."** Lycanthropy is, of course, the ability to transform into a werewolf. Although close in behavior to antisocial personality disorder, lycanthropy is **NOT** caused by mirtazapine but rather by the bite of another lycanthrope. Mirtazapine is a potent antihistamine, and an α_2 -adrenergic antagonist, potentially leading to orthostatic hypotension. Sedation is present in over 50% of patients taking the drug, while weight gain is reported in as many as 12%. It can also lead to increased triglycerides. Paradoxically, the side effect of sedation lessens with increasing doses. It is a great antidepressant for patients who have lost their appetite, lost weight, or have insomnia. Typical doses range from 15 to 60 mg/day, with a starting dose between 7.5 and 15 mg.

Question 23.9.7 Which of the following antidepressants has a black box warning about hepatic failure?

- A) Nefazodone (Serzone)
- B) Bupropion (Wellbutrin)
- C) Paroxetine (Paxil)
- D) Nortriptyline (Pamelor)
- E) Phenelzine (Nardil)

Answer 23.9.7 The correct answer is “A.” Nefazodone (Serzone) is a 5HT-2A receptor antagonist and is an effective antidepressant with sedative properties. It has significant inhibitory effects on CYP3A4 and has several significant drug interactions as a result. In the recent past, several cases of hepatic failure have been reported with this drug, leading to a black box warning on the package insert and limiting its clinical use. None of the other antidepressants listed have had such problems.

Question 23.9.8 Venlafaxine (Effexor) has been noted to typically cause all of the following side effects EXCEPT:

- A) Increased blood pressure
- B) Dizziness
- C) Dry mouth
- D) Weight gain
- E) Sexual disturbance

Answer 23.9.8 The correct answer is “D.” Venlafaxine (Effexor) and duloxetine (Cymbalta) are both norepinephrine and serotonin reuptake inhibitors and have minimal activity on the cholinergic, histaminergic, and α -receptors. There is a dose-related increase in blood pressure (“A”), with a mean elevation of 10 to 15 mm Hg in diastolic pressure at doses of 300 mg or greater in up to 10% of patients. There is a slight increase in pulse, as well. “D” is not true. In fact, weight loss is a common complaint. Otherwise, venlafaxine (Effexor) and duloxetine (Cymbalta) generally have the same side-effect profile as the SSRIs, potentially causing sexual dysfunction (“E”), dizziness (“B”), and dry mouth (“C”). Patients can have a significant withdrawal from venlafaxine mimicking a “flu-like” illness and should be tapered off it slowly.

HELPFUL TIP: ANTIDEPRESSANTS AND BIRTH DEFECTS

Fluoxetine (Prozac) and paroxetine (Paxil) are **associated** with birth defects in some studies. Most studies do not control for maternal mental illness, which is likely a confounding variable. This doesn't prove causality and the chance is slight (e.g., anencephaly risk goes from 2 in 10,000 to 7 in 10,000). However, it is worth discussing risks and benefits with the prospective parents. The other SSRIs do not seem to have the same association (*BMJ*. 2015;351:h3190). SSRI *do* predispose to persistent pulmonary hypertension of the newborn. We still don't like paroxetine (Paxil).

HELPFUL (AND SCARY) TIP:

Venlafaxine (Effexor) and duloxetine (Cymbalta) are toxic in overdose. They cause QT and QRS prolongation in overdose. Treatment is the same as the treatment of TCA overdose (bicarbonate, etc.), although data is limited. Remember that citalopram (Celexa)/escitalopram (Lexapro) can cause a prolonged QT interval with both regular doses and in overdose.

You decide to switch the patient to fluoxetine (Prozac) and she does well.

► Objectives: Did you learn to ...

- Identify SSRI discontinuation syndrome?
- Recognize important antidepressant interactions?
- Describe adverse effects of various antidepressants?

QUICK QUIZ: MAOIS

You are seeing a new patient with a history of recurrent major depression. Many years ago a different physician put him on phenelzine (Nardil), which you recognize as having potentially serious food and drug interactions. You are considering switching him to an SSRI.

How long after an MAOI is discontinued can an SSRI be started?

- A) 1 day
- B) 3 days
- C) 7 days
- D) 14 days
- E) SSRIs and MAOIs can be given together

The correct answer is “D.” Because of significant drug–drug interactions (see next question), SSRIs should not be started until 2 weeks after discontinuation of an MAOI.

QUICK QUIZ: MAOI + SSRI = BADNESS

What is the drug–drug interaction of concern with SSRIs and MAOIs?

- A) Stevens–Johnson syndrome
- B) Serotonin syndrome
- C) Anticholinergic crisis
- D) Hypertensive crisis
- E) Existential crisis

The correct answer is “B.” Serotonin syndrome is caused by an excess of serotonin and can be caused by drug–drug interactions involving serotonergic agents including SSRIs, buspirone (Buspar), meperidine (Demerol), dextromethorphan, lithium, tramadol (Ultram), and triptans, among others. MAOIs inhibit monoamine oxidase, which is an enzyme involved in the

metabolism of many neurotransmitters, including serotonin. Therefore, MAOIs increase serotonin as well. Serotonin syndrome is characterized by muscle rigidity, hyperreflexia, hyperthermia, confusion, and agitation among other symptoms. It can be fatal. As a result, the concurrent use of an SSRI and MAOI is absolutely **CONTRAINDICATED**. Stevens–Johnson syndrome (“A”) is an autoimmune dermatological disorder that leads to desquamation of mucosal surfaces and is not associated with antidepressant use (although it can be seen with other drugs). Anticholinergic crisis (“C”) is not a term used in common medical parlance but does evoke the idea of anticholinergic syndrome, caused by excess anticholinergic drugs, such as TCAs, etc. (see Chapter 1). Hypertensive crisis (“D”) occurs when foods containing tyramine (e.g., aged cheese and cured meats) interact with MAOIs to release catecholamines, causing hypertension, headaches, nausea, and diaphoresis. In severe cases, it can lead to strokes or death.

HELPFUL TIP(S):

Linezolid (Zyvox) is absolutely contraindicated with MAOIs. It is a serotonergic drug. Among the foods that cause a hypertensive crisis with an MAOI are banana peels (but not the banana ... we are not sure who figured this one out ...), aged meats (best avoided anyway if you think about it), draught beer (boo) but not bottled beer (yes!), and kimchi/sauerkraut.

► CASE 23.10

A 43-year-old man who you started on citalopram (Celexa) for depression 4 weeks ago returns for a follow-up visit. He feels better but complains of delayed ejaculation. You consider changing him to an antidepressant that is less likely to cause sexual dysfunction.

Question 23.10.1 Which of the following would you AVOID?

- A) Nefazodone (Serzone)
- B) Bupropion (Wellbutrin)
- C) Mirtazapine (Remeron)
- D) Trazodone (Desyrel, Oleptro)
- E) Nortriptyline (Pamelor)

Answer 23.10.1 The correct answer is “E.” Sexual dysfunction is a common side effect of most psychotropics. There are few controlled data to guide us as to how to approach this issue, but sildenafil (Viagra) and similar drugs are effective in antidepressant-induced erectile dysfunction. Of the options given, nortriptyline (Pamelor)—and other TCAs—are more frequently associated with sexual dysfunction.

HELPFUL TIP:

St. John’s wort may be effective in mild-to-moderate depression. However, it is a known inducer of the CYP450 enzyme, reducing the efficacy of oral contraceptives.

It has also been associated with decreased efficacy of antiretrovirals, cyclosporine, digoxin, theophylline, and warfarin.

This patient is also having sleep difficulties and asks what herbal therapy he might be able to use.

Question 23.10.2 Which of the following is a herbal alternative to benzodiazepines for anxiety and insomnia?

- A) Valerian root
- B) St. John’s wort
- C) Saw palmetto
- D) Ginseng
- E) Ginkgo

Answer 23.10.2 The correct answer is “A.” Valerian root (*Valeriana officinalis*) has been touted to have anxiolytic properties, similar to benzodiazepines, and its mechanism of action is thought to be similar (e.g., inhibition of GABA). It appears to be safe and has the same drug interactions and contraindications as benzodiazepines. The other options are not known to affect sleep to a significant degree.

HELPFUL TIP:

Kava-kava is advertised as an anxiolytic but should generally be avoided. Kava-kava (*Piper methysticum*) has been reported to cause liver damage, in some cases leading to liver transplant or eventual death.

► **Objectives: Did you learn to ...**

- Identify which antidepressants are less likely to cause sexual dysfunction?
- Recognize herbal therapies that might be employed in treating symptoms of depression?

► CASE 23.11

You are seeing a 28-year-old female whose first child you delivered a month ago. She comes to your clinic with her son for his 1-month well-child check. You observe that she seems tired and is less animated than usual. She is gentle with her infant, but her face doesn’t seem to light up with the glow that you often see with new mothers. You know ... the glow of terror, sleeplessness, and anxiety? That’s the one.

Question 23.11.1 Which of the following best explains your observations?

- A) Sleep deprivation
- B) Marital discord at home
- C) Postpartum depression
- D) Thyroid dysfunction
- E) Any of the above

Answer 23.11.1 The correct answer is “E.” Your patient’s symptoms could be due to any of these problems and more, including difficulty with role adjustment, alcohol or drug abuse, and anemia.

You want to gather more information to see if there is a pathological process underlying her behavior.

Question 23.11.2 You would do all of the following EXCEPT:

- A) Ask her to fill out an Edinburgh Postnatal Depression Scale (EPDS)
- B) Order thyroid function tests
- C) Order a sleep study
- D) Ask more questions about how things are at home and how she is coping
- E) Ask about a previous history of depression

Answer 23.11.2 The correct answer is “C.” In this case, there are many other more likely problems than a primary sleep disorder, and a sleep study is unlikely to be helpful (plus as those of us who have had infants know, your sleep is naturally disordered). The EPDS is a validated self-rated scale that is useful for detecting postpartum depression. Hypothyroidism can always mimic depression and might need to be ruled out. A thorough history is always essential.

Question 23.11.3 The incidence of postpartum depression is about:

- A) 1%
- B) 10%
- C) 30%
- D) 50%

Answer 23.11.3 The correct answer is “B.” About 7 in 10 women suffer from “baby blues,” postpartum symptoms that can manifest as mood swings, anxiety, fatigue, and sadness occurring within a few days of delivery and lasting only a week or so. However, postpartum depression affects approximately 10% of women, and symptoms can appear anywhere from weeks to months after birth. The diagnosis is often missed because many mothers are ashamed to admit feeling unhappy at a time when they think (and society tells them) that they should be happy. Physicians may focus on the infant’s physical health and miss assessing the mother–baby interaction.

In obtaining more history, you realize that this patient was having some troubles with depression even during her pregnancy.

Question 23.11.4 When is the most common time for pregnancy-related depression to occur?

- A) At conception
- B) First trimester
- C) Second trimester
- D) Third trimester
- E) Postpartum

Answer 23.11.4 The correct answer is “D.” A large epidemiological study from the United Kingdom followed pregnant women prospectively throughout the course of their pregnancies and found that the **incidence of depression was actually higher in the third trimester than it was in the postpartum period.** This suggests the need for the physician to begin to enquire about symptoms earlier. Updated USPSTF recommendations in 2016 for depression screening included screening pregnant and postpartum women. The EPDS, PHQ-9, or other screening tools can be used to assist with screening.

HELPFUL TIP:

Repeat after us, “Pregnancy does not treat depression.” For some reason, it had been assumed in the past that a woman’s depression would abate during pregnancy. Studies in the last couple of years have disproved this myth making ongoing treatment for depression crucial.

If you had been aware of her depression earlier and wanted to prescribe an antidepressant during her pregnancy, you would have been cautious, hoping to prescribe a drug with the most robust safety data in pregnancy—you’re just that kind of doctor.

Question 23.11.5 Which of the following antidepressants is generally considered safest in pregnancy?

- A) Sertraline (Zoloft)
- B) Bupropion (Wellbutrin)
- C) Nortriptyline (Pamelor)
- D) Mirtazapine (Remeron)
- E) Paroxetine (Paxil)

Answer 23.11.5 The correct answer is “A.” There is no antidepressant (or any medication for that matter) that is 100% safe in pregnancy. There is also a growing field of study examining the impact of untreated maternal depression and other mental illness on pregnancy. This is not to say that antidepressants must be avoided in pregnancy, but the benefits and risks should be weighed carefully.

Question 23.11.6 Risks associated with SSRI use during pregnancy include all of the following EXCEPT:

- A) Irritability of the neonate
- B) Preterm delivery
- C) Low birth weight
- D) Persistent pulmonary hypertension
- E) Tetralogy of Fallot

Answer 23.11.6 The correct answer is “E.” SSRIs have not been linked to development of Tetralogy of Fallot. However, some studies suggest adverse effects with SSRI use in pregnancy, including neonatal irritability, low birth weight, and preterm labor. In many of the studies, it is difficult to determine whether adverse effects are related to the SSRI, maternal depression, or other factors. Infants exposed to SSRIs during the

second half of pregnancy (i.e., after 20 weeks gestation) had an increased risk (approximately 1% absolute risk) of developing **persistent pulmonary hypertension, not a birth defect** but still a potentially life-threatening condition, after birth (*BMJ*. 2012;344:d8012). Other studies have not demonstrated this association, and more information is needed. Shared decision-making, including weighing the risks and benefits, with the patient is crucial. *Mothertobaby.org* and *womensmentalhealth.org* have resources to aid this discussion.

Question 23.11.7 If you had decided to prescribe an antidepressant medication for her during pregnancy, which one of the following would have been LEAST desirable?

- A) Paroxetine (Paxil)
- B) Sertraline (Zoloft)
- C) Nortriptyline (Pamelor)
- D) Citalopram (Celexa)

Answer 23.11.7 The correct answer is “A.” Although no antidepressant medication has been shown to be risk-free when used during pregnancy, paroxetine (Paxil) is the only antidepressant with increased incidence of cardiac anomalies (mainly atrial and ventricular septal defects) in infants who were exposed in utero. Do you still think we don’t like paroxetine?

You start her on sertraline (Zoloft) and offer to watch her baby for a few days (she’s so cute!), and everyone is happy.

► **Objectives: Did you learn to ...**

- Recognize the high incidence of depression and depressive symptoms in the postpartum period?
- Diagnose postpartum depression?
- Treat depression in the pregnant and postpartum patient?

► **CASE 23.12**

A couple, you have known for some time, brings in their 7-year-old son, Jimbo, to your clinic because his behavior has changed over the past month. His school performance has worsened, and he has started to get into fights at school. He is not eating as well and is having frequent nightmares. He now has frequent headaches and stomach aches and clings to his mother when it is time to go to school. The parents cannot understand what is going on and report no antecedent trauma.

Question 23.12.1 Which of the following is the most likely diagnosis?

- A) MDD
- B) Disruptive mood dysregulation disorder
- C) Adjustment disorder
- D) Bereavement
- E) Normal childhood difficulties

Answer 23.12.1 The correct answer is “A.” Up to 3% of children and 9% of adolescents suffer from depression. DSM-5 criteria are the same as in the adult, except **irritability can be**

substituted for the depressed mood requirement in children. Disruptive mood dysregulation disorder (“B”) is a new addition to DSM-5. It is characterized by severe, persistent irritability. There must be frequent temper outbursts, grossly out of proportion to the inciting event, that occur over the course of at least a year and must be in two different settings. Symptoms are present before age 10. Adjustment disorder (“C”) is not likely since there have been no major changes in the child’s regimen, and bereavement (“D”) is not likely since there have been no losses in the child’s life. This patient’s symptoms are clearly not part of normal childhood (“E”), even if his name is Jimbo.

HELPFUL TIP:

Of course, bullying at school and other social problems need to be investigated when any child presents with symptoms of depression.

Question 23.12.2 Which of the following is NOT true about depression in children?

- A) Abuse or neglect increases the risk of depression
- B) Having a depressed parent increases the risk of being a depressed child
- C) The clinical course is roughly the same as in adults
- D) “Masked” symptoms, such as abdominal pain, are more common in children than the typical symptoms of depression, such as sleep disturbance
- E) Male and female children are equally affected by depression

Answer 23.12.2 The correct answer is “D.” Although clinicians should be aware of age-appropriate manifestations (see Table 23-2), symptoms of depression are similar in children and adults. In fact, typical symptoms of depression are more common in children than are “masked” symptoms such as stomach aches and fear of leaving home.

You tell the family about Jimbo’s prognosis.

TABLE 23-2 COMMON MANIFESTATIONS OF DEPRESSION IN CHILDREN

- Being bored
- Reckless behavior
- Outbursts of shouting, complaining, unexplained irritability, or crying
- Poor school performance
- Fear of death
- Alcohol or substance abuse
- Frequent nonspecific physical complaints such as headaches, muscle aches, stomach aches, or fatigue

Depression in Children and Adolescents, National Institutes of Health Publication No. 00-4744. <http://www.nimh.nih.gov/publicat/depchildresfact.cfm>.

Question 23.12.3 Which of the following statements regarding prognosis is FALSE?

- A) Childhood MDD confers a two- to fourfold increase in risk for adult MDD
- B) About 25% of adolescents with MDD develop substance abuse disorders
- C) Almost half of children with MDD will attempt suicide sometime in their life
- D) Roughly 20% of adolescents have suffered at least one episode of MDD by age 18, while 65% report transient symptoms of depression
- E) After the initial episode, only 10% of children/adolescents will suffer a relapse

Answer 23.12.3 The correct answer is “E.” Between half and two-thirds (not 10%) of children/adolescents will have a recurrence within 5 years after resolution of their first episode. The other options are all true. In children and adolescents, the mean depression episode length is 7 to 9 months with remission typically occurring over 1.5 to 2 years.

**HELPFUL TIP:**

The risk of suicide is very high among depressed youths. It is the third leading cause of death in the 15- to 24-year age group, and children with MDD have a four- to fivefold higher lifetime incidence of suicide attempts than non-depressed children. Fifteen to twenty percent of adolescents have suicidal ideation each year, and 5% to 8% will attempt suicide each year. Pretty depressing statistics, eh?

You recommend treatment for Jimbo.

Question 23.12.4 Which of the following therapies has NOT shown efficacy in childhood depression in randomized controlled trials?

- A) Fluoxetine (Prozac)
- B) Sertraline (Zoloft)
- C) Cognitive Behavioral Therapy (CBT)
- D) Venlafaxine (Effexor)
- E) Interpersonal therapy (IPT)

Answer 23.12.4 The correct answer is “D.” Early reports have demonstrated concerns of increased incidence of emotional lability with use of venlafaxine (Effexor) in children. More importantly, venlafaxine (Effexor) lacks efficacy data in children. The bottom line is that fluoxetine (Prozac) is probably the SSRI of choice in children, followed by sertraline (Zoloft). The number needed to treat for SSRIs is 10 to benefit one child; it may be as low as 4 for fluoxetine (Prozac). Avoid paroxetine (Paxil) since it may be associated with a higher suicide risk (there is a pattern developing here ...). TCAs should be avoided because of lack of efficacy and potential suicide risk. Cognitive behavioral therapy and interpersonal therapy (“C” and “E”) have been shown to be effective in children and adolescents.

**HELPFUL TIP:**

As you would expect, CBT/counseling/therapy plus an antidepressant are more effective than either modality alone. Adverse effects of medication in children are similar to those in adults and include: insomnia, fatigue, headaches, and nervousness. Suicidal thoughts, but not completed suicide, are more common in children and adolescents with SSRI treatment which has led to a black box warning being placed by the US Food and Drug Association (FDA) on SSRI agents for children and adolescents in 2004. This was further extended to the age of 25 in 2006. Despite this, the benefits of antidepressant therapy and SSRIs are felt to outweigh these risks. Moral of the story: Keep a close eye on adolescents who you start on antidepressants, and warn patients and their parents that depression can worsen in the early phase of treatment. Have them return often in the first few months of treatment.

► Objectives: Did you learn to ...

- Increase your awareness of childhood depression?
- Diagnose depression in children?
- Describe the natural history of depression in children?
- Generate an appropriate treatment plan for children with depression?

► CASE 23.13

Tommy is a 9-year-old male who has been having difficulty with his behavior since he started first grade. He is often fidgety and squirming in his chair and has difficulty remaining in his seat. He talks out of turn, is often “on the go,” and is not liked by the other kids because he intrudes into games and has a hard time waiting his turn. His mom also notes similar problems at home. He is the product of an uncomplicated pregnancy and has no significant past medical history.

Question 23.13.1 What is the most likely diagnosis?

- A) Attention-deficit/hyperactivity disorder (ADHD)
- B) Adjustment disorder
- C) Oppositional defiant disorder (ODD)
- D) Conduct disorder (CD)
- E) Specific learning disorder

Answer 23.13.1 The correct answer is “A.” The symptoms of ADHD are listed here. “B,” adjustment disorder, is unlikely since there is no history of a significant life event. ODD (“C”) and CD (“D”) are characterized by aggressive behavior and a disregard for rules and adults. These are not given as part of Tommy’s history. Specific learning disorders (“E”) present with school performance problems and may be associated with ADHD, but would not be directly responsible for this patient’s hyperactivity.

For the diagnosis of ADHD, patients must meet one of the following criteria:

1. At least six symptoms of inattention for at least 6 months that is maladaptive and inconsistent with the level of development:
 - Careless mistakes, poor attention to details
 - Cannot sustain attention
 - Does not seem to listen
 - Poor follow through on tasks
 - Difficulties with organization
 - Avoids or dislikes tasks that require sustained attention
 - Often loses things required for a task (notebooks, pens, etc.)
 - Easily distracted from a task
 - Forgetful in daily activities
2. Six or more of the following hyperactive-impulsive symptoms for 6 months, which are maladaptive and inconsistent with the level of development:
 - Hyperactivity symptoms
 - Fidgets or squirms in seat
 - Leaves seat at inappropriate times
 - Hyperactivity in inappropriate settings
 - Cannot play or relax quietly
 - Always in motion
 - Talks too much
- Impulsivity symptoms
 - Blurts out answer before questions completed
 - Trouble waiting for turn in games, school, etc.
 - Interrupts others (verbally, in games, etc.)
3. In addition to fulfilling criteria 1 and/or 2 above, the following are required:
 - Symptoms must be present *before* age of 12 years.
 - Impairment in two settings (home, work, school, worship, etc.)
 - Clinically significant impairment in social, academic, or occupational spheres
 - Symptoms are not due to another problem (developmental delay, personality disorder, mood disorder, etc.)

Question 23.13.2 Which of the following is FALSE about ADHD?

- A) It affects 3% to 7% of children
- B) There are genetic and environmental influences on the risk of developing ADHD
- C) Males are more likely to be diagnosed with ADHD than females
- D) The incidence of ADHD has increased over the years
- E) Comorbid disorders are not common

Answer 23.13.2 The correct answer is “E.” ADHD affects 3% to 7% of children. Heritability is 70%, similar to that for schizophrenia and bipolar disorder. Alcohol and tobacco exposure in utero have both been linked to at least a twofold increase in risk. Males are twice as likely to be diagnosed with ADHD as females. Comorbid disorders are very common in ADHD with CD, ODD, depression, anxiety, learning disabilities, and developmental delay being the most frequently seen.

Question 23.13.3 Which of the following is NOT TRUE of the prognosis and treatment of Tommy’s ADHD?

- A) The natural history of ADHD is that one-third of children will outgrow the symptoms, one-third will have the same frequency and intensity of symptoms, and one-third will have residual symptoms, which are subclinical
- B) Tommy has a 70% to 80% chance of responding to stimulants
- C) If Tommy is treated with stimulants, his risk of drug abuse is halved
- D) Tommy is at increased risk of getting into accidents
- E) Behavior therapy is effective for reducing ADHD symptoms

Answer 23.13.3 The correct answer is “E.” Unfortunately, intensive behavior therapy has been shown to be ineffective. The breakdown of the prognosis for children with ADHD symptoms is that roughly one-third will experience complete symptom resolution, one-third will get some improvement, and one-third will remain ill with the disorder. Stimulants, which are first-line therapy, will work in 70% to 80% of the patients. If a patient does not respond to the first stimulant, there is still a 70% to 80% chance of responding to a second stimulant. Children treated with stimulants are half as likely to abuse substances as those who are not treated. Children with ADHD are at risk for impulsive behavior and risk-taking, which leads to substance abuse, accidents, etc. There are nonstimulant medication options as well. Atomoxetine (Strattera) guanfacine (Tenex), and clonidine (Catapres) are all FDA approved for the treatment of ADHD.

You decide to start Tommy on methylphenidate.

Question 23.13.4 Which of the following is NOT true about treatment with methylphenidate?

- A) It improves handwriting
- B) Optimal dosing is 0.6 to 1 mg/kg/day
- C) It can cause reduced growth
- D) Short-term memory is not affected
- E) Tommy might get along better with his classmates

Answer 23.13.4 The correct answer is “D.” In fact, stimulants improve short-term memory in patients with ADHD. The rest are true. As to “A,” do you think this is why doctors have notoriously bad handwriting? Maybe we all need stimulants.... Stimulants have a widespread effect on multiple domains, some of which are listed in Table 23-3.

Tommy’s father is happy with his son’s response to methylphenidate and wonders if he too would benefit from a similar medication. He recalls being in trouble ever since grade school for talking “out of turn” and always being put in detention. He was always restless and fidgety, but this has improved as he has aged. He has a hard time at work sitting through meetings, as he tends to daydream, and he has numerous fights with his wife because she accuses him of not listening to her. He has been unable to get promoted because he cannot pass the examinations he has to take, but he thinks that he is smart enough. He says that he just cannot concentrate.

TABLE 23-3 STIMULANT EFFECTS ON PATIENTS WITH ADHD**Effects of Stimulants on Motor Response**

- Reduce activity to normal
- Decrease excessive talking, noise, and disruption in the classroom
- Improve handwriting
- Improve fine motor control

Effects of Stimulants on Social Skills

- Reduce off-task behavior in classroom
- Improve ability to play and work independently
- Decrease intensity of behavior
- Reduce bossiness with peers
- Reduce verbal and physical aggression
- Improve (but not normalize) peer social status
- Reduce noncompliance, defiance, and oppositional behavior with adults
- Parents and teachers become less controlling and more positive

Effects of Stimulants on Cognitive Ability

- Improve ability to sustain attention, especially in boring tasks (like studying for the FM Board Exam)
- Reduce distractibility
- Improve short-term memory
- Reduce impulsivity
- Increase amount of academic work completed
- Increase accuracy of academic work

Side Effects

- Lack of appetite
- Decreased growth, especially initially
- Insomnia
- Headaches and stomach aches
- Irritability
- Tachycardia or blood pressure increase (rare)
- Muscle tics or twitches (rare)
- Psychosis or delirium (rare)

TABLE 23-4 PRESENTATIONS OF ADHD SYMPTOMS IN CHILDREN AND ADULTS

Children	Adults
<i>Hyperactive child:</i> squirms, cannot stay in his seat, and constantly on the go	<i>Hyperactive adult:</i> has subjective inner restlessness and trouble relaxing
<i>Impulsive child:</i> blurts out answers, interrupts others, and talks incessantly	<i>Impulsive adult:</i> speeding tickets, car crashes, impatient, smokes more, higher divorce rate, higher substance use rate, and overeating
<i>Inattentive child:</i> does not follow through, is forgetful, does not listen Fewer enter college and graduate, compared with children their age without ADHD	<i>Inattentive adult:</i> often late for appointments, forgets anniversaries, has difficulty with work meetings; problems with focusing, planning, organizing, and completing tasks at home and at work; advances more slowly at work than peers; misplaces keys, glasses, and other items; may forget to pay bills, pick up the kids on time, etc.

compensate by pursuing careers that reward their intellectual curiosity, endless energy, and desire for change (like family medicine?). Table 23-4 compares adult and child presentations of ADHD.

**HELPFUL TIP:**

Remember that an adult who had ADHD as a child may have residual symptoms, which do not meet full criteria for ADHD at the time of evaluation. A clear history of symptoms starting in childhood before age 12 must be present to diagnose an adult with ADHD. **There is no such thing as “Adult-Onset ADHD” in DSM-5 (but there is such thing as adult stimulant abuse).** Confirmation of the history can be obtained from collateral sources, including old school reports and family members. Think about other diagnoses such as anxiety disorder and depression in patients who think they have “adult-onset ADHD.”

Question 23.13.5 Which of the statements below is NOT true for an adult presenting with ADHD?

- Adults present with the same core symptoms as children but in a different fashion
- Adults are less likely to have overt hyperactivity symptoms compared with children
- Adults often present when their children are diagnosed
- Adults are less likely to smoke than same-age persons without ADHD
- Adults often seek professions that allow them to use their symptoms to their advantage

Answer 23.13.5 The correct answer is “D.” Adults with ADHD are more likely to smoke than their same-aged peers (perhaps it’s because nicotine is a stimulant?). Adults present differently than children, but have the same core symptoms of hyperactivity, inattention, and impulsivity. Many adults are diagnosed with ADHD only when their children have been diagnosed or when increasing difficulty at work or at home leads them to seek help. Often, comorbidities drive them to seek help, and the primary diagnosis of ADHD is made only incidentally. Adults typically present seeking help for their inattention and concentration difficulties, as overt hyperactivity lessens with age. Some adults

After thorough history and evaluation, you decide to treat Tommy’s father with a medication. He would prefer not to have a stimulant, and he asks if there are other options for treatment.

Question 23.13.6 Which of the following medications would you recommend?

- Fluoxetine (Prozac)
- Bupropion (Wellbutrin)
- Mirtazapine (Remeron)
- Phenelzine (Nardil)
- Risperidone (Risperdal)

Answer 23.13.6 The correct answer is “B.” In addition to stimulants, which are also first-line agents in adults, there are a variety of medications that can be used to treat ADHD, although

most studies are undertaken in children and most of these medications are not FDA approved for treating ADHD. Second-line agents include the antidepressants bupropion (Wellbutrin), desipramine (Norpramin), imipramine (Tofranil), and nortriptyline (Pamelor). The α -blockers guanfacine (Tenex) and clonidine (Catapres) are also used, mostly as an adjunct in children with concomitant conduct disorder or sleep problems. Remember that a history of substance abuse or psychotic disorder should be carefully evaluated with cautious consideration of whether to initiate a stimulant vs. nonstimulant in a patient.

**HELPFUL TIP:**

Stimulants do not cause cardiac problems and seem to be safe in both children and adults (*JAMA*. 2011;306:2673; *JAMA*. 2011;306:2723; *N Engl J Med*. 2011;365:1896). However, stimulants *can* increase heart rate and blood pressure, and these should be monitored carefully. Use of stimulants in those with underlying cardiac conditions is not well studied and generally avoided in those with serious heart conditions.

**HELPFUL TIP:**

Atomoxetine (Strattera) is a nonstimulant drug approved for ADHD (it is a selective norepinephrine reuptake inhibitor) and is the only nonstimulant drug approved by the FDA for adult ADHD. It is not a controlled prescription, as it has no apparent abuse potential. Its place in therapy is not yet well defined but might be used in those with a drug abuse history. Maximum efficacy of atomoxetine is achieved in a few weeks, and it has a similar side-effect profile to the stimulants.

► **Objectives: Did you learn to ...**

- Recognize childhood and adult presentations of ADHD?
- Prescribe efficacious treatments for ADHD?
- Recognize side effects and advantages of various medications for ADHD?

► **CASE 23.14**

A gentleman calls your office because he is concerned that his wife of 2 years is acting strangely. She has not slept for most of the past week, staying up at night cleaning the house and sending multiple texts to friends and family. She even went out and spent \$3000 on a dress that left nothing to the imagination and was seen kissing another man (Santa Claus, you hope). You ask him to bring his wife in as soon as possible.

That afternoon you find a provocatively dressed 30-year-old female sitting in your office and laughing giddily as her husband gives most of the intelligible history. She keeps reaching over to touch you on the leg as you interview her. You find her hard to understand because she talks so fast. You manage to catch something about “running for President.”

Question 23.14.1 What is the most likely diagnosis?

- A) Mania
- B) Psychosis
- C) Agitated depression
- D) Anxiety disorder
- E) ADHD

Answer 23.14.1 The correct answer is “A.” Mania is the correct diagnosis. None of the other conditions can fully explain the abnormal elevation in mood and the subsequent behavior changes. Patients with **bipolar I disorder** must have had at least one episode of mania: a distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary). In addition, there must be at least three of the following symptoms concurrently: (1) inflated self-esteem or grandiosity, (2) decreased need for sleep, (3) more talkative than usual, (4) flight of ideas or racing thoughts, (5) distractibility, (6) increased goal-directed activity or psychomotor agitation, and (7) excessive involvement in pleasurable activities that have a high risk for negative consequences/impulsivity (gambling, spending spree, risky sexual behaviors, etc.). The episode must cause impairment in occupational or social functioning and cannot be substance induced.

Patients with **bipolar II disorder** have had at least one episode of depression and one episode of hypomania: a distinct period of persistently elevated, expansive, or irritable mood, lasting for at least 4 days, which is clearly distinct from the usual, nondepressed mood. During the hypomanic episode, at least three of the manic symptoms listed above must be present, although the episode is not severe enough to cause marked impairment in occupational or social functioning, require hospitalization, or include psychotic symptoms.

**HELPFUL TIP:**

Although patients with bipolar disorders often have depressive episodes as well as manic or hypomanic episodes, depression is not required for the diagnosis of bipolar I disorder. (“So why is it called bipolar,” you ask? Well, who are you to question tradition?)

Question 23.14.2 Regarding the epidemiology of bipolar illness, which of the following is FALSE?

- A) The prevalence of bipolar I is about 0.6% to 1.5%
- B) Many patients are misdiagnosed initially with depression
- C) Untreated, the suicide rate is almost 20%
- D) Women are twice as likely to be affected as men
- E) Suicide risk is highest in the depressed or mixed state

Answer 23.14.2 The correct answer is “D.” Unlike depression, bipolar illness affects males and females equally. Bipolar I affects about 0.6% to 1.5% of the population, while bipolar II affects about 0.8% to 3%. Untreated, nearly 20% will commit suicide—a rate about 20 times that of the general population. Risk is highest in depressed states or the mixed states (both mania and

depression present at the same time). Bipolar disorder typically has its onset in early adulthood, although it can begin in childhood or adolescence. Depression is present 20% to 30% of the time, even with ongoing maintenance treatment. Over half of bipolar patients are initially misdiagnosed with depression, and the average patient is only accurately diagnosed after 5 years of symptoms.

HELPFUL TIP:

Up to 50% of people with bipolar disorder have concomitant alcohol abuse or dependence.

You want to start a medication for this patient ... or commit her ... or both.

Question 23.14.3 Which of the following would NOT be an appropriate treatment choice for her mania?

- A) Lithium
- B) Olanzapine (Zyprexa)
- C) Divalproex (Depakote)
- D) Carbamazepine (Tegretol)
- E) Buspirone (Buspar)

Answer 23.14.3 The correct answer, and the medication to avoid, is “E.” Buspirone (Buspar) is not effective in the treatment of bipolar disorder. Lithium (“A”) was the first medication approved for treatment of bipolar mania and depression. It reduces the incidence of recurrence of mania, hypomania, and depression by about two-thirds. Lithium has a significant anti-suicide effect with an estimated eight- to ninefold reduction in risk. It is dosed at nighttime or twice daily. Lithium has a narrow therapeutic window, and there are numerous drug–drug interactions (including serotonergic drugs).

Both olanzapine (Zyprexa) (“B”) and divalproex (Depakote) (“C”) have FDA approval for treatment of acute mania and appear to be somewhat effective in the prevention of recurrent episodes. However, only lithium and lamotrigine (Lamictal) are FDA-approved mood stabilizers for bipolar treatment and maintenance. Lamotrigine (Lamictal) should not be used for acute mania, though. Carbamazepine (Tegretol) (“D”) is a second-line agent that is also effective, but side effects limit its use. Atypical antipsychotics like olanzapine (Zyprexa), risperidone (Risperdal), ziprasidone (Abilify), and quetiapine (Seroquel) can also be used to treat acute mania. Side effects of atypical antipsychotics include extrapyramidal symptoms, sedation, and weight gain.

You decide to start lithium.

Question 23.14.4 Which of the following is a well-recognized side effect of lithium?

- A) Diabetes mellitus
- B) Hypothyroidism
- C) Immunosuppression
- D) Abnormal hair growth
- E) The ability to donate an electron

Answer 23.14.4 The correct answer is “B.” Patients who take lithium should have their thyroid function monitored. Also, lithium can affect renal function and electrolyte levels, so check serum electrolytes periodically. As lithium has a narrow therapeutic window, serum lithium levels should be measured ideally 12 hours after the last dose, with a goal of 0.6 to 1 mEq/L.

Question 23.14.5 Which of the following drug classes do NOT alter lithium levels?

- A) NSAIDs
- B) Diuretics
- C) ACE inhibitors
- D) ARBs
- E) Opioids

Answer 23.14.5 The correct answer is “E.” Lithium is cleared by the kidney. Anything that can cause a change in renal function can affect lithium levels. NSAIDs, diuretics, ACE inhibitors, and ARBs can all affect renal function.

► Objectives: Did you learn to ...

- Recognize and diagnose bipolar disorder?
- Initiate treatment of bipolar disorder?
- Describe some potential adverse effects of treatment of bipolar disorder?

► CASE 23.15

A 20-year-old female gymnast presents to you because she has missed her period for 6 months. She feels cold all the time and has noticed that when she crosses her legs, she gets pins-and-needles sensations down her leg. She had a stress fracture of her right tibia 5 years ago but denies any other medical history. She denies being sexually active and the review of systems is positive for frequent heartburn, constipation, and fatigue.

Question 23.15.1 Which of the following diagnoses would be in your differential?

- A) Pregnancy
- B) Hyperthyroidism
- C) Malignancy
- D) Anorexia nervosa (AN)
- E) All of the above

Answer 23.15.1 The correct answer is “E.” All the answers should be part of a reasonably broad differential diagnosis in this young woman. In patients presenting with weight loss and a possible eating disorder, you should eliminate medical causes of weight loss, using history, physical examination, and appropriate labs. Despite her denial of sexual activity, a pregnancy test is a necessary part of the evaluation, given that pregnancy is the most common cause of amenorrhea in this population. Hyperthyroidism and malignancy can present with vague complaints similar to this patient. Likewise,

AN can give rise to this patient's constellation of symptoms, though amenorrhea is no longer a diagnostic criteria for AN in DSM-5.

As you take more history, you realize that this patient is a very finicky eater. She is a strict vegan (So? What is wrong with that?) and restricts her calories to <1,000 kcal/day in order to stay in shape. She is 5 ft 3 in tall and weighs 100 lb, but she thinks she is overweight.

Question 23.15.2 Which of these additional findings would you expect on physical examination?

- A) Bradycardia
- B) Hypertension
- C) Adnexal mass
- D) Clonus
- E) Proptosis

Answer 23.15.2 The correct answer is "A." Common physical findings in weight loss, and specifically AN, include emaciation, sunken cheeks, hypotension, bradycardia, lanugo, mottled teeth, and dry or yellow skin. Peripheral edema may develop during weight gain (refeeding syndrome... see below) or when laxative or diuretic abuse is stopped. Murmurs can occasionally be auscultated.

Question 23.15.3 Patients with AN may present with:

- A) Paresthesia
- B) Cold intolerance
- C) Constipation
- D) Fatigue
- E) All of the above

Answer 23.15.3 The correct answer is "E." All of the above are symptoms of AN. These are common symptoms seen in starvation. "A" is not intuitive but is true. Loss of fat allows for greater exposure of superficial nerves, so the act of crossing the legs or sitting down on a hard chair can cause paresthesia.

HELPFUL TIP:

Patients with AN rarely have insight into the illness and often deny that weight loss is a problem. These patients are often perfectionists and overachievers who are sensitive to criticism and come from families with conflict. Weight loss is a method of control and is seen as a significant achievement.

HELPFUL TIP:

The word "anorexia" in AN is a misnomer, as loss of appetite is exceedingly rare in this illness. Patients are hungry but voluntarily restrict their caloric intake. The initial weight loss may be precipitated by appetite loss caused by depression, medical illness, dieting, or stressful life event.

Question 23.15.4 Which would be an expected laboratory finding in this patient?

- A) Leukocytosis
- B) Hyperkalemia
- C) Increased amylase
- D) Decreased cholesterol
- E) Erythrocytosis

Answer 23.15.4 The correct answer is "C." Amylase may be increased as a result of purging behavior (and thus salivary stimulation). "A" and "E" are incorrect. Leukopenia, not leukocytosis, with a mild, normochromic, normocytic anemia is a common hematologic finding, although the CBC may be normal. "B" is incorrect. There is usually whole-body depletion of potassium, zinc, magnesium, and phosphate (from vomiting and/or inadequate intake). "D" is also incorrect, as cholesterol is often elevated (as are BUN and liver enzymes). This cholesterol elevation is neither intuitive nor well understood but is observed to occur in patients with AN. See Table 23-5 for more medical complications of AN.

TABLE 23-5 SELECTED MEDICAL COMPLICATIONS OF ANOREXIA NERVOSA

Neurologic	Seizures Peripheral neuropathy Cortical atrophy Cognitive impairment
Cardiovascular	Bradycardia Orthostatic hypotension Heart failure ECG changes: low voltage, nonspecific ST segment changes, QT prolongation
Endocrine	Amenorrhea Low T3, T4, and TSH (transient central hypothyroidism, previously called "euthyroid sick syndrome") Osteopenia/osteoporosis Growth retardation Hypoglycemia Hypothermia
Fluids and electrolytes	Dehydration Metabolic alkalosis Hypokalemia Hypomagnesemia Hypocalcemia
Gastrointestinal	Elevated liver enzymes Constipation Esophagitis Mallory–Weiss tears Parotid gland hypertrophy
Dermatologic	Lanugo Brittle nails and hair Acrocyanosis Dry, scaly skin
Hematologic	Bone marrow suppression Leukopenia/Neutropenia Anemia

In order to increase your patient's motivation to comply with medical recommendations, you describe some of the adverse effects of excessively low weight.

Question 23.15.5 All of the following abnormal findings will resolve when an adequate body weight is regained EXCEPT:

- A) Bradycardia
- B) Muscle wasting
- C) Osteoporosis
- D) Infertility

Answer 23.15.5 The correct answer is "C." Patients with AN are usually young and therefore experience some of their lowest weights and amenorrhea at the same time they are expected to reach peak bone mass. If a patient becomes osteopenic or osteoporotic when she is young, she will remain so as she ages (sans treatment). Return to good nutrition will not add bone mass that has been lost. Typical treatment for osteoporosis in this group remains combined estrogen–progesterone oral contraceptive agents as there are adverse effects related to bisphosphonates. All of the other physical changes listed should return to normal with return to a normal weight.

Question 23.15.6 Which of the following is the most appropriate next step in the management of this patient?

- A) Tell her to stop gymnastics, withdraw from classes, and go to live with her mother
- B) Start an antidepressant
- C) Admit her to the hospital
- D) Consult psychiatry and nutrition specialists
- E) All of the above are equally valid options at this time

Answer 23.15.6 The correct answer is "D." This patient is most likely to benefit from a coordinated plan involving a multidisciplinary team, including primary care, psychiatry, and nutrition. "A" is incorrect, as it is a dramatic reaction that does not address the patient's primary problem, and the patient is unlikely to comply with it. "B" is incorrect. An antidepressant may be helpful in patients with a clearly defined depressive or anxiety disorder. However, the use of antidepressant therapy for AN specifically has not been successful, and certain antidepressants are associated with weight loss. "C," hospitalization, is not likely to be beneficial at this point. The utility of hospitalization has been difficult to determine in AN. Commonly accepted reasons for hospital admission include the following: severe low weight (70–75% of ideal body weight), marked symptomatic acute food refusal, hypotension or syncope, acute psychiatric emergency (threatened suicide), significant dehydration or severe bradycardia (<40 bpm) or cardiac arrhythmia, electrolyte disturbances, and failed intensive outpatient therapy.

While you plan to involve psychiatric and nutritional services, you continue your discussion of eating disorders with this patient.

Question 23.15.7 Which of the following is NOT TRUE about the epidemiology of eating disorders?

- A) At least 90% of eating disorder patients are female
- B) Rates are higher in industrialized, Western nations
- C) A family history of depression increases the risk of females developing eating disorders
- D) Male wrestlers have a higher risk of eating disorders than the average male
- E) Mortality rates in AN are similar to the general population

Answer 23.15.7 The correct answer is "E." AN is characterized by a high mortality, one of the highest of psychiatric illnesses. It must be taken very seriously. Up to 10% of hospitalized patients die from direct effects of starvation, suicide, electrolyte imbalances leading to arrhythmias, or refeeding syndrome. At least 90% of eating disorder patients are female with prevalence rates higher in certain groups, such as models, actresses, athletes, and dancers. Western, industrialized societies endorse thinness and dieting as an ideal for women, resulting in higher rates of eating disorders. Despite having a normal body weight, over 40% of 9- and 10-year-old American girls believe they are overweight and consider dieting as an option! Eating disorders are uncommon in poorer countries where starvation is a potential reality and no cultural endorsement of thinness exists. "C" is true. A family history of depression or obesity increases risk of an eating disorder by two- to fivefold, with a family history of depression alone increasing the risk about fivefold. "D" is also true. In males, wrestlers have a higher prevalence of eating disorders because of weight requirements in their sport. In males, body shape and not necessarily absolute body weight is the typical focus of concern.

HELPFUL TIP:

There are two subtypes of AN: restrictive and binge/purge. Therefore, a patient who binges and purges (through forced emesis, laxatives, etc.) does not necessarily have bulimia.

HELPFUL TIP:

Comorbidities are prevalent in eating disorder patients and include MDD (50–75%), anxiety disorders, obsessive-compulsive disorder, and substance abuse. Personality disorders are also prevalent with the anxious, sensitive, rigid, and perfectionistic types predominating (Cluster C).

In your discussion of eating disorders, your patient asks about bulimia and how you distinguish between AN and bulimia nervosa (BN).

Question 23.15.8 Which of the following is NOT TRUE when comparing patients with AN and BN?

- A) BN is more prevalent than AN
- B) BN patients are more likely to be of normal weight than AN patients
- C) The prognosis for AN is better than that for BN
- D) BN patients are more likely to have esophageal tears
- E) Medications are effective in BN but less so in AN

Answer 23.15.8 The correct answer is “C.” BN has a better prognosis than AN, with only 20% of patients still meeting diagnostic criteria 5 to 10 years after initial presentation. BN is more common than AN, but with the prevalence increasing just like it has with AN. “B” is true. Patients with BN are usually close to normal weight. However, they show several stigmata: loss of dental enamel and chipped teeth with cavities; enlarged parotid salivary glands with elevated serum amylase from repeated vomiting episodes; menstrual irregularities; bradycardia, hypotension, and decreased metabolic rate. Rare complications include esophageal tears from frequent vomiting or gastric rupture due to gastric dilatation secondary to bingeing. “E” is true. Treatment of BN involves the same principles as AN with the caveat that medications can be helpful. Fluoxetine (Prozac) is the first-line drug with a target dose of 60 mg being shown to be effective in trials. Other SSRIs are second line. Third-line agents include TCAs, MAOIs, and trazodone. These agents reduce binge eating and bulimic symptoms whether patients are depressed or not.

HELPFUL TIP:

The mean age of onset of eating disorders is 18 to 21 years, with very rare onset after the age of 40 (although recurrence can occur in this population).

► **Objectives: Did you learn to ...**

- Evaluate a young person with a suspected eating disorder?
- Diagnose AN?
- Recognize medical complications of eating disorders?
- Distinguish between AN and bulimia?
- Initiate appropriate treatment and referral for a patient with an eating disorder?

QUICK QUIZ: BINGE AND PURGE

In order to be diagnosed with BN according to DSM-5, a patient must meet all of the following criteria EXCEPT:

- A) Recurrent purging via self-induced vomiting
- B) Recurrent binge eating
- C) Symptoms are present on average at least once per week for at least 3 months
- D) Self-evaluation is unduly influenced by body shape and weight

The correct answer is “A.” For the diagnosis of BN, self-induced vomiting need not be present. Rather, some sort of compensatory behavior must be present during bulimic episodes. This behavior might include vomiting, but is not limited to vomiting, and may also include laxative or diuretic use, fasting, or excessive exercise. “B,” “C,” and “D” are required for the diagnosis of BN. BN affects about 1% to 3% females (more common in white females) and 0.1% to 0.3% males. Comorbidities of depression, anxiety, substance abuse, and personality disorders are also common. Dramatic, unstable personality traits (cluster B) predominate in this illness unlike the sensitive, rigid (Cluster C) personality traits in AN.

QUICK QUIZ: EATING DISORDERS (OR, HOLD THE PIE FOR NOW, PLEASE)

A previously healthy 17-year-old female is hospitalized for AN. She has her weight rapidly restored with intravenous fluids and a 3,000 kcal/day diet. She gains 10 lb in her first 2 days (so gaining 10 lb in 2 days sounds like a good thing?) and seems to be doing well. However, when you round the next morning, she is unresponsive. Physical examination reveals evidence of JVD, pulmonary rales, and lower extremity edema.

What is the most likely cause of this patient’s apparent heart failure?

- A) Previously undiagnosed heart disease
- B) Refeeding syndrome
- C) Suicide attempt by SSRI overdose
- D) Myocardial infarction
- E) Takotsubo cardiomyopathy

The correct answer is “B.” The scenario described fits with the clinical picture caused by refeeding syndrome. Refeeding syndrome occurs when rapid expansion of the circulating volume overwhelms the cardiovascular system’s ability to adapt, leading to heart failure. It also involves changes in electrolytes and glucose. It typically occurs in malnourished patients. Prevention involves careful monitoring of electrolytes including magnesium, phosphorus, potassium, and calcium, while advancing caloric intake in a small, linear fashion and keeping track of volume status. “A,” “D,” and “E” are incorrect as the patient is unlikely to have significant heart disease given her age and gender.

HELPFUL TIP:

There is no case for this table but editors hate it when there is no “call out” for a table. So, see Table 23-6 for warning signs that an agitated patient may become violent. See Table 23-7 for ways to calm the agitated patient (although in the editors’ experience nothing beats IM haloperidol and IM lorazepam—after other options are exhausted, of course).

TABLE 23-6 WARNING SIGNS THAT AN AGITATED PATIENT MAY BECOME VIOLENT

Hyperactivity: pacing or other increase in psychomotor activity
 Loud, angry, or profane speech
 Increased muscle tension, manifested by clenched jaw, fist, rigid posture, gripping chair, sitting on chair edge, etc.
 Intoxication
 Suspicious, angry, or irritable affect
 Breathlessness, tachycardia, diaphoresis, pupillary dilation, visibly palpating temporal arteries
 Uncooperativeness with requests
 Door slamming, chair toppling, or other form of property destruction
 Grabbing objects that could be potential weapons
 Verbal or physical threats
 The clinician's response to the patient: if you feel anxious, take it seriously and be alert to possible danger

TABLE 23-7 TECHNIQUES TO CALM THE AGITATED PATIENT

Remove the patient to a quiet and nonstimulating environment
 Keep a distance from the patient and avoid physical contact
 Identify exits and alarms
 Maintain nonthreatening demeanor and stance
 Keep your hands at your side where they are easily visible
 While maintaining steady eye contact, speak in a steady but authoritative voice, using the patient's name with each sentence
 Avoid sudden jerky movements and remain calm
 Have familiar faces nearby if possible
 Show the patient concern but tell him that violence is not acceptable and you are willing to work with him if he calms down
 There is strength in numbers; have other personnel nearby to help if necessary
 Call for help from police or security if needed; a back-up system, which has been tested, should be in place
 Consider antipsychotics, such as haloperidol (available in oral and parenteral forms) and risperidone (available in liquid); a benzodiazepine may be used as an adjunct, but should **not** be used alone
 Mechanical restraints may be employed if absolutely necessary
 Remember to figure out **why** the patient is agitated (e.g., take history, perform mental status examination, and order appropriate tests)

TABLE 23-8 FACTORS AFFECTING SUICIDE RISK**Risk Factors**

- Previous history of suicide attempt
- Family history of suicide attempt or completion
- Substance misuse
- Mood disorders (e.g., depression, bipolar disorder)
- History of trauma or abuse
- Loss of spouse/significant other, separation or end of a relationship
- Having access to a gun or other readily lethal means
- Loss of activity, job, property, academic difficulty, financial difficulty, bullying
- Mild/minimal cognitive impairment
- Exposure to suicidal behavior or others
- Chronic illness including chronic pain

Protective Factors

- Contact with providers (e.g., follow-up phone calls, communications)
- Effective treatment of mental and physical disorders
- Social, community, faith, and familial support with strong connections
- Effective problem solving and conflict resolution skills

Adapted from Parekh R and American Psychiatric Association. Suicide prevention. June 2018. Available at: <https://www.psychiatry.org/patients-families/suicide-prevention>. Accessed February 2, 2019.

in men and women is equivalent. This occurs despite the fact that female physicians have fewer attempts than the general female population. Physicians have roughly the same rate of depression as the general population, while medical students and residents have higher rates than the general population (15–30% vs. 16% in the general population ... if you were ever a medical student or resident, we are sure you got this one right). Other factors affecting suicide risk (in addition to being a physician) are noted in Table 23-8.

**QUICK QUIZ: SUICIDE RISK****QUICK QUIZ: PHYSICIAN HEAL THYSELF?**

Which of the following is true about physicians' risk of suicide compared to the general population?

- Female physicians have a risk of successful suicide equal to male physicians
- Physicians are more likely to be depressed than the general population
- Female physicians are more likely to attempt suicide than the general female population
- Medical students and residents are less likely to be depressed than the general population

The correct answer is "A." In the general population, women have two to four times more suicide attempts than men, while men are four times more likely than women to complete a suicide. However, among physicians, the rate of successful suicide

You have a colleague who is depressed and has transient thoughts of suicide.

Which of the following would suggest that he should be hospitalized today?

- He thinks about suicide only infrequently
- He has not formulated a plan to commit suicide
- He has updated his will within the past few days
- He is willing to follow up in clinic tomorrow

The correct answer is "C." If a person admits to suicidal ideation, ask the following questions to assess his level of risk and to determine whether or not he should be hospitalized:

- How often does he think about suicide?
- Does he have a concrete plan? And if so, is it plausible? (Tying oneself to a rocket does not count ... for most people.)
- Is he giving away treasured belongings, updating his will, making final plans, etc.?

- Is he in danger of acting on his thoughts?
- Why has he not attempted suicide yet? What keeps him from doing it?
- Does he have access to harmful means (e.g., guns and drugs)?

Asking about suicidal thoughts does not increase the likelihood of suicide. There are evidence-based interventions, developed by the Action Alliance for Suicide Prevention, that can be completed in a clinic or office setting if suicide risk is identified. First, develop a safety plan with the patient, which may include providing the patient with the National Suicide Prevention Lifeline or local crisis resources. Next, evaluate the presence or thoughts of lethal means with mechanisms to remove the lethal means or minimization of its access if possible. Lastly, make a referral to a mental health professional and contact the patient within 48 hours for a caring contact. **Contracting for safety doesn't work. Do not depend on this to prevent a patient from committing suicide.**

QUICK QUIZ: PSYCHOTROPIC DRUGS

Which of these antidepressants can be administered once weekly?

- A) Paroxetine (Paxil)
- B) Bupropion (Wellbutrin)
- C) Fluoxetine (Prozac)
- D) Escitalopram (Lexapro)
- E) Venlafaxine (Effexor-SR)

The correct answer is "C." Fluoxetine has a long-enough half-life that it can be administered once a week. You don't need to prescribe the "long-acting" fluoxetine. Any fluoxetine can be dosed once weekly. It is traditionally dosed daily, but if patients are experiencing side effects or have difficulties adhering to a daily medication, dosing can be adjusted to every other day or weekly.

▶ CASE 23.16

You are on call and have been paged to see a 21-year-old female who has just overdosed on a handful of acetaminophen because her boyfriend left her after their most recent fight. She has had similar overdoses three times in the past (they fight a lot). According to a friend, she has a history of tumultuous relationships. In the emergency department, she is combative and yelling, "I'm so angry that I'm still alive!" She has a blood alcohol level of 106 mg/dL. There are scars on her arms, presumably from cutting.

Question 23.16.1 What is the most likely primary diagnosis?

- A) Antisocial personality disorder
- B) Bipolar affective disorder
- C) MDD
- D) Borderline personality disorder
- E) Intermittent explosive disorder

TABLE 23-9 CHARACTERISTICS OF BORDERLINE PERSONALITY DISORDER

- Fears of abandonment
- Unstable and intense relationships
- Unstable sense of self
- Impulsivity
- Suicidal behavior, threats or gestures or self-mutilation (cutting is often a feature of borderline personality disorder)
- Significant mood reactivity
- Chronic feelings of emptiness (Camus or Nietzsche?)
- Intense anger outbursts
- Transient stress-related paranoid ideation or dissociation

Answer 23.16.1 The correct answer is "D." This patient's history is consistent with a diagnosis of borderline personality disorder. Persons with borderline personality disorder often have stormy relationships, characterized by extremes of emotional intensity (e.g., "love-hate" relationships). You might also consider depression as a diagnosis here, but the history does not support MDD. However, concomitant depression is common in patients with borderline personality disorder. "A," "B," and "E" are not supported by the clinical presentation. Borderline personality disorder is mostly a diagnosis of females (over 90%). Characteristics are listed in Table 23-9.

HELPFUL TIP:

A personality disorder is an enduring pattern of relating to the world in ways that are inflexible, ineffective, and markedly different from cultural norms. Personality disorders cause distress or functional impairment and start by adolescence in most people. The prevalence rate of personality disorders varies widely across studies, with borderline personality disorder being the most prevalent of all.

Your patient's boyfriend storms into the emergency department and demands to see her. He has "love" and "hate" tattooed on his knuckles and another less savory symbol tattooed on his arm—although he swears it's just a Tibetan good luck charm. The nurse recognizes him immediately as a frequent visitor. Apparently, he has been in the emergency department on multiple occasions for injuries sustained from fights. Your patient pulls you aside to tell you that she is afraid of him, saying, "I just worry when he gets mad. He went to jail for beating and raping his last girlfriend." The nurse also informs you that he is suspected of stealing narcotics from a pharmacy in town. You call security.

Question 23.16.2 Which of the following personality disorders is most likely in this man?

- A) Paranoid personality disorder
- B) Histrionic personality disorder
- C) Schizotypal personality disorder
- D) Antisocial personality disorder
- E) None. This patient is just a character on MTV's Jersey Shore.

TABLE 23-10 CHARACTERISTICS OF ANTISOCIAL PERSONALITY DISORDER

- Recurrent criminality
- Deceitfulness shown by repeated lying, use of aliases, or conning others
- Impulsivity
- Irritability and aggression
- Reckless disregard for safety
- Consistent irresponsibility, failing to fulfill financial obligations or work
- Lack of remorse
- History of childhood conduct disorder before age 15

Answer 23.16.2 The correct answer is “D.” Antisocial personality disorder is primarily seen in males, and of the options given, it is the only personality disorder that really fits. Antisocial personality disorder is quite prevalent in prison populations. “A” and “C” are incorrect because these are Cluster A disorders, which are characterized by strange rather than violent behavior. “B” is incorrect. Histrionic personality disorder shows attention-seeking and seductive behavior. Although patients with antisocial personality disorder can be charming, they also use violence and threats to achieve their purposes. Characteristics of antisocial personality disorder are listed in Table 23-10.

Question 23.16.3 Besides borderline personality disorder, which other personality disorder increases the risk of completed suicide the most?

- A) Paranoid personality disorder
- B) Histrionic personality disorder
- C) Schizotypal personality disorder
- D) Avoidant personality disorder
- E) Antisocial personality disorder

Answer 23.16.3 The correct answer is “E.” Along with borderline personality disorder, antisocial personality disorder is the other personality disorder most likely to be seen in completed suicides.

Question 23.16.4 Borderline personality disorder and antisocial personality disorder fall within what cluster or category of personality disorders?

- A) Cluster A
- B) Cluster B
- C) Cluster C
- D) Cluster D

Answer 23.16.4 The correct answer is “B.” There are three clusters of personality disorders that are categorized based on their characteristics.

- Cluster A: “the weird cluster”—patients are aloof, act strange, and prefer to be alone. Paranoid, schizoid, and schizotypal personality disorders are included here.
- Cluster B: “the wild cluster”—patients have significant problems with mood lability, impulsivity, or are preoccupied with being admired for their sexuality or intelligence. Borderline, antisocial, histrionic, and narcissistic personality disorders are included here.

- Cluster C: “the whiny or worried cluster”—patients are clingy, sensitive, and rigid. Avoidant, dependent, and obsessive-compulsive personality disorders are included here.

**HELPFUL TIP:**

You will be happy to know (as are we) that, as of DSM-5, the old “axis” designation system (axis 1, axis 2, etc.) for psychiatric disease has gone the way of the dodo bird (or pick your favorite extinct species).

**HELPFUL TIP:**

Impulsivity is a risk for completed suicide. Even though patients may not truly intend to die, an impulsively taken overdose or other suicide attempt may inadvertently lead to death. This is why patients with borderline personality disorder and antisocial personality disorder have a high risk of completed suicide.

You have a frank discussion with your female patient about suicide.

Question 23.16.5 Which of the following is NOT TRUE about suicide in the general population?

- A) Medical diagnoses can increase the risk of suicide
- B) Over 90% of people who commit suicide have a diagnosed mental health disorder
- C) Older Americans are at higher risk of suicide than the general population
- D) The rate of successful suicides has increased over the years
- E) Suicide is one of the top 10 causes of death in the United States

Answer 23.16.5 The correct answer is “B.” The rate of successful suicide has increased nationally from 1999 to 2016, with half of states experiencing a greater than 30% increase in suicides during this time. Of those that completed suicide, only 46% had a known mental illness, excluding substance use disorder. “A” is a correct statement. Medical diagnoses can be risk factors for suicide. Particularly problematic are chronic illness, terminal illness, chronic pain, or recent surgery. Older Americans commit suicide at a rate four times than that of the general population with a peak incidence at age 75 for men and 60 for women. “E” is also correct. Suicide is the seventh leading cause of death in the United States and the third leading cause of death in those aged 15 to 24 years. There are two mnemonics that are useful for assessing suicide risk: “NO HOPE” and “SAD PERSONS” (see Table 23-11).

**HELPFUL TIP:**

Seventy-five percent of older Americans who commit suicide have seen their primary care physician within the preceding 4 weeks and 39% within the same week. Up to half of successful suicides have made a prior attempt.

TABLE 23-11 MNEMONICS FOR SUICIDE RISK ASSESSMENT

NO HOPE	SAD PERSONS
No framework for meaning (Reading Nietzsche?)	Sex—male
Overt change in clinical condition	Age—older
Hostile interpersonal environment	Depression
Out of hospital recently	Previous attempt
Predisposing personality factors	Ethanol abuse
Excuses for dying to help others	Rational thought loss
	Social support lacking
	Organized plan
	No spouse
	Sickness

▶ Objectives: Did you learn to ...

- Identify borderline and antisocial personality disorders?
- Classify personality disorders?
- Assess suicide risk?

▶ CASE 23.17

A 21-year-old man presents to your clinic because his girlfriend dragged him in. He just started his first year in college but quit 2 days ago because he feels that “they are all out to get me.” (“If he’s talking about the IRS, or New World Order, he’s probably right,” you think to yourself.) He has not been sleeping because he thinks he might be murdered in his sleep. He tells you that the FBI has bugged your office and that the NSA is tapping your phone (OK, that one’s probably right); therefore, he does not want to answer your questions.

Question 23.17.1 Which of the following would you NOT expect to find on mental status examination?

- Delusions
- Hallucinations
- Lack of insight
- Decreased psychomotor activity
- Poverty of speech

Answer 23.17.1 The correct answer is “D.” The patient described is acutely psychotic. You would expect him to have increased psychomotor activity. All of the other options would also be anticipated findings in this patient. Common symptoms of psychosis include delusions, hallucinations, psychomotor agitation, flight of ideas, nonsensical speech and behavior, lack of insight into one’s behavior, and lack of judgment. Note that “poverty of speech” refers to brief, empty replies to questions and not to content, which may be quite fanciful.

Question 23.17.2 All of the following are potential causes of this patient’s psychosis EXCEPT:

- Substance abuse
- Alcohol withdrawal
- Bipolar disorder
- Bereavement
- Schizophrenia

TABLE 23-12 CAUSES OF PSYCHOSIS AND DELIRIUM: A PARTIAL LIST**Potentially Imminently Life-Threatening Causes**

- Meningitis or encephalitis
- Hypoxemia
- Hypertensive encephalopathy
- Wernicke encephalopathy
- Intracranial bleed
- Drug withdrawal, intoxication, or reaction to prescribed drugs

Other Medical Causes

- Metabolic disorders (e.g., hyperglycemia and hyponatremia)
- Neurologic disorders
- Nutritional deficiencies (e.g., pellagra, beriberi, and pernicious anemia)
- Industrial exposure to toxins

Psychiatric Causes

- Schizophrenia or schizophreniform disorders
- Brief psychotic disorder
- Mood disorders including bipolar disorder and psychotic depression
- Schizoaffective disorder
- Dementia
- Delirium
- Delusional disorder

Answer 23.17.2 The correct answer is “D.” Bereavement may result in mild delusions and sometimes hallucinations regarding the bereaved subject (Hey? Is that mom back from the dead?), but it should not cause overt psychosis. Moreover, there is nothing in the history here to support a diagnosis of bereavement. The remaining options are potential cause of psychosis, and they are listed along with other potential causes in Table 23-12.

**HELPFUL TIP:**

Psychosis is a symptom and not a diagnosis. It should prompt a search for an etiology. Some of the causes are potentially life threatening as listed in Table 23-12.

Hypnotized by your calm and steady voice, the patient relaxes and becomes cooperative, and you are able to obtain a history and perform a physical examination. He denies drug use or medical illnesses. Your patient worries that he is going “crazy” and admits that he has been having these symptoms “for a while” but did not want to tell anybody, for fear of being institutionalized. Your physical examination and labs (TSH, BMP, glucose, urine drug screen) are unremarkable.

Question 23.17.3 Which of the following diagnoses is the most likely cause of this patient’s psychosis?

- Schizophrenia
- Psychotic depression
- Delirium
- Drug intoxication
- Dementia

Answer 23.17.3 The correct answer is “A.” Schizophrenia is a heterogeneous group of disorders characterized by the following: positive symptoms (delusions, hallucinations, disorganized behavior, disorganized speech); negative symptoms (poverty of speech, anhedonia, affective flattening, avolition, withdrawal from social activities); mood symptoms (dysphoria, suicidal thoughts, hopelessness); and cognitive symptoms (attention and memory deficits and difficulty with abstract thinking). It is the most common of the psychotic disorders. A negative laboratory evaluation and physical examination make drug intoxication unlikely, while this patient’s ability to converse with you and give a history makes delirium and dementia unlikely. Psychotic depression is unusual in young people, but rather is more commonly seen in older patients with severe depression.

Question 23.17.4 Which of the following is NOT true about schizophrenia?

- A) Nearly 50% of patients attempt suicide with a 10% success rate
- B) Lifetime prevalence is 1% worldwide, consistent across cultures
- C) Schizophrenia is a disease of late adolescence or early adulthood
- D) Men are more likely to be affected than women
- E) Risk of relapse is at least 50% after successful treatment in patients who do not remain on antipsychotic maintenance therapy

Answer 23.17.4 The correct answer is “D.” Schizophrenia has a worldwide prevalence of about 1%, which is true for all cultures, countries, and both genders (“B”). It generally begins in late adolescence or early adulthood, and onset after age 50 is rare and should prompt the search for other etiologies to explain the psychosis (“C”). Men have a slightly earlier age of onset (early twenties) than women (late twenties), but men and women are affected equally by the illness. The course is variable with some patients having exacerbations and remissions (although full remissions are rare), while others remain chronically ill. About half of the patients who develop schizophrenia have a family history of schizophrenia. Suicide attempts are common, usually the result of depression or a response to command hallucinations, paranoid delusions, or agitation. Nearly 50% of patients will attempt suicide, while about 10% will be successful (“A”). After successful treatment of the first episode, about 50% will relapse if not on maintenance medication (“E”).

Question 23.17.5 Which of the following medication options is the proper treatment choice?

- A) Olanzapine (Zyprexa)
- B) Risperidone (Risperdal)
- C) Haloperidol (Haldol)
- D) Aripiprazole (Abilify)
- E) Any of the above

Answer 23.17.5 The correct answer is “E.” All of the antipsychotics listed are first-line treatment choices for schizophrenia. Most psychiatrists have replaced older “typical” (now known as “first-generation” agents like haloperidol, chlorpromazine, fluphenazine, thioridazine) with newer “atypical” (now known as

“second-generation” agents, such as risperidone, clozapine, ziprasidone, paliperidone, and olanzapine) because of better tolerability and possibly increased benefit for negative symptoms. Although, the newer agents are significantly more expensive than the older agents, more generics are becoming available. Also, many “atypicals” cause significant weight gain, and some have been linked to new-onset diabetes and metabolic syndrome. Of the newer agents, aripiprazole (Abilify) and ziprasidone (Geodon) are less associated with weight gain and diabetes.

Question 23.17.6 Which of the following is TRUE of the course of schizophrenia?

- A) Positive symptoms usually occur first
- B) Negative symptoms are easier to treat than positive symptoms
- C) Negative symptoms often look like depression
- D) Schizophrenia is not typically associated with brain changes
- E) Family therapy is not helpful in this illness

Answer 23.17.6 The correct answer is “C.” Negative symptoms often precede the development of the positive symptoms by many years, are often nonspecific, and can be mistaken for depression. A typical history is that of a normal young man or woman who begins to fail classes and avoid his old friends as he gets to the end of high school. This is often mistaken for teenage rebellion, depression, or drug use until the onset of positive psychotic symptoms of hallucinations or delusions develop several years later. “B” is incorrect. Negative symptoms are chronic and are resistant to treatment with all currently available antipsychotics. Antipsychotic drugs modulate dopamine and/or serotonin and are much better at treating positive symptoms. “D” is not true, as brain imaging may reveal enlargement of cerebral ventricles and decreased brain volume. However, these findings are neither sensitive nor specific enough to have much value in diagnosis. “E” is incorrect. A large body of literature supports the fact that family therapy, especially directed at support and psychoeducation, reduces the risk of relapse. Recent evidence indicates that individual CBT can also be effective.

HELPFUL TIP: DUAL ANTIPSYCHOTICS

There is almost never an indication for more than one antipsychotic at a time. Don't do it.

► Objectives: Did you learn to ...

- Recognize psychosis and its causative diagnoses?
- Treat psychosis?
- Recognize schizophrenia and understand its epidemiology and prognosis?

► CASE 23.18

A 33-year-old factory worker comes to your clinic complaining of sleep difficulty since he moved to the “graveyard shift.” He complains of falling asleep at work and having difficulty sleeping during the day.

Question 23.18.1 Which of the following is the most likely diagnosis?

- A) Narcolepsy
- B) Circadian rhythm sleep–wake disorder
- C) Obstructive sleep apnea
- D) Primary insomnia
- E) Fatal familial insomnia

Answer 23.18.1 The correct answer is “B.” This patient suffers (as do most residents and a significant number of physicians) from a circadian rhythm sleep–wake disorder, which is defined as a sleep disruption leading to excessive sleepiness when the patient wishes to be awake or insomnia when the patient wishes to be asleep. It occurs as a result of a mismatch between the biological circadian rhythm and the person’s environment. He does not give a history consistent with narcolepsy or obstructive sleep apnea, and primary insomnia is a diagnosis of exclusion. Fatal familial insomnia (“E”) is a rare genetically determined prion disease resulting in complete inability to sleep, dementia, and death within a few years.

He asks your advice on how to treat his sleeplessness.

Question 23.18.2 What would be the best advice to offer at this time to help adapt to the nighttime schedule?

- A) Have him sleep at work
- B) Have him take naps throughout the day
- C) Tell him to quit his job
- D) Recommend bright light at night before going to work
- E) Prescribe stimulants for when he is at work

Answer 23.18.2 The correct answer is “D.” This patient’s circadian rhythm disturbance might also be called a “phase-advance” type sleep disorder (early sleep onset with insomnia at the desired sleep period). Such problems respond best to bright light in the evening to keep one awake during the time the individual would usually be asleep. Light boxes are available commercially and should provide white light at 2,500 lux or more. The light should be fairly close to the patient’s eyes, and a bit off to the side. The other options are not likely to be helpful if this patient wants to keep his job.

Question 23.18.3 If this patient wished to use a nutritional or herbal supplement, which of the following would you recommend?

- A) Melatonin
- B) Kava-kava
- C) Ginkgo
- D) Ginseng
- E) St. John’s wort

Answer 23.18.3 The correct answer is “A.” There is some evidence to suggest that melatonin can help with circadian rhythm disorders (and may decrease sleep onset latency in insomnia). Melatonin should be taken at the time of day the patient wants to sleep. In this case, you should advise him to take it in the

morning. The doses used for circadian rhythm disturbances are much less than the dose used for primary insomnia, typically 0.5 mg or less, compared with 3 to 5 mg. The other herbal supplements have no evidence for use in sleep disturbances except for kava-kava, which is too dangerous to recommend.

Question 23.18.4 Which of the following is NOT a delayed sleep phase type of circadian rhythm sleep disorder?

- A) Re-adaptation to day work from night work
- B) West-to-east jet lag
- C) East-to-west jet lag
- D) All of the above are delayed sleep phase disorders

Answer 23.18.4 The correct answer is “C.” Delayed sleep phase involves a persistent pattern of late sleep onset and late morning awakening. This is exemplified by the average teenager during summer vacation (just try to get him to mow the lawn before noon!). West-to-east jet lag and re-adapting to day shift after working night shift also cause similar problems; sleep onset can be late and one wants to sleep longer in the morning. “C” does not cause a delayed sleep phase disturbance. East-to-west jet lag causes the opposite problem, advancing sleep phase so that persons are sleepy early in the evening but then awake early in the morning. A potentially effective treatment of delayed sleep phase would include prescribing a bright light in the morning and melatonin in the afternoon.

► **Objectives: Did you learn to ...**

- Recognize circadian rhythm disorders?
- Recommend treatment of circadian rhythm disorders?

QUICK QUIZ: LEST YOU FORGET

A 70-year-old man presents with memory loss that has been progressive over the years. He often has fluctuating attention and is rigid with bradykinesia. He frequently experiences visual hallucinations.

Which of the following is the most likely diagnosis?

- A) Alzheimer disease
- B) Dementia with Lewy bodies (DLB)
- C) Parkinson disease
- D) Vascular dementia
- E) Frontotemporal dementia

The correct answer is “B.” DLB shares many features in common with Parkinson disease including parkinsonian motor symptoms, such as rigidity, tremor, and bradykinesia. Both Parkinson disease and DLB are characterized histologically by the presence of Lewy bodies. However, in DLB, Lewy bodies are diffusely spread in the cortical regions and brainstem, whereas in Parkinson disease, Lewy bodies are primarily present in the subcortical nuclei (substantia nigra). Fluctuating cognition that resembles delirium, visual hallucinations, and an exquisite sensitivity to the adverse effects of neuroleptics all characterize

DLB. Cholinesterase inhibitors may have modest benefit on cognitive symptoms, though none are FDA approved, and only rivastigmine is FDA approved for Parkinson's dementia.

QUICK QUIZ: DEMENTIA

A 65-year-old man with a history of hypertension, diabetes, and peripheral vascular disease has been noted to have abrupt deterioration in his cognitive ability following an episode of disorientation and word-finding difficulty 1 month ago.

Which of the following is the most likely diagnosis?

- A) Alzheimer disease
- B) Dementia with Lewy bodies
- C) Parkinson disease
- D) Vascular dementia
- E) Frontotemporal dementia

The correct answer is "D." Vascular dementia (previously known as multi-infarct dementia) is caused by vascular disease (Surprise! An illness with a name that makes sense!). After Alzheimer and Lewy body dementias, vascular dementia is one of the most common causes of dementia. It classically presents with an abrupt onset followed by step-wise deterioration of cognitive function. Medical comorbidities are common, including hypertension, diabetes, and obesity. Evidence of vascular disease is usually present on clinical examination with focal neurological signs, such as are seen after a stroke involving motor areas. Imaging typically shows infarctions of periventricular and deep subcortical white matter, presenting as white matter hyperintensities on T2-weighted MRI. Treatment includes modifying vascular risk factors.

► CASE 23.19

A 37-year-old female patient returns to see you for follow-up of depression. You last saw her 4 weeks ago, and at that time she was experiencing her third relapse of recurrent major depression. She had been in remission for 3 years before, and until 2 years ago she had been taking sertraline 150 mg daily, a regimen that she had found effective during an 18-month course of treatment. At her visit last month, you assessed her symptoms with the Patient Health Questionnaire-9 (PHQ-9), and her score at that time was 21. You reinstituted sertraline at 50 mg daily for 2 weeks and then 100 mg daily. At her visit today, now on sertraline 100 mg daily for 2 weeks, her PHQ-9 score is 17. She denies having thoughts of death or suicide.

Question 23.19.1 Which of the following statements is NOT true regarding the PHQ-9?

- A) The PHQ-9 is a clinician-administered questionnaire to evaluate for symptoms of major depression
- B) It takes 3 to 5 minutes to complete the PHQ-9
- C) A score of 10 or more on the PHQ-9 is a positive screen

- D) The PHQ-9 can be used to screen for depression as well as to monitor symptom severity over time
- E) The PHQ-9 does NOT assess for suicide risk

Answer 23.19.1 The correct answer is "A." The PHQ-9 is a *patient*-administered, nine-item questionnaire that takes 3 to 5 minutes to complete. It can be used to screen for major depression as well as to monitor symptom severity over time. A score >10 is considered a positive screen, while a score <5 is considered to be negative or in remission. The maximum score is 30. While the PHQ-9 does ask about the presence of "thoughts of death or dying," it does not assess whether someone is at low or high risk for suicide attempt.

Question 23.19.2 Which of the following options is LEAST appropriate to recommend to your patient at this time?

- A) Continue sertraline 100 mg daily and return for follow-up in 1 month
- B) Continue sertraline 100 mg daily, add weekly CBT, and return for follow-up in 1 month
- C) Increase sertraline to 150 mg daily and return for follow-up in 1 month
- D) Stop the sertraline and start citalopram/escitalopram 20 mg daily and return for follow-up in 1 month
- E) Continue sertraline 100 mg daily and add bupropion SR 150 mg BID, return for follow-up in 1 month

Answer 23.19.2 The correct answer is "D." At the current visit, the patient has been taking sertraline for 1 month and has been at the present dose for 2 weeks. It can take up to 6 to 8 weeks for an antidepressant medication to reach its full effect, so it is reasonable to maintain the medication at its present dose and reassess in 1 month. However, options "B," "C," and "E" are reasonable as well. Combination treatment with CBT and an antidepressant medication has been shown to be more effective for treating depression than either treatment strategy alone. You can also consider the addition of an augmentation agent (bupropion, lithium, or a second-generation antipsychotic). Since she has had a partial response to the current regimen, adding an augmentation agent is a reasonable option. Switching to a new antidepressant at this time is not indicated.

Despite increasing the dose of sertraline, your patient's depression does not improve. She's been watching a lot of TV (no wonder she's depressed) and seen ads for a medication called Happify, which is used to augment traditional antidepressant therapy. She says, "I think I need one of those new wonder drugs, Doc" (the so-called "wonder drugs" because it is a wonder that they ever got FDA approval).

Question 23.19.3 Which of the following have gained FDA approval as therapy for depression?

- A) Aripiprazole (Abilify)
- B) Haloperidol (Haldol)
- C) Olanzapine (Geodon)
- D) Quetiapine (Seroquel)
- E) A, C, and D

Answer 23.19.3 The correct answer is “E.” Aripiprazole (Abilify), quetiapine (Seroquel), and olanzapine (Geodon) are FDA approved as add-on medications to augment antidepressants in monopolar depression. The benefits are marginal, when examining a population with treatment resistant depression. For example, aripiprazole added to a traditional antidepressant in this population improved depression by 3-point difference on a 60-point scale and then only in men. For aripiprazole, the number needed to treat to achieve this small reduction in depressive symptoms is 10. On the bright side, aripiprazole is less associated with weight gain compared with other atypical antipsychotics.

► **Objectives: Did you learn to ...**

- Develop strategies to treat resistant depression?
- Describe a widely used depression assessment tool, the PHQ-9?

The world of psychiatric drugs is constantly moving (akathisia?). See <https://www.ncbi.nlm.nih.gov/books/NBK84656/> OR <https://www.empr.com/clinical-charts/psychotropic-drug-indications/article/123832/> for a list of indications of psychiatric medications.

HELPFUL TIP:

Random things to remember for the examination: clozapine (Clozaril) mandates a CBC monthly (and that prescribers be certified in a national registry) because of bone marrow suppression; second-generation antipsychotics can cause diabetes and are not free of neurologic side effects (e.g., extrapyramidal reactions), and patients on them should be monitored with periodic glucose and/or A1c; anticholinergics (e.g., benztropine) should be used with first-generation antipsychotics to prevent parkinsonian side effects.

Clinical Pearls

- Avoid first-line use of antipsychotic medication for indications other than psychotic disorders (e.g., depression in any patient, insomnia in any patient, behavioral disorders in children, or demented elders).
- Do not prescribe benzodiazepines as first-line therapy for the treatment of anxiety disorders.
- Do not diagnose “adult-onset” ADHD. Explore the history and if the patient has had ADHD symptoms since childhood, he/she may have a missed or delayed diagnosis of ADHD.
- Do not prescribe two antipsychotic medications simultaneously.
- Ensure that systems are in place to treat and refer patients diagnosed with depression, and screen for depression in the general adolescent and adult patient population. This includes assessing suicide risk.

- Offer pharmacotherapy and professional counseling services to all patients diagnosed with depressive disorders, as the combination results in better outcomes than either intervention alone.
- Screen for metabolic syndrome periodically in patients taking second-generation antipsychotics (e.g., olanzapine, risperidone, quetiapine).

Nutrition and Herbal Medicine

Jason K. Wilbur

► CASE 24.1

A 59-year-old male presents for follow-up. He is well-known to you, receiving chronic anticoagulation with warfarin for a mechanical aortic valve. His PT and INR have been in the therapeutic range for years. When asked, he denies taking any other medications. He has had no new medical problems and is feeling well. Today his INR is 6.2 (therapeutic range 2.5–3.5). You inquire about dietary changes, focusing on foods rich in vitamin K.

Question 24.1.1 Which of the following is true regarding vitamin K?

- A) Vitamin K is a water-soluble vitamin
- B) Broccoli and olive oil are good sources of vitamin K
- C) Vitamin K deficiency results in a hypercoagulable state
- D) Warfarin reduces the absorption of vitamin K
- E) Vegetarians are at risk for developing vitamin K deficiency

Answer 24.1.1 The correct answer is “B.” Vitamin K is a fat-soluble vitamin present in leafy green vegetables such as spinach and cabbage and in other foods such as milk, butter, bacon, and vegetable oils. Olive oil and broccoli are particularly rich in vitamin K. Therefore, vegetarians who consume these regularly are not at high risk for developing vitamin K deficiency. Vitamin K deficiency causes a **hypocoagulable** state resulting in a reduction in clotting factors and elevated prothrombin time and INR, leading to poor clotting ability and hemorrhage. Warfarin does act on vitamin K, but by reducing conversion of vitamin K to its active form rather than reducing absorption.

Question 24.1.2 You would be more likely to suspect vitamin K deficiency in this patient if he also suffered from which of the following conditions?

- A) Crohn disease
- B) Irritable bowel syndrome
- C) Well compensated hepatitis C with mild fibrosis
- D) Coronary artery disease (CAD)
- E) All of the above

Answer 24.1.2 The correct answer is “A.” Vitamin K deficiency can occur with chronic small bowel disease, after small bowel resection, and with use of broad-spectrum antibiotics. Microorganisms in the bowel synthesize vitamin K, and use of broad-spectrum antibiotics reduces the number of these organisms. The majority of vitamin K is absorbed in the distal small bowel, and any disease affecting this area—including Crohn disease and celiac disease—can reduce the absorption of the vitamin. Irritable bowel syndrome is a functional disease not associated with impaired absorption. “C” is of special note. Patients with cirrhosis and *decompensated* liver disease are often vitamin K deficient. However, the mere presence of hepatitis C does not cause vitamin K deficiency.

Upon more direct questioning, the patient denies any changes in his diet but admits to recently starting a vitamin therapy program. He has no clue what he is actually taking and calls his wife to find out what the products contain (it was Miracle Mega Man... something). Meanwhile, you suspect that he is taking excessive doses of vitamins that may affect his INR.

Question 24.1.3 Large doses of which of the following vitamins are most likely to result in an increased INR in patients taking warfarin?

- A) Vitamin A
- B) Vitamin C
- C) Vitamin D
- D) Vitamin E
- E) Zinc

Answer 24.1.3 The correct answer is “D.” Large doses of vitamin E (>400 IU/day) can interfere with vitamin K metabolism and platelet function, resulting in increased prothrombin time and therefore increased INR in some patients. In patients taking warfarin, starting a high-dose vitamin E supplement should be done cautiously. Extra monitoring of INR and/or warfarin dose adjustments may be needed. See Table 24-1 for more on supplements that can affect the INR.

TABLE 24-1 COMMON VITAMINS AND HERBALS THAT INTERACT WITH WARFARIN (PARTIAL LIST)

Warfarin Interaction	Vitamin/Herbal
↑ INR and risk of bleeding	Danshen Dong quai Fish oil Garlic Ginkgo Policosanols Vitamin E
↓ INR and risk of bleeding	Coenzyme Q10 St. John wort Vitamin K

The other options are unlikely to affect the INR. Vitamin A (“A”) consumed in quantities exceeding 10 times the *recommended daily allowance* (RDA) for several months may cause alopecia, ataxia, glossitis, and hepatotoxicity. Vitamin C (“B”) is usually well tolerated but large doses can cause nausea, diarrhea, and abdominal pain. Excessive intake of vitamin D (“C”) may cause hypercalcemia, hypercalciuria, nausea, vomiting, myalgia, and, paradoxically, bone demineralization. Symptoms of zinc (“E”) toxicity include nausea, anemia, loss of sense of smell and taste (when administered nasally), and depressed immune function.

**HELPFUL TIP:**

Patients with cholestasis (pregnancy, central venous nutrition, sclerosing cholangitis, cystic fibrosis, etc.), including those with postobstructive jaundice, are often vitamin K deficient due to poor absorption of vitamin K (*Nutr Res.* 2009 Sep;29(9):676–683 and others).

**HELPFUL TIP:**

Compared with water-soluble vitamins (B and C), fat-soluble vitamins (A, D, E, and K) are more likely to accumulate, resulting in toxicity. In related news, Americans are said to have the most expensive urine in the world due to the numerous water-soluble, and mostly useless mega dose vitamins and supplements we take ... simply to pass them through our kidneys.

**(VERY) HELPFUL TIP:**

Vitamin K can be useful in patients with a hard to control INR. Start a vitamin K supplement of 100 to 200 µg/day. This will help to eliminate diet-dependent INR fluctuations.

back next week for another PT/INR. Before leaving, he asks about taking a multivitamin, complaining, “Gotta do something to get my mojo back, Doc.”

Question 24.1.4 From available evidence, and regarding his **mojo** (whatever that is), you are able to tell him:

- A) “Most multivitamins do not contain enough vitamin E to cause a problem”
- B) “Multivitamins should be standard preventive medicine and have a well-described role in improving health”
- C) “Iron supplements are recommended for middle-aged males”
- D) “Folic acid and B vitamins should be taken by everyone with aortic stenosis to reduce homocysteine”

Answer 24.1.4 The correct answer is “A.” Most multivitamins contain less than 400 IU of vitamin E and usually will not cause a problem. A fairly well-balanced diet based of whole, unprocessed foods provides the necessary nutrients to avoid vitamin deficiency syndromes. Supplementation with multivitamins is *not* necessary unless there are dietary intake deficiencies related to an unbalanced diet or a specific malabsorption issue, such as might occur with Crohn disease or bowel resection.

Taking a multivitamin has **not** been linked to improved health status. Average adult males generally have adequate iron stores and should not receive supplemental iron due to the potential for exacerbating undiagnosed iron storage disease. While folate, vitamin B6, and vitamin B12 lower serum homocysteine levels, there is no evidence that this intervention is helpful in reducing disease burden or improving health in those with known coronary artery disease or venous thromboembolism. While you may be able to lower serum homocysteine levels in patients with hyper-homocysteinemia, doing so *does not* lower risk of atherosclerotic cardiovascular disease or VTE risk.

Question 24.1.5 Regarding vitamin and mineral supplementation, which of the statements is FALSE?

- A) Folate supplementation during pregnancy is recommended to decrease the risk of neural tube defects
- B) Calcium and vitamin D supplementation in postmenopausal females are recommended to reduce the risk of osteoporosis and fractures
- C) Vitamin D supplementation is recommended for breastfed infants, starting in the first few days of life
- D) Vitamin D supplementation in elderly patients does not reduce the risk of falling
- E) Vitamin E supplementation in elderly patients reduces the risk of cardiovascular disease

Answer 24.1.5 The correct answer (and false statement) is “E.” Vitamin E supplementation has not been shown to reduce the risk of cardiovascular disease and has been associated with an increased risk of all-cause mortality at doses >400 IU/day. Additionally, high-dose (>400 IU/day) vitamin E is associated with an increase in prostate cancer in men and does not improve cognition in those with mild cognitive impairment or dementia. Basically, vitamin E has lost its “mojo.” The other answers are

The patient learns that the vitamin therapy he currently takes has large amounts of vitamin E, but no vitamin K. You counsel him to discontinue this supplement, hold a dose of warfarin, and then continue on the same dose. You ask him to come

true statements. “A” has plenty of evidence to back it up. Folate supplementation is universally recommended during the prenatal period and should be started even before pregnancy actually occurs. “B” is widely recommended, although the evidence for calcium-reducing fracture risk is weak. As for “C,” the American Academy of Pediatrics (AA) and the CDC recommend that totally or partially breastfed infants take 400 IU of vitamin D daily, starting in the first few days of life and continue until taking at least 1 liter per day of vitamin D fortified formula or milk. “D,” Vitamin D, a mighty force in medicine just a few years ago, has fallen far. In fact, it is no longer recognized as an intervention for fall prevention in the elderly. Several negative studies have been published, and the Cochrane Collaboration concluded, “Overall, vitamin D supplementation does not appear to prevent falls.”

HELPFUL TIP:

In general, daily multivitamins do not contain large enough doses of vitamins to result in toxicity, and any unneeded water-soluble vitamins are excreted in the urine. So, taking a daily multivitamin is a good way for patients to make expensive, vitamin-fortified urine.

► **Objectives: Did you learn to ...**

- Describe signs and causes of vitamin K deficiency?
- Identify common vitamins and herbals that interact with warfarin?
- Recognize symptoms of fat-soluble vitamin toxicities?
- Identify benefits, risks, and limitations of vitamin supplementation?

QUICK QUIZ: SUPPLEMENTS TO BREAST MILK

A 6-month-old male infant presents for routine health examination and immunizations. His mother is a strict vegan and has been nursing him exclusively. She has not introduced any foods and she wants to keep breastfeeding him primarily for at least the next 6 months ... or until his friends start to tease him, she jokes (you hope). She takes no medicines and no supplements of any kind.

For this mother and her child, you recommend all of the following EXCEPT:

- A) Vitamin B12 supplementation for the mother
- B) Vitamin C supplementation for the mother
- C) Vitamin D supplementation for the infant
- D) Iron supplementation for the infant

The correct answer is “B.” Children breastfed by strict vegan mothers should have vitamin B12 supplementation for either themselves or their mother. Vitamin C supplementation is not required. As above, vitamin D is recommended for all breastfed infants. According to the AAP and CDC, iron supplementation is recommended in all breastfed infants starting at 4 months of age until iron-containing foods become a routine part of their

diet (supplemental dose is 1 mg/kg/day). There are a variety of liquid multiple vitamins to choose from (e.g., Poly-Vi-Sol®).

► **CASE 24.2**

A 34-year-old female presents to your office with concerns about weight gain. She has gained over 100 lb since she graduated from high school. She tearfully reveals that the weight gain has come despite “not eating much.” She walks for exercise, but is unable to quantify her walking (the Fitbit battery died).

She denies chronic illnesses. Her only surgery was a tubal ligation after her last child. She smokes 10 cigarettes per day and is unwilling to quit due to fears of further weight gain. She drinks alcohol once or twice per week, never consuming more than three beers. The review of systems is positive for a dry cough, bilateral knee pain, and fatigue.

On physical examination, you find an afebrile female with an elevated blood pressure (142/94 mm Hg). She is 5 ft 3 in tall and weighs 231 lb. Her body mass index (BMI) is 41 kg/m². You find trace pitting edema at the ankles bilaterally. There is increased pigmentation in the folds of the neck and the knuckles. The remainder of the examination is unremarkable.

The patient realizes that she is overweight and asks, “How bad am I?”

Question 24.2.1 Regarding definition and classification of obesity, which of the following is true?

- A) Obesity is defined as BMI ≥ 25 kg/m²
- B) Severe obesity is defined as BMI > 30 kg/m²
- C) Underweight is defined as BMI < 20 kg/m²
- D) Obesity is defined as BMI ≥ 30 kg/m²
- E) Malnourished supermodel status is defined as BMI < 30 kg/m²

Answer 24.2.1 The correct answer is “D.” Obesity is defined by BMI ≥ 30 kg/m²; therefore, only “D” is correct. See Table 24-2 for definitions of weight status by BMI. The calculation for BMI is as follows:

$$\text{BMI (kg/m}^2\text{)} = \text{weight (kg)} / [\text{height (m)}]^2.$$

TABLE 24-2 DEFINITION OF WEIGHT STATUS BY BMI

Weight Status		BMI (kg/m ²)
Underweight		<18.5
Normal		18.5–24.9
Overweight		25.0–29.9
Obese	Class I	30.0–34.9
	Class II	35.0–39.9
Extremely/Severely obese	Class III	≥ 40.0

Example: weight = 110lb(50kg), height = 59in(1.5m),
therefore

$$\text{BMI} = 50/(1.5)^2 = 22.2\text{kg/m}^2.$$

HELPFUL TIP:

In American adults in 2016, the CDC estimated that the prevalence of obesity was 39.8%, which does not include people in the “overweight” category. Now that’s what we call an epidemic! Prevalence of obesity appears to be somewhat socioeconomically determined, with poorer and less educated populations having higher rates of obesity. There are many reasons for this: epigenetics, “food deserts” where it is hard to find fresh foods, the cost of fresh foods versus high calorie carbohydrates and fats, etc.

HELPFUL TIP:

There has been controversy regarding whether the current BMI cut-offs are applicable across different ethnic populations, as there is evidence that body fat percentage, distribution of body fat (waist-hip ratio), and BMI may differ within different ethnic groups. Further, there is evidence that waist-to-hip ratio correlates more strongly with mortality and obesity-related disease than does BMI (*Ann Intern Med.* 2017;166(12):917–918).

You ask her about medications, focusing on those related to obesity.

Question 24.2.2 All of the following drugs are associated with weight gain and an increased risk of obesity EXCEPT:

- A) Olanzapine
- B) Topiramate
- C) Gabapentin/Pregabalin
- D) Valproic acid
- E) Glipizide

Answer 24.2.2 The correct answer is “B.” Topiramate may actually help patients lose weight. In fact, it is one of the components of the weight loss drug Qsymia® (phentermine/topiramate). Note especially that gabapentin and pregabalin cause weight gain, a bad thing when used in diabetes. See Table 24-3 for a list of medications associated with weight gain.

Question 24.2.3 Which of the following is the most appropriate next step in the evaluation of this patient’s weight gain?

- A) Refer for a sleep study
- B) Check urinary free cortisol level
- C) Draw blood for thyroid-stimulating hormone level
- D) Evaluation for adrenal adenoma causing Cushing disease
- E) Cast your gaze down realizing that affecting behavior change is difficult

TABLE 24-3 DRUGS ASSOCIATED WITH WEIGHT GAIN (NOT AN EXHAUSTIVE LIST)

Class	Specific Agents
Alpha Blockers	Prazosin, doxazosin, terazosin
Anticonvulsants	Valproate, carbamazepine, gabapentin
Antidepressants	Tricyclics (e.g., amitriptyline) and monoamine oxidase inhibitors (MAO-Is), selective serotonin reuptake inhibitors (SSRIs) in some patients
Antihistamines	Cyproheptadine, diphenhydramine
Antipsychotics	Olanzapine, thioridazine, haloperidol, risperidone
Beta blockers	Propranolol, metoprolol, atenolol
Diabetes drugs	Insulin, sulfonylureas, thiazolidinediones
Steroid hormones	Corticosteroids, oral contraceptives, estrogen, progesterone, testosterone

Answer 24.2.3 The correct answer is “C.” Because of her obesity, this patient is also at risk for sleep apnea, diabetes, hypertension, and hyperlipidemia. These concerns will need to be addressed. However, her chief complaint is weight gain, which could certainly be due to an underlying disease. Although in most overweight patients a cause for weight gain is not found, the physician is obligated to search for potentially treatable causes of weight gain, including hypothyroidism. The symptoms of hypothyroidism are often nonspecific and include weight gain and fatigue. That said, an exhaustive search for underlying causes of obesity is not required for the vast majority of patients. History, exam, and limited laboratory evaluation should be sufficient for most patients.

HELPFUL TIP:

Complications of obesity include heart disease, type 2 diabetes, hypertension, stroke, hyperlipidemia, gallbladder disease, obstructive sleep apnea, reduced fertility, increased risk of certain cancers (prostate, colon, breast, endometrial), and emotional distress.

Question 24.2.4 On physical examination of this patient, you note velvety patches of hyperpigmentation in her axillary areas and at her posterior neck. This finding raises concern for which of the following diseases?

- A) Skin cancer
- B) Diabetes
- C) Hemochromatosis
- D) Colon cancer
- E) Hypertriglyceridemia

Answer 24.2.4 The correct answer is “B.” Acanthosis nigricans, classically described as velvety hyperpigmentation in skin creases (axilla, back, neck, flexor aspects of arms), is associated

with a number of diseases. Acanthosis nigricans occurs in insulin-resistance syndromes, commonly in patients with type 2 diabetes. It is also associated with other endocrine abnormalities, including Cushing disease and hypothyroidism. Acanthosis nigricans can be an external sign of internal malignancy, most commonly gastrointestinal (GI) cancers. However, this patient is at lower risk of colon cancer than diabetes, given her age, weight gain, and lack of other signs and symptoms of cancer. Hemochromatosis, hypertriglyceridemia, and skin cancer are not associated with acanthosis nigricans.

She wonders which popular diet she should use to lose weight.

Question 24.2.5 You let her know that the most effective popular diet is:

- A) Low carbohydrate (“Atkins diet”)
- B) Low fat (“Ornish diet”)
- C) Low glycemic load diet (“Zone diet”)
- D) High protein (“Paleo diet”)
- E) No one particular diet is more effective than others for weight loss. The key to success is choosing a diet that you can maintain

Answer 24.2.5 The correct answer is “E.” Any diet you can stick to seems to work. There does not seem to be any advantage to one diet over another for weight loss (except for making the proprietors wealthy). For example, Weight Watchers may have a bit better success because of peer pressure, weekly meetings, and motivational techniques (*BMJ*. 2011;343:d6500). But any diet that you can maintain long-term will work. Of note, the common belief that maintaining a 3,500 calorie weekly deficit will result in 1 lb (0.45 kg) of weight loss per week is a myth. But reducing calorie intake by 100 calories per day may lead to a gradual weight loss of approximately 10 lb over 1 to 3 years (*Am Fam Physician*. 2015;91(9):634–638).

HELPFUL TIP:

If you want to give your patients a more realistic (and, sadly, more complicated) method of determining how much weight they can expect to lose when making lifestyle changes, point them to the evidence-based Body Weight Planner produced by the NIH, available online at www.niddk.nih.gov/bwp. The website links to multiple tools for patient education and self-management.

She is wondering about her level of physical activity and is afraid that her obesity will decrease her ability to become functionally fit with exercise.

Question 24.2.6 Your response to this is that:

- A) Gluttony and sloth go together, so give up the exercise
- B) One cannot improve one’s physical performance without weight loss
- C) Dante did not know what he was talking about; it is TV and sloth that go together

- D) Exercise is beneficial for fitness regardless of whether or not one loses weight
- E) Exercise is useless for weight loss—every cookie you eat is another mile on the treadmill, minimum

Answer 24.2.6 The correct answer is “D.” Losing weight is notoriously hard to do. Thankfully, exercise, in and of itself, increases functional capacity regardless of weight loss (*N Engl J Med*. 2011;364(13):1218–1229). Obviously, patients do better if they both exercise and lose weight. But sticking to an exercise regimen is still helpful. With regard to the others, there was no evidence-based medicine or TV during the time of Dante, so we will never know.

HELPFUL TIP:

Aside from weight loss, some of the popular diets have other health benefits. A low-glycemic index diet (vegetables, chicken, fish, whole grains, beans, nuts, etc.) can lower HbA_{1c} in patients with type 2 diabetes when compared with a high whole-grain carbohydrate diet (brown rice, whole wheat foods, etc.). Psyllium (Metamucil and others) can also help reduce HbA_{1c}. A Paleolithic diet based on meat, fish, fruits, vegetables, root vegetables, eggs, and nuts also results in lower mean values of HbA_{1c}, diastolic blood pressure, weight, BMI, and waist circumference over a 3-month period when compared to an American Diabetes Association diet (*Cardiovasc Diabetol*. 2009;8:35). In a “dose-dependent” fashion, the Mediterranean diet improves glycemic control and reduces cardiovascular risk, including stroke risk (*Stroke*. 2018;0:2415–2420).

You find that the patient’s thyroid function is normal. After consultation with a nutritionist and a prescription for exercise, she returns 3 months later. Her weight is 222 lb. Clearly frustrated, she tells you that she barely eats and needs something more to help her lose weight.

Question 24.2.7 According to evidence-based consensus guidelines, which of the following is/are generally accepted criteria that patients must fulfill to be candidates for weight loss pharmacotherapy?

- A) BMI of 30 kg/m² or greater
- B) BMI of 27 to 29.9 kg/m² with an obesity-related comorbidity
- C) BMI of 25 kg/m² or greater and an acting career in jeopardy
- D) All of the above
- E) None of the above

Answer 24.2.7 The correct answer is “E.” Sorry, readers. This fits under the category of “trick question.” Here’s the issue: there are **no** evidence-based consensus guidelines for weight loss pharmacotherapy. However, expert recommendations and insurance coverage for drugs (if it exists, which often is not the case) generally agree with “A” and “B.” Pharmacotherapy may be considered when comprehensive lifestyle modification fails

to achieve reasonable weight loss goals (e.g., 5% body weight) for patients with BMI 30 kg/m² or greater or with BMI 27 to 29.9 kg/m² with health complications. “C” is clearly incorrect—hopefully. Don’t prescribe weight loss drugs simply for patients whose BMI is in the overweight range (25–29.9 kg/m²) and who are not suffering any obesity-related health effects.

As your patient is not meeting with an ounce of success (literally), you engage in a discussion about weight loss pharmacotherapy.

Question 24.2.8 Which of the following medications is indicated by the FDA to treat obesity?

- A) Levothyroxine (Synthroid, Levoxyl)
- B) Methylphenidate (Ritalin)
- C) Orlistat (Xenical, Alli)
- D) Paroxetine (Paxil)

Answer 24.2.8 The correct answer is “C.” Drug therapy is considered appropriate as an add-on to lifestyle management for people with a BMI of 30 kg/m² or greater, or a BMI of 27 kg/m² or more who already have a comorbid condition such as diabetes, hypertension, or hyperlipidemia. Of the choices listed, only orlistat is indicated by the FDA to treat obesity (more below). “A” and “B” are incorrect. Although patients treated with these medications might lose weight as a side effect, obesity alone is not an indication for levothyroxine or methylphenidate. Paroxetine (“D”) may be associated with weight gain and is not indicated for obesity.

Question 24.2.9 Which of the following weight loss drugs results in GI side effects in up to 40% of patients using it?

- A) Orlistat (Alli, Xenical)
- B) Topiramate (Topamax)
- C) Phentermine (Adipex-P, Ionamin)
- D) Lorcaserin (Belviq)

Answer 24.2.9 The correct answer is “A.” Orlistat is a lipase inhibitor that functions in the intestines and prevents the absorption of about 30% of dietary fats. Because of its mechanism of action, orlistat is associated with GI side effects in 40% of patients taking the drug. The most bothersome potential adverse effects include fecal incontinence and abdominal pain. Orlistat should be taken with meals. The prescription dose is 120 mg three times per day (Xenical); while an over-the-counter version (Alli) is available at half the dose—and far less than half the cost with relatively similar efficacy. Weight loss is modest: 3 to 4 kg over 1 year compared with placebo. Topiramate (“B”) alone is not approved by the FDA for use as a weight loss drug, but the combination phentermine/topiramate (Qsymia) is. Phentermine (“C”) is a sympathomimetic and carries adverse effects of hypertension, tachycardia, etc., and is indicated for up to 12 weeks due to concerns about the potential for abuse. Lorcaserin (“D”) is a 5HT_{2c} selective serotonin agonist that is FDA-approved for treating obesity, and it is relatively safe. Unlike serotonin agonists that preceded it, lorcaserin has not (yet) been associated with cardiac valvulopathy.

HELPFUL TIP:

Orlistat may result in fat-soluble vitamin deficiencies. If a patient is taking orlistat long-term, advise them to take a multivitamin separated in time from orlistat—experts often recommend this before bedtime since orlistat is taken with meals.

Your patient points out that she has a family history of diabetes and wonders about taking a weight loss medication that could help her prevent or treat diabetes.

Question 24.2.10 Which of the following medications is FDA-indicated to treat both obesity and type 2 diabetes (albeit at different doses and under different brand names)?

- A) Glipizide
- B) Liraglutide
- C) Metformin
- D) Sitagliptin

Answer 24.2.10 The correct answer is “B.” Liraglutide is a GLP-1 agonist (also called an incretin mimetic) which is marketed as Saxenda® for obesity and Victoza® for diabetes. Its maximum dose varies depending on the indication: for obesity the maximum daily dose is 3 mg and for diabetes it is 1.8 mg. Compared to placebo, patients taking liraglutide lose 2 to 4 kg of body weight and significantly more patients reach 5% total body weight reduction. GI side effects are the most common adverse events, and cost may be prohibitive for many patients. Glipizide (“A”) is associated with weight gain. Although metformin (“C”) and sitagliptin (“D,” Januvia®) are associated with modest weight loss, they are not FDA-indicated for treating obesity.

You initiate a medication to help her lose weight and refer her to a weight loss program that focuses on overall lifestyle modification. When she returns in 3 months, her weight is 235 lb, and she is very frustrated.

Question 24.2.11 You appropriately recommend which of the following?

- A) Adding a second drug for weight loss
- B) Referral to psychiatry
- C) Referral to bariatric surgery
- D) Referral to plastic surgery

Answer 24.2.11 The correct answer is “C.” This patient now meets accepted indications for bariatric surgery. See Chapter 22 for more information about weight loss surgery.

HELPFUL TIP:

Drug therapy and surgery are no substitute for basic lifestyle modifications, including appropriate dietary modifications and regular aerobic exercise. These lifestyle approaches should be continued during drug treatment and are absolutely essential after surgery.

► **Objectives: Did you learn to ...**

- Define normal weight, overweight, and obesity?
- Appropriately evaluate the obese patient?
- Recognize goals and methods of treating obesity?
- Recognize complications that occur as a result of obesity?

**QUICK QUIZ: VITAMIN DEFICIENCIES**

A 63-year-old male presents to the office after his daughter came home for the holidays and found him confused. At first she thought he was drunk, but after a few days, the confusion persisted. He has never had problems with complicated alcohol withdrawal before. According to the daughter, the patient drinks about half of a bottle of vodka per day and has done so for years (Hawkeye Vodka is the Iowa favorite ...). Although the patient is not able to give much of a coherent history, you are able to determine that he has developed shortness of breath and leg edema. His appetite has been poor for “a long time” and he may have lost some weight although he is not sure.

Physical examination reveals a malnourished, disoriented male who appears older than his stated age and is disheveled. He is mildly tachycardic, but his other vital signs are normal. He has bibasilar crackles on lung examination, 2+ pedal edema, hepatomegaly, and spider telangiectasias.

What is your first action to take with this patient?

- A) Administer D50 intravenous (IV)
- B) Administer thiamine IV
- C) Administer vitamin B12 IM
- D) Administer niacin orally
- E) Administer folate orally

The correct answer is “B.” This patient almost certainly has thiamine (vitamin B1) deficiency and appears to be symptomatic. In the United States, thiamine deficiency is most often seen in malnourished alcoholics. Early symptoms of thiamine deficiency are vague (similar to how the author/editors wrote the case) and include anorexia, fatigue, and irritability. Thiamine-deficient patients may progress to beriberi (wet or dry), possessing symptoms of heart failure and/or neuropathy (motor and sensory). Other possible manifestations of thiamine deficiency include Wernicke encephalopathy (ataxia, ocular-motor abnormalities [e.g., gaze paralysis], mental status changes, dietary deficiency) and Wernicke–Korsakoff syndrome (Wernicke syndrome plus additional memory loss and confabulations). **Note that most patients do not have all of the findings. Most have a partial syndrome.** Treatment is to administer thiamine IV and then to continue oral supplementation. IV carbohydrates, such as D50 (“A”), should be avoided until thiamine is given as they can worsen encephalopathy (although if the patient is neuroglycopenic, treatment is still warranted).

**HELPFUL TIP:**

The dosage of thiamine administered for treatment and prevention of Wernicke encephalopathy differs. For prevention of Wernicke encephalopathy, give thiamine

100 mg daily. For treatment of Wernicke encephalopathy, give thiamine 500 mg IV BID–TID for 2 days followed by 500 mg IV daily for 5 more days (although recommendations vary and no randomized trials support one regimen over another).

**HELPFUL TIP:**

Other micronutrient deficiencies that occur in alcoholic patients include niacin deficiency resulting in pellagra (dermatitis, diarrhea, and dementia); folate deficiency resulting in macrocytic anemia; vitamin B12 deficiency (generally due to problems with GI absorption rather than as a direct effect of alcoholism) resulting in anemia, neuropathy, and dementia. A multivitamin is certainly reasonable in this patient population.

► **CASE 24.3**

A 58-year-old postmenopausal female presents to your office with concerns about osteoporosis. A review of her medical history shows a bone density T-score of –1.8 from 2 years ago, suggesting moderate osteopenia. As you review her medical record, you note that last year she had lipids measured which were: total cholesterol of 210 mg/dL, LDL 140 mg/dL and HDL 45 mg/dL, and triglycerides 125 mg/dL. She had a partial thyroidectomy 15 years ago and currently takes levothyroxine 88 µg/day.

Question 24.3.1 Based on the evidence, which of the following supplements is most appropriate for this patient?

- A) Calcium alone
- B) Calcium and vitamin D
- C) Vitamin D alone
- D) Ipriflavone

Answer 24.3.1 The correct answer is “B.” Postmenopausal women should take 1,200 mg/day of **elemental** calcium with total of diet plus supplements not exceeding 2,000 mg of elemental calcium per day. The recommendations for supplemental calcium are muddled a bit by the observation that higher calcium **supplement** intake is associated with greater risk of CAD. Vitamin D is also appropriate, and many women do not get enough. As supplements go, vitamin D may be more important than calcium.

In terms of vitamin D, recommended doses are 400 IU/day for infants, 600 IU/day for ages 1 to 70, and 800 IU/day in those over age 70 (Institute of Medicine, 2011). The guideline also concludes that there is not any good evidence for vitamin D beyond its use for bone health.

Ipriflavone is a semisynthetic isoflavone produced from soy isoflavones. There is evidence that it can prevent bone mineral density loss when used with calcium in postmenopausal women, but it has not been shown to reduce fracture rates. There are also concerns that it might cause lymphocytopenia in some patients.

**HELPFUL TIP:**

If you are concerned about prevention of osteoporosis, start early, really early. Counsel adolescent females to get at least 1,300 mg of elemental calcium and 600 IU of vitamin D daily.

You counsel her to take 1,200 mg of elemental calcium per day.

Question 24.3.2 In order to improve GI absorption of calcium, you recommend:

- A) Taking 1,200 mg at one time with a meal
- B) Taking 1,200 mg at one time an hour before eating
- C) Taking 1,200 mg in three divided doses with meals
- D) Taking 1,200 mg in three divided doses on an empty stomach
- E) Taking 1,200 mg with her levothyroxine

Answer 24.3.2 The correct answer is “C.” Calcium is best absorbed when taken with food. Theoretically, GI absorption of calcium is limited, and for that reason divided dosing in 500 to 600 mg aliquots or less is recommended. Patients should take levothyroxine separately from their calcium. If taken together, calcium reduces levothyroxine absorption. This is also true of iron and levothyroxine.

She then asks you about her cholesterol levels and whether taking soy would be helpful. A friend told her that older women should take soy to prevent heart disease, breast cancer, osteoporosis—basically, they told her soy will help her to cheat death.

Question 24.3.3 Which of the following is appropriate to tell this patient?

- A) Soy isoflavone supplements are preferred for reducing lipid levels
- B) Dietary soy protein is not associated with a reduced risk of developing heart disease in Western women
- C) Soy protein is as effective as a statin for lowering cholesterol
- D) Soy isoflavones are an acceptable alternative to calcium and vitamin D for preventing osteoporosis

Answer 24.3.3 The correct answer is “B.” Soy protein can modestly reduce lipid levels in some patients but has been shown not to affect important outcomes such as heart attack or death in Western women. Soy isoflavone supplements have not been shown to reduce lipid levels. Soy protein is not nearly as effective as statin drugs (e.g., atorvastatin and simvastatin) are. Soy protein or soy isoflavone supplements are not an appropriate alternative to calcium and vitamin D.

Your patient is hoping you can settle a bet. She asks about her younger sister who is going through “the change” (quarters, nickels, pennies ...) and started taking black cohosh. Her sister swears the black cohosh helps her hot flashes, but your patient thinks it’s “all in her head.”

Question 24.3.4 Regarding the use of black cohosh for the treatment of perimenopausal vasomotor symptoms, you tell her:

- A) Black cohosh is equivalent to hormone replacement therapy
- B) Black cohosh is equivalent to placebo
- C) Black cohosh is not good for vasomotor symptoms but does promote liver health
- D) Black cohosh is only effective when taken as part of a multi-botanical supplement

Answer 24.3.4 The correct answer is “B.” Most studies of black cohosh are not well done. A Cochrane Collaboration review in 2012 found insufficient evidence for black cohosh for menopausal symptoms. The arguments against its use are the *rare* (if any) cases of hepatotoxicity, so “C” is wrong.

**HELPFUL TIP:**

Soy protein integrated into the diet is generally recognized as safe and is acceptable for women who want to try it. But it should not replace proven therapies. Soy is a common food allergen. See Table 24-4 for an overview of soy benefits.

**HELPFUL TIP:**

While other herbal products like phytoestrogens, wild yam, primrose oil, and vitamin E claim efficacy in treating menopausal symptoms, rigorously designed clinical trials performed to date have not confirmed their efficacy.

Question 24.3.5 Which of the following natural products could be recommended for lowering LDL cholesterol?

- A) Fish oil
- B) Psyllium
- C) Garlic
- D) Policosanol (a drug derived from sugar cane)
- E) All of the above

Answer 24.3.5 The correct answer is “B.” Taking a psyllium supplement (e.g., Metamucil) 10 to 12 g daily can reduce total cholesterol by up to 14% and LDL by up to 10%. Fish oil (“A”) is effective for lowering triglycerides, but not total cholesterol or LDL cholesterol. Clinical outcomes do not seem to change with the use of fish oil and it has fallen by the wayside. Garlic (“C”) was long considered effective for modest reduction in cholesterol, but the evidence shows that garlic does not significantly reduce cholesterol in most people. Similarly, policosanol (“D”) was once considered effective for reducing cholesterol, but evidence is inconsistent. The most reliable evidence shows that it is ineffective. To be complete, “red yeast rice” does lower LDL and contains lovastatin, though the dose, and thus the response, is inconsistent; it is a poor substitute for a statin.

TABLE 24-4 OVERVIEW OF THE EFFECTIVENESS OF SOY

Condition	Effectiveness Data	Comment/Recommendation
Breast cancer	Higher intake of soy in the diet is associated with decreased risk of breast cancer. But most research limited to Asian populations. May not apply to Western populations. No clinical trials.	Unknown benefits in Western populations. Data are not strong enough to recommend dietary soy for this use.
Hyperlipidemia/ cardiovascular disease	Consuming soy protein in place of other protein sources might modestly reduce lipid levels. Does not apply to soy isoflavone supplements. No evidence that eating soy improves outcomes such as death or heart attack. Population research shows no decreased risk of these outcomes in Western women.	Substituting dietary soy for other proteins is acceptable, but only modest benefit expected; not an alternative to mortality or cardiovascular event-reducing therapies such as statins.
Osteoporosis	Consuming dietary soy protein might improve bone mineral density in postmenopausal women and possibly reduce fracture risk; however, not all evidence is consistent.	There is possible benefit to adding soy protein to the diet, but benefit is likely to be modest at best. Soy is not a substitute to calcium and vitamin D.

Question 24.3.6 What percentage of Americans use alternative therapies?

- A) 10%
- B) 20%
- C) 30%
- D) 40%
- E) 50%

Answer 24.3.6 The correct answer is “D.” Thirty-eight percent of adults and 12% of children use complementary or alternative therapy (*Natl Health Stat Report*. 2015;79:1–15). Only 40% of patients informed their physicians. Examples of complimentary therapies used include:

Relaxation	Self-help groups	Homeopathy	Spiritual healing
Chiropractic	Biofeedback	Lifestyle diets	Acupuncture
Massage	Energy healing	Herbal medicine	Exercise
Imagery	Hypnosis	Megavitamins	Prayer

At least 15 million patients take prescription medications along with their alternative medications, sometimes with adverse outcomes.

Question 24.3.7 Which of these is *NOT* a reason that patients might use alternative therapies?

- A) They believe they are safer than medications
- B) Conventional medicine is too technical or impersonal
- C) Prescription medicines are too expensive
- D) Cultural practices
- E) They didn’t like the shark in *Jaws* and therefore use shark cartilage in an attempt to rid the oceans of sharks

Answer 24.3.7 The correct answer is “E.” Many patients use alternative therapies including herbal supplements for various reasons, some of which are listed above. Other reasons cited include perceived physician apathy, difficulty with physician

access, fear of medication side effects, belief that medications lack efficacy, and the fact that they are not “natural.” Many patients do not inform their physicians about their use of these products, mistakenly believing that “natural” means safe. As for “E,” unfortunately there is a large demand for shark cartilage including its use as chondroitin sulfate. Shark populations have been severely stressed as a result. Up to 100 *million* sharks per year are killed for their fins and cartilage.

Question 24.3.8 What is the current status of the regulation of “natural” therapies?

- A) The FDA does not have a regulatory role with regard to natural therapies
- B) Natural products have to be proven safe and effective in order to be marketed in the United States
- C) Natural therapies are regulated by the Department of Health and Human Services
- D) As long as they contain the ingredients claimed, natural therapies can be marketed in the United States

Answer 24.3.8 The correct answer is “A.” The FDA has no regulatory role with regard to natural therapies. They are classified as dietary supplements and not medications. All of the rest are incorrect. “B” is incorrect because natural therapies need **not** be proven safe and effective in order to be marketed. “D” is incorrect. There is no quality control on “natural” therapies in the United States. Products may contain varying amounts of the advertised therapy or, in some cases, none at all. In fact, there are data suggesting that some products for sale do not contain what they advertise and in other cases, contain prescription drugs such as warfarin, steroids, alprazolam, and diethylstilbestrol.

HELPFUL TIP:

The FDA can remove natural therapy products if it can show that they are hazardous. This is a slow and laborious process as evidenced by how long it took to remove ephedra from the US market.

A partial list of unsafe alternative remedies is as follows:

- Hepatotoxic: Chaparral, germander, life root
- Carcinogenic: Borage, calamus, coltsfoot, comfrey, life root, and sassafras
- Miscellaneous toxicity: Ma Huang (ephedra), poke root

HELPFUL TIP: SOMETHING IS A BIT FISHY ...

The role of omega 3 fatty acids from fish oil in cardiovascular disease (CVD) is pretty settled. The best studies show no benefit in those with preexisting CVD. Nor is there a benefit in primary prevention (*N Engl J Med.* 2019;380:23–32). Bottom line: save your money.

Question 24.3.9 Grapefruit juice interacts with multiple medications. Which of the following IS NOT affected by grapefruit juice?

- A) Tacrolimus
- B) Itraconazole/Ketoconazole
- C) Benzodiazepines
- D) Clopidogrel
- E) Aspirin

Answer 24.3.9 The correct answer is “E.” All of the other drugs interact with grapefruit juice. Grapefruit juice is a potent CYP3A4 inhibitor and can interact with numerous medications including: those listed above, some calcium channel blockers, carbamazepine, benzodiazepines, amiodarone, atorvastatin, lovastatin, simvastatin, and others. This underscores the importance of knowing what “alternative” medications your patient might be using.

Question 24.3.10 Which of the following supplements has been touted as being effective for memory problems and peripheral circulatory problems?

- A) Ginkgo biloba
- B) S-Adenosylmethionine (SAM-e)
- C) Glucosamine
- D) None of the above

Answer 24.3.10 The correct answer is “A.” Ginkgo biloba is one of the most popular herbal products and is promoted for mild memory loss, dementia, and peripheral circulatory disorders. Ginkgo has some antiplatelet effect and is touted for helping with vascular disease and dementia, although proof is lacking. Given its antiplatelet effects, ginkgo should be used with caution or not at all in patients taking aspirin. Side effects include GI disturbances, headaches, and dizziness. “B,” SAM-e, is used for arthritis and depression and has been shown to be “likely effective.” “C,” glucosamine, has NOT been shown to be effective for osteoarthritis, either alone or in combination with chondroitin—so lay off the sharks!

Question 24.3.11 Which herbal product has aldosterone-like properties and can cause a pseudohyperaldosteronism?

- A) Ma Huang
- B) Ginseng
- C) Licorice
- D) Melatonin

Answer 24.3.11 The correct answer is “C.” Licorice (*Glycyrrhiza* spp.) has aldosterone-like effects and can lead to fluid retention, hypertension, and hypokalemia. Thus, it should not be combined with other potassium-wasting drugs such as thiazides and loop diuretics. It is also contraindicated in patients with severe liver disease and in pregnant patients (may induce premature labor).

Question 24.3.12 For which of the following diseases is SAM-e “likely effective”?

- A) Depression
- B) Fibromyalgia
- C) Cirrhosis
- D) Osteoarthritis
- E) Both A and D

Answer 24.3.12 The correct answer is “D.” SAM-e is “likely effective” in treating osteoarthritis and comparable to NSAIDs (though maximum effect takes 14 days versus 7 with NSAIDs). It is “possibly effective” in treating depression and fibromyalgia, and there is insufficient evidence to rate its use in cirrhosis. SAM-e is contraindicated in bipolar patients as it can induce mania. SAM-e can possibly interact with antidepressants, including MAOIs, leading to serotonin syndrome. GI disturbance is the only notable side effect.

Question 24.3.13 Which of these is useful in the treatment of migraine headaches?

- A) St. John wort
- B) Valerian root
- C) Ginger
- D) Feverfew
- E) Saw palmetto

Answer 24.3.13 The correct answer is “D.” Feverfew is “possibly effective” in treating migraine headaches, although there is limited moderate-quality evidence for this conclusion. On the bright side, feverfew is deemed safe, so you might consider it as a prophylactic intervention for patients with frequent migraine headaches. “A,” St. John wort, is useful for depression. **However, there are major interactions between St. John wort and other multiple drugs including: cyclosporine, nevirapine, and digoxin among others.** “B,” valerian root, is useful for insomnia and has been shown to reduce sleep latency. Ginger is used for nausea and seems to be effective; it is likely safe though there are anecdotal reports of miscarriage and bleeding and it *may* interfere with sex hormones in the doses required for its anti-nausea properties. Remember that OTC ginger supplement products are not regulated, so that they might contain other substances that could be unsafe in pregnancy. Recommend

ginger supplements with some degree of caution in pregnant patients. On the other hand, dietary ginger is probably safe, and fresh ginger rhizome is efficacious. Saw Palmetto is used for benign prostatic hypertrophy but is ineffective.

Question 24.3.14 Which of these is NOT potentially useful for women with pregnancy-related nausea and vomiting?

- A) Acupressure
- B) Vitamin B6
- C) Doxylamine
- D) Black cohosh

Answer 24.3.14 The correct answer is “D.” Vitamin B6 (“B,” pyridoxine) and doxylamine (“C”), an antihistamine, have been shown individually and together to be safe and effective in pregnancy-related nausea and vomiting. Acupressure (“A”) has no known adverse effects, and there is some suggestion of efficacy. Black cohosh (“D”) can stimulate uterine contractions and has no known efficacy for nausea and vomiting in pregnancy, and so it is contraindicated in pregnancy.

► **Objectives: Did you learn to ...**

- Describe the prevalence of alternative therapy use?
- Appreciate the various indications for various herbal products and the evidence base for them?
- Recognize herbs considered safe and those considered unsafe?
- Recognize problematic drug interactions with a variety of alternative therapies?

HELPFUL TIP:

Did you know that metformin, PPIs, and H2 blockers can all cause B12 deficiency? Now you do.

QUICK QUIZ: ALTERNATIVE CURE FOR THE COMMON COLD?

One of your patients who often uses complementary and alternative medicine comes into your office with several days of rhinorrhea, sore throat, and ear pain. Your examination reveals a viral upper respiratory infection. He asks you to recommend an alternative cure.

Which of these are touted as alternative remedies for the common cold?

- A) Echinacea
- B) Zinc
- C) Vitamin C
- D) All of the above
- E) None of the above

The correct answer is “D.” The three choices listed above have the reputation of helping alleviate the symptoms of the common cold. The efficacy of all of these is questionable, however. Intranasal zinc has been removed from the market in the United

States due to reports of permanent loss of sense of taste and smell after its use.

► **CASE 24.4**

A 17-year-old male patient of yours comes to your office for a sports pre-participation physical. He is a little smaller than most of his classmates and has heard that creatine supplementation can help him increase muscle mass and improve his performance.

Question 24.4.1 Which of the following is NOT true about creatine?

- A) Creatine exists primarily in skeletal muscle
- B) It causes weight gain by increasing muscle mass
- C) It is possibly effective in boosting performance in aerobic exercise
- D) It can lead to increased creatinine levels in patients with normal renal function

Answer 24.4.1 The correct answer is “B.” Creatine monohydrate is a naturally occurring protein in the body that exists primarily in skeletal muscle (“A”). High levels of creatine are thought to enhance the ability to renew ATP for short bursts of energy. It is “possibly effective” for enhancing muscle performance (“C”). Studies in rowers seem to be positive. Studies in cyclists, sprinters, swimmers, and “high intensity training” are inconsistent. It is “possibly effective” in older adults seeking to build muscle mass but only when combined with weight training. *It causes weight gain by increasing water retention and not by effecting muscle mass.* Creatine can cause elevated creatinine levels in patients with normal renal function as creatine is metabolized to creatinine (“D”). Complicating this is the fact that creatine has been linked to renal dysfunction in some cases.

Question 24.4.2 Which of these is NOT a disease that creatine is purported to treat?

- A) Heart failure
- B) Neuromuscular disease
- C) Mitochondrial cytopathies
- D) Muscular dystrophies
- E) Diabetes

Answer 24.4.2 The correct answer is “E.” Creatine is also promoted for heart failure, neuromuscular diseases, mitochondrial cytopathies, and various muscular dystrophies. Oral creatine may improve exercise tolerance in patients with heart failure but has no effect on ejection fraction. IV creatine seems to improve ejection fraction temporarily. When used orally, it seems to *marginally* improve muscle strength and daily-life activity in adults and children with various muscular dystrophies in the *short term (although data are contradictory)*. There is no evidence of its efficacy in the treatment of diabetes. It appears to be safe when used orally and in appropriate doses, though high doses raise the concern of adverse hepatic, renal, or cardiac

function. Side effects include GI pain, nausea, and diarrhea, while college athletes taking it frequently complain of muscle cramping.

Confused about creatine? Given that at best it is “possibly effective” for most indications and is relatively safe in “normal” doses, sure, have patients give it a try if they want to. But give them reasonable expectations; there are both positive and negative studies out there.

► **Objective: Did you learn to ...**

- Describe the use and adverse effects of creatine?

QUICK QUIZ: KRAZY FOR KRATOM

A 51-year-old female patient presents with her adult son for chronic and severe pain due to knee osteoarthritis. Her son is convinced that she needs kratom to treat her pain, and relates stories of multiple friends with chronic pain who were able to stop using opioids with the help of kratom. Since you are a rational human being, you don't recommend a treatment without knowing something about it, so you quickly consult your favorite point-of-care reference to educate yourself.

Which of the following safety concerns is present with kratom?

- A) Kratom has been associated with liver toxicity
- B) Cessation of kratom results in withdrawal symptoms
- C) Kratom use has been associated with depression
- D) Some kratom products have been found to contain opioids
- E) All of the above

The correct answer is “E.” Kratom has emerged as a herbal treatment for pain, opioid addiction, and fatigue. However, evidence for efficacy is lacking. It is derived from the plant *Mitragyna speciosa*, which has been used medicinally for centuries in Asia. Kratom is believed to act at opioid receptors and can have stimulant effects at low doses. Known side effects include: nausea, vomiting, dry mouth, constipation, weight loss, appetite loss, liver damage, and myalgia. In larger doses, it may cause hallucinations, depressed mood, sedation, and respiratory depression. Some products have been removed from the market due to contamination with opioids or *Salmonella* (really!). Withdrawal phenomena have been described, and there appears to be potential for addiction. In short, we don't recommend it.

HELPFUL TIP:

Cannabidiol is another product promoted for its effects on pain and potential to help curb the opioid epidemic. While cannabidiol does appear to work to reduce frequency and severity of seizures in certain types of epilepsy (Epidiolex® is FDA-approved as an anticonvulsant), its effectiveness for pain is questionable. Better studies are required.

QUICK QUIZ: A BLOODY HERB

A 51-year-old patient of yours is about to have a scheduled cholecystectomy. He is in otherwise good health and is taking the following herbs and supplements.

Which would you recommend him to stop before surgery because of association with prolonged bleeding time?

- A) Valerian root
- B) Ginseng
- C) Vitamin B complex
- D) Echinacea
- E) Ginkgo

The correct answer is “E.” Ginkgo is the only one above that has been associated with a prolonged bleeding time. Thus, it should be stopped prior to planned surgery. Other supplements that have antiplatelet effects include garlic, feverfew, vitamin E (at doses of greater than 800 IU/day), and fish oil.

Clinical Pearls

- All breast-fed infants should receive supplemental vitamin D within the first few days of life and supplemental iron at 4 months of life if not eating iron-containing foods.
- All women considering becoming pregnant should take a prenatal vitamin or a folate supplement.
- Do not recommend more than 400 IU per day of vitamin E.
- Do not routinely recommend multivitamins to patients for general health.
- Recognize that 40% of patients use complementary and alternative therapies, often in addition to traditional medical treatments, and that the FDA does not regulate natural therapies.
- Recognize that alcoholics may have multiple nutritional deficiencies, including folate, thiamine, B vitamins, and vitamin K in addition to protein deficiency.

Substance Use Disorders

25

Dustin Z. DeYoung

► CASE 25.1

A 45-year-old male presents to your clinic to establish care for his chronic back and leg pain. He denies any other medical conditions. He reports being injured at work approximately 5 years ago, at which time he was started on oxycodone. He reports being on a stable dose for the past few years. He appears slightly drowsy during the appointment, has small pupils, and is having moderate difficulty describing his injury and previous treatments. He reports his mood as okay but becomes irritable when you begin to ask specifics about his injury. He has not been able to keep a job for the last year because “everyone fires me.” He states that he needs the oxycodone to function and that he ran out of his medication one week ago. He does report occasional alcohol use, although he states that he knows not to mix alcohol with his oxycodone.

Question 25.1.1 What is the most likely explanation of the patient’s current presentation?

- A) Opioid withdrawal
- B) Opioid intoxication
- C) Uncontrolled pain
- D) Alcohol intoxication
- E) Alcohol withdrawal

Answer 25.1.1 The correct answer is “B.” The patient presents with pupillary constriction, drowsiness, impairment in attention and memory, psychological changes (dysphoria/irritability), and impairment in functioning (not able to keep a job). All of these findings are included in the diagnostic criteria for opioid intoxication. The *Diagnostic and Statistical Manual of Mental Disorders Fifth Edition* (DSM-5) criteria for opioid intoxication include: (1) recent use of an opioid; (2) clinically significant problematic behavioral or psychological changes (euphoria followed by apathy, dysphoria, psychomotor agitation or retardation, impaired judgment, or impaired social or occupational functioning) that develop during, or shortly after, opioid use; (3) pupillary constriction (or pupillary dilation from severe overdose) and one or more of the following signs: drowsiness or

coma, slurred speech, and impairment in attention or memory; (4) and the symptoms are not due to a general medical condition or another mental disorder.

“A” is incorrect and will be discussed later in this case. “C” is incorrect because a patient would not display the above symptoms with significant pain. “D” could be correct because acute alcohol intoxication is characterized by slurred speech and impairments in memory and judgment; however, the patient does not have other findings consistent with alcohol intoxication such as an unsteady gait or nystagmus. “E” is incorrect as the patient was not hypertensive, febrile, diaphoretic, and did not have tremors or vomiting.

You are hesitant to prescribe oxycodone partly because you recently reviewed the CDC report estimating over 72,000 overdose deaths in 2017 (with opioids accounting for almost 50,000), a record number reflecting an increase of approximately 7%. In 2016, there were over 19,000 overdose deaths from opioid pain relievers alone. You offer him alternatives for pain control, including a referral to physical therapy, NSAIDs, and acupuncture.

Question 25.1.2 Which of the following nonopioid treatments has NOT shown to be more effective than placebo in reducing chronic low back pain?

- A) Nonsteroidal anti-inflammatories (NSAIDs)
- B) Acetaminophen
- C) Duloxetine (Cymbalta)
- D) Gabapentin
- E) B and D

Answer 25.1.2 The correct answers is “E.” NSAIDs have been shown to be more effective than placebo in reducing pain in a variety of acute and chronic pain conditions, including back pain. Although frequently recommended, there is little quality clinical evidence to support the efficacy of acetaminophen for chronic back pain. Duloxetine, an SNRI, has been shown to decrease low back pain intensity, but tricyclic antidepressants

(TCAs) and selective serotonin reuptake inhibitors (SSRIs) do not help chronic low back pain. Gabapentin (and pregabalin) are not effective for low back pain (*PLoS Med* 2017;14:1002369, *CMAJ* 2018;190:E786). Acupuncture reduces pain more than sham in nonspecific musculoskeletal pain, including low back pain. According to a Cochrane review of TENS units for low back pain, there is no evidence to support the use of a TENS unit for low back pain.

**HELPFUL TIP:**

For chronic, noncancer pain, guidelines recommend prioritizing nonopioid medications over opioid analgesics in all patients but particularly in patients with substance use disorders. While evidence for some of the pain medications and modalities we often use is lacking, given the known adverse events and abuse/addiction issues with opioids, it is worth trying the less harmful options (e.g., acetaminophen, TENS unit) prior to considering opioids for chronic, noncancer pain.

He says he has tried them all and none of them work (ever heard that before?). When not offered an opioid, he gets upset and walks out of your office. Two days later, while you are covering an emergency department (ED) shift, the same male presents to the ED for severe, uncontrolled pain. He is vomiting, complains of muscle aches and diarrhea, his pupils are dilated, and he is febrile.

Question 25.1.3 What is the most likely explanation for the patient's current presentation?

- A) Opioid withdrawal
- B) Opioid intoxication
- C) Uncontrolled pain
- D) Alcohol intoxication
- E) Alcohol withdrawal

Answer 25.1.3 The correct answer is "A." The criteria for opioid withdrawal are cessation (or reduction in) opioid use that has been heavy or prolonged (several weeks or longer) or administration of an opioid antagonist after opioid use with three or more of the following developing within minutes to several days after the above: dysphoric mood, nausea or vomiting, muscle aches, lacrimation or rhinorrhea, pupillary dilation, piloerection, sweating, diarrhea, yawning, fever, or insomnia. These signs and symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning and are not due to another medical condition or better accounted for by another mental disorder.

After stabilization, the patient is transferred to a substance abuse treatment center voluntarily. Based on the available resources in your community, you decide on buprenorphine induction and maintenance treatment.

Question 25.1.4 All of the following are true of buprenorphine EXCEPT:

- A) Buprenorphine should be administered prior to onset of withdrawal symptoms
- B) The typical first dose of buprenorphine is 4 mg
- C) Combination buprenorphine/naloxone is preferred over buprenorphine monotherapy due to lower abuse potential, unless a patient is pregnant, lactating, or allergic to naloxone
- D) After initiation, the buprenorphine dose should be increased if withdrawal symptoms continue
- E) Nearly all patients will stabilize on 8 to 16 mg daily, but some patients do require higher doses

Answer 25.1.4 The correct answer, and false statement, is "A."

Buprenorphine is started when patients are exhibiting early signs of withdrawal. For short-acting opioids (e.g., heroin, oxycodone) this may be 12 hours after the last use; while for longer-acting opioids such as methadone, withdrawal symptoms may not manifest until 48 hours after last use. The first day dose should be 4 mg ("B"), and patients should be monitored for withdrawal symptoms for 2 to 4 hours, with the opportunity to administer an additional dose (up to 8 mg in the first day). The addition of naloxone to buprenorphine ("C") is to deter intravenous buprenorphine use as naloxone is poorly absorbed when administered sublingually but precipitates opioid withdrawal if buprenorphine/naloxone is injected. After initiation, the buprenorphine dose should be titrated to relieve withdrawal symptoms ("D") by doubling the previous total daily dose plus adding 2 to 4 mg. Most patients will stabilize on 8 to 16 mg daily; however, some may require doses up to 32 mg daily, which is the maximum dosage ("E").

**HELPFUL TIP:**

Advantages of buprenorphine over methadone are that it can be dispensed at a physician's office with an appropriate DEA waiver which requires the ability to provide or refer the patient for counseling, unlike methadone, which can only be dispensed at designated treatment centers. Because of its partial agonist action, buprenorphine has a "ceiling effect" with regard to overdose making it safer than methadone; whereas, methadone produces increasing respiratory suppression with increasing doses. Suboxone is a patented combination of buprenorphine and naloxone that requires a physician to obtain a special "X" DEA number in order to prescribe.

► **Objectives: Did you learn to ...**

- Define opioid intoxication and withdrawal?
- Describe the use of buprenorphine to manage opioid dependence?

► **CASE 25.2**

A 70-year-old female is brought into the clinic by her daughter due to concerns about her mother's sleeplessness, isolation, weight loss, falls, and anxiety over the past year. In

addition, since the patient has been staying at her daughter's home the past 3 days, she began vomiting, hallucinating, perspiring profusely, and wanting to return to her own home. The patient has no history of medical problems. She is disheveled, confused, diaphoretic, and tremulous. Her blood pressure is 162/110 mm Hg, pulse is 120 bpm, and temperature is 38.5°C. She blames her symptoms on being unable to have a cigarette. She also blames her daughter's nagging. When asked about alcohol use, the patient says she has had a cocktail every evening since she retired from her job last year, and that this helps her to sleep.

Question 25.2.1 Which of the following best describes the patient's current clinical condition?

- A) Alcohol withdrawal
- B) Alcohol intoxication
- C) Alcohol tolerance
- D) Alcohol use disorder

Answer 25.2.1 The correct answer is "A." The patient presents tachycardic, hypertensive, and febrile, with diaphoresis, tremors, vomiting, and hallucinations. All of these findings are included in the diagnostic criteria for alcohol withdrawal. "B" is incorrect. Acute intoxication is characterized by slurred speech, unsteady gait, nystagmus, and impaired memory and judgment. "C" and "D" are incorrect and are discussed later in this case.

The criteria for alcohol withdrawal include: (1) cessation or reduction of a previously heavy alcohol intake **and** (2) at least two of the following within hours or days: autonomic hyperactivity (hypertension, sweating, tachycardia, etc.), hand tremor, insomnia, nausea/vomiting, hallucinations, agitation, anxiety, grand mal seizures. In addition, one must have significant distress or impairment in functioning with the withdrawal and no other illness causing the symptoms.

Question 25.2.2 Which class of drugs would you choose to treat the symptoms of alcohol withdrawal?

- A) Benzodiazepines
- B) Antipsychotics
- C) Antibiotics
- D) Alcohol
- E) Phenytoin

Answer 25.2.2 The correct answer is "A." The treatment of choice is metabolic support and the use of benzodiazepines to decrease physical distress and to prevent major withdrawal (e.g., delirium tremens) from occurring. "B" is incorrect. Antipsychotics may control behavior but they do not prevent withdrawal seizures and vasomotor instability. "C" is incorrect as this patient is not displaying signs of infection. "D" is incorrect. Although alcohol will work to prevent withdrawal, it has a fairly short half-life, and you generally do not want to endorse the use of alcohol in a patient with an alcohol use problem. "E" is incorrect. Phenytoin does nothing to prevent alcohol withdrawal seizures.

HELPFUL TIP:

The traditional "banana bag" of IV multivitamins is unnecessary. Oral vitamin supplements are just as effective and less expensive. The only exception is thiamine, which you may want to give IV or IM if you suspect thiamine deficiency.

Question 25.2.3 What would be the best approach to evaluating this patient for alcoholism?

- A) Ask her the average amount she drinks
- B) Ask her how often she drinks
- C) Ask her how frequently she gets drunk
- D) Ask what her family and friends say about her drinking

Answer 25.2.3 The correct answer is "D." The defense mechanism of denial is so strongly evident in alcoholism that the best approach is to explore how alcohol affects her life, rather than direct questions about drinking behavior. Information from family and friends may provide a more accurate account of the problem. The "CAGE" questionnaire is a very brief and useful screening tool, employed effectively in the primary care setting. A positive answer to two or more questions is very sensitive and specific for an alcohol use disorder. It consists of asking the patient the following four questions:

Have you ever

- **C:** felt that you should **Cut Down** on your drinking?
- **A:** been **Annoyed** that people criticized your drinking?
- **G:** felt bad or **Guilty** about your drinking?
- **E:** taken a drink first thing in the morning (**Eye Opener**) to get rid of a hangover or steady your nerves?

HELPFUL TIP:

Asking the question "How many times in the past year have you had five or more drinks in a day (for men) or four or more drinks (for women) in a day?" is a useful screening question for frequency of heavy drinking. A positive screen is one or more incidents of heavy drinking. If you have a positive screen, ask about usual frequency and quantity of alcohol consumed to help determine the presence or absence of alcohol abuse or dependence. This question alone is about 82% sensitive for detecting an alcohol use disorder. Specificity is comparable at about 79%. Sensitivity for the CAGE ranges from about 75% to 95%, but the CAGE may miss nondependent alcohol use disorders (e.g., binge drinking). Yet another possible screen for alcohol use disorders, and one commonly found in primary care clinics, is the Alcohol Use Disorders Identification Test (AUDIT). This is a 10-question survey that has a sensitivity of 92% and a specificity of 94%.

HELPFUL TIP:

Unfortunately, when it comes to substance use, you cannot always trust the family's history either. They

may be enabling the alcohol addiction or unaware of it. Also, laboratory workups (e.g., liver enzymes) are not sufficiently reliable to make the diagnosis of alcohol abuse/dependence. Although elevated GGT and AST/ALT in a ratio of 2:1 are supportive, their specificity is only 90%. Others that may cause a high AST/ALT ratio are hepatitis C, Wilson's disease, hepatitis-associated cirrhosis.

Upon further questioning, you begin to uncover a long history of heavy drinking—seems that there was more than just a nightcap.

Question 25.2.4 Which of the following statements about this patient's situation is TRUE?

- A) Cerebellar degeneration is uncommon
- B) She is at risk for developing peripheral neuropathy
- C) Alcoholic "fatty liver" is irreversible
- D) She is at decreased or average risk for heart disease
- E) Immune function should remain relatively intact

Answer 25.2.4 The correct answer is "B." Peripheral neuropathy can be seen in 10% of heavy drinkers as a result of vitamin deficiencies and the direct impact alcohol has on nerve function. "A" is incorrect because cerebellar degeneration—suggested by ataxia and nystagmus—does occur as a result of alcohol overuse. "C" is incorrect because alcoholic "fatty liver" will reverse with abstinence from alcohol. "D" is incorrect. Heavy drinking raises blood pressure and levels of triglycerides, increasing risk of myocardial infarction. Finally, "E" is incorrect. Heavy drinking lowers the white blood cell count and interferes with specific aspects of the immune system; for example, it compromises T-cell function.

This patient reports to you that she has needed to drink increasing amounts of alcohol to help her fall asleep.

Question 25.2.5 The need for increasing amounts of alcohol is an example of:

- A) Intoxication
- B) Dependence
- C) Tolerance
- D) Relapse
- E) Abuse

Answer 25.2.5 The correct answer is "C." Tolerance is defined as the need for increasing amounts of a drug to achieve the same response as initial use of the drug. "A" is incorrect. Intoxication is a characteristic syndrome of maladaptive behavior or psychological changes that occur with substance use, is drug-specific, and reverses when the drug use is discontinued. "D" is incorrect. Relapse involves re-starting use of the drug after being abstinent for a while.

HELPFUL (CLARIFYING) TIP:

DSM-IV divided substance abuse and substance dependence. DSM-5 views these two categories as different points on a spectrum of substance use disorder. The criteria for substance use disorder are at least 2 of the following 11 criteria (clustered in 4 groups):

- A. Impaired control: (1) taking more or for longer than intended, (2) unsuccessful efforts to stop or cut down use, (3) spending a great deal of time obtaining, using, or recovering from use, or (4) craving for substance.
- B. Social impairment: (5) failure to fulfill major obligations due to use, (6) continued use despite problems caused or exacerbated by use, or (7) important activities given up or reduced because of use.
- C. Risky use: (8) recurrent use in hazardous situations and (9) continued use despite physical or psychological problems caused or exacerbated by use.
- D. Pharmacologic dependence: (10) developing tolerance or (11) withdrawal.

Question 25.2.6 Which of the following lab test results are you most likely to find in this patient?

- A) Microcytic anemia
- B) Low ferritin
- C) Decreased serum triglycerides
- D) Hyperglycemia
- E) Increased gamma-glutamyltransferase (GGT)

Answer 25.2.6 The correct answer is "E." Elevated GGT is considered to be a highly sensitive indicator of alcohol intake and is often present along with elevation of the alanine and aspartate transaminases (ALT and AST). Remember that GGT is not specific, as it is an inducible enzyme and can be induced by a number of medications. The classic AST:ALT ratio in active alcohol abusers is 2:1. Remember, however, that these laboratory findings are **not specific** for alcohol use and have multiple potential causes. The other answers are incorrect. Patients with alcoholism typically have **macrocytic** anemia, **elevated** serum triglycerides, and **hypoglycemia**. Ferritin is often **increased** in active alcohol users in the absence of iron overload. In addition, the transferrin saturation may be elevated because alcohol inhibits transferrin synthesis.

You have ordered liver function tests, but the results will not be available until the next day. The laboratory technician is out getting Botox.

Question 25.2.7 Which of the following medications would be indicated to prevent delirium tremens (DT) in a patient with hepatic impairment?

- A) Alprazolam (Xanax)
- B) Chlordiazepoxide (Librium)
- C) Diazepam (Valium)
- D) Lorazepam (Ativan)
- E) Clonazepam (Klonopin)

Answer 25.2.7 The correct answer is “D.” Benzodiazepines that are metabolized by the cytochrome P450 system will build up in the presence of liver disease, so using those with intermediate half-lives and no active metabolites is essential. Only lorazepam, oxazepam, and temazepam meet these criteria. “B” is incorrect. Although chlordiazepoxide (“B”) is often used to prevent symptoms of alcohol withdrawal, it is hepatically metabolized and has an exceptionally long half-life and, therefore, should be avoided in patients with liver problems. Conversely, alprazolam (“A”) is too short acting to use in this situation.

HELPFUL TIP:

Carbamazepine has been used extensively in Europe to treat the symptoms of alcohol withdrawal and prevent seizures. Evidence for its use in alcohol withdrawal is somewhat limited, and studies are generally underpowered. But guess what? The same is true for benzodiazepines. Don't go switching all your patients to carbamazepine, but it could serve as an alternative in the rare patient with a benzodiazepine allergy or adverse reaction.

You remember from a lecture that patients without serious comorbidities, either medical or psychiatric, who have mild-to-moderate withdrawal symptoms can safely be withdrawn in an outpatient setting. The tool that has been best validated is the revised “Clinical Institute Withdrawal Assessment for Alcohol” (CIWA-Ar) which involves assessment of the severity of 10 signs and symptoms associated with alcohol withdrawal (see MD-Calc: <https://www.mdcalc.com/ciwa-ar-alcohol-withdrawal>).

Question 25.2.8 Assessment of the severity of which of the following symptoms is NOT included in that tool?

- A) Headache or feelings of fullness in head
- B) Palpitations
- C) Paroxysmal sweats
- D) Tactile disturbances
- E) Tremor

Answer 25.2.8 The correct answer is “B.” Palpitations are not included in the CIWA-Ar scale. In addition to “A,” “C,” “D,” and “E,” the other signs and symptoms are nausea/vomiting, anxiety, agitation, auditory disturbance, visual disturbance, and orientation/clouding of sensorium. Each sign or symptom is given 0 to 7 points according to its severity except for orientation/clouding of sensorium, which is only 0 to 4 points. Withdrawal is considered mild if the score is <15, moderate if 16 to 20, and severe if >20.

You are considering whether or not this patient has delirium tremens (DT).

Question 25.2.9 Which of the following is true of DT?

- A) The majority of patients with alcohol withdrawal develop DT if not treated

- B) Auditory hallucinations are more common than visual hallucinations in DT
- C) Symptoms of DT could easily be confused for dementia
- D) DT does not occur until at least 1 week has passed since the last drink of alcohol
- E) Autonomic instability is present in DT

Answer 25.2.9 The correct answer is “E.” Autonomic instability with elevated pulse, blood pressure, and fever are common in DT. “A” is incorrect. Minor withdrawal symptoms are quite common, but DT develops in only 3% to 5% of patients undergoing alcohol withdrawal. “B” is incorrect. Visual hallucinations are common in DT; auditory hallucinations are less likely. “C” is incorrect. Withdrawal **delirium** typically presents acutely over a matter of hours or days; whereas, in **dementia**, the cognitive decline is over a course of months to years. In addition, autonomic instability is not a feature of early dementia (OK, maybe in Shy-Drager syndrome although cognition is usually well preserved—unlike our patient's liver). Finally, “D” is incorrect because the risk for DT usually peaks 72 hours after the last drink.

Question 25.2.10 Which medication would be the best choice for DT in a patient who is vomiting profusely and who has no IV access?

- A) Diazepam (Valium)
- B) Alprazolam (Xanax)
- C) Chlordiazepoxide (Librium)
- D) Lorazepam (Ativan)
- E) Clonazepam (Klonopin)

Answer 25.2.10 The correct answer is “D.” Lorazepam is absorbed well intramuscularly and can also be provided IV. This makes it a good choice for the vomiting patient. Diazepam is **erratically** absorbed IM and should be administered either orally or IV. One could argue that diazepam given rectally is a reasonable alternative to lorazepam IM/IV. However, for reasons stated earlier in this case, lorazepam is the preferred drug of those listed.

HELPFUL TIP:

The IV form of lorazepam can also be administered sublingually to speed absorption if you want to use an oral medication. Obviously IV is even faster yet (if you have access).

Question 25.2.11 In 2018, DT carries a fatality rate of:

- A) <1%
- B) 5%
- C) 10%
- D) 25%
- E) 50%

Answer 25.2.11 The correct answer is “B.” Prior to modern treatment, the mortality reached almost 40% per episode. The rest are incorrect.

Question 25.2.12 Which of the following does NOT predispose to developing DT?

- A) Prior episodes of DT
- B) Pneumonia
- C) Gastrointestinal (GI) bleed
- D) Female gender
- E) Hepatic failure

Answer 25.2.12 The correct answer is “D.” Female gender does not predispose an individual to DT but the other options do.

Question 25.2.13 Which of the following is NOT a complication of alcoholism?

- A) Dementia
- B) Pancreatitis
- C) Hypermagnesemia
- D) Megaloblastic anemia
- E) Marchiafava–Bignami disease

Answer 25.2.13 The correct answer is “C.” All of the above, with the exception of hypermagnesemia, are associated with alcohol abuse. **Hypomagnesemia** is a complication of alcoholism and may decrease the response to thiamine administration in patients who also have thiamine deficiency. Alcoholic dementia may be related to direct effects of alcohol on the brain or to nutritional deficiencies. Marchiafava–Bignami disease is demyelination and/or necrosis of the corpus callosum and the adjacent white matter. It presents with dementia, dysarthria, spasticity, and inability to ambulate. It can occasionally be seen in nondrinkers as well.

HELPFUL TIP:

Elderly patients with alcohol problems often go unrecognized. Have a high index of suspicion in patients with signs and symptoms such as labile hypertension, insomnia, legal or marital problems, frequent falls and injuries, headaches or blackouts, and vague GI complaints.

Question 25.2.14 Which of the following is FALSE about alcohol use disorders?

- A) Most studies have found the prevalence of alcohol use disorders is highest among older adults
- B) The lifetime prevalence of alcohol use disorders is approximately 30%
- C) Alcohol use disorders are frequently comorbid with psychiatric and other substance use disorders
- D) Rates of current (past year) alcohol use disorders are more than twice as common in males than in females
- E) Approximately 25% of men and almost 50% of women with alcohol dependence will meet criteria for major depressive disorder in their lifetime

Answer 25.2.14 The correct answer is “A.” Actually, most studies have shown that the highest prevalence of alcohol use disorders is in a younger age group (18–29 years old). The rest are

correct statements. Especially noteworthy is “C.” Half of all people with alcohol abuse have a comorbid psychiatric diagnosis. For example, about 50% to 60% of people with bipolar illness have problems with alcohol abuse or dependence. Results from the National Epidemiologic Survey on Alcohol and Related Conditions in 2007 and 2015 found that persons with an alcohol use disorder had a lifetime prevalence of mental illness of about 30%. “E” is a correct statement as well. Data from the National Comorbidity Survey estimated lifetime prevalence of major depressive disorder among persons with alcohol dependence to be 24.3% and 48.5% among men and women, respectively. A useful way to approach patients who complain of depression along with their alcohol abuse is to obtain a longitudinal history to see which came first. If it is impossible to tease out, as is often the case, observe for 1 to 3 weeks off alcohol. If depression is still present without alcohol use, it is prudent to treat with an antidepressant. Be careful when treating alcohol abusers with antidepressants: active substance use severely reduces the efficacy of these medications.

HELPFUL TIP:

Substance use rates are highest between ages 18 and 25. A lot of this is experimentation that will end as the individual matures. Some, of course, will go on to chronic use and possible development of a substance use disorder.

HELPFUL (AND IMPORTANT) TIP:

Multiple studies have shown that symptom-triggered protocols for benzodiazepine treatment of alcohol withdrawal are superior to scheduled administration of benzodiazepines. Patients receive less medication, have shorter hospital stays, and experience similar or better outcomes with symptom-triggered administration. Symptom-triggered approaches use the CIWA-Ar scoring system every 4 to 8 hours (or more frequently depending on the severity of symptoms) with benzodiazepines provided for scores >8 up to every hour. Do not use fixed dose regimens. They increase length of stay and benzodiazepine dose. Benzodiazepine regimens utilized include: lorazepam, diazepam, and chlor-diazepoxide. Use the smallest effective dose of an oral benzodiazepine as needed to improve symptoms. IV formulations of diazepam and lorazepam may be utilized in the acute setting if the oral route is unavailable. Of note, true DT may require absurdly large doses of benzodiazepines (our personal best is 70 mg of IV diazepam in 1 hour or a lorazepam drip at 8 mg/hour—but not in the same patient!).

► **Objectives: Did you learn to ...**

- Recognize signs and symptoms of alcohol withdrawal?
- Describe diagnostic criteria for alcohol withdrawal?
- Identify adverse effects of heavy alcohol use?

- Treat alcohol withdrawal?
- Appreciate how denial of the illness plays a role in the assessment of substance abuse?
- Identify laboratory abnormalities observed in alcohol abuse and understand the limitations of laboratory studies?

QUICK QUIZ: NIGHTMARE IN MARGARITAVILLE

A 50-year-old divorced male presents to your clinic in an agitated state, complaining of nausea, vomiting, and double vision. He smells of alcohol, and reports that his last drink was today... about 15 minutes ago... in your clinic parking lot. He has gross bilateral hand tremors and is disheveled. He is picking at his shirtsleeves and is oriented to name only. On physical examination, you observe lateral nystagmus and an ataxic gait. Vital signs include: blood pressure 160/92 mm Hg, pulse 100 bpm, and respirations 20 bpm. Labs are drawn, and his GGT is moderately elevated.

Which of the following is the most likely cause of his symptoms?

- A) Wernicke encephalopathy
- B) Normal pressure hydrocephalus
- C) Dementia
- D) Stroke
- E) Alcohol withdrawal

The correct answer is "A." Wernicke encephalopathy is the result of thiamine deficiency and can occur in alcoholics and other patients with poor nutrition. See the next question for a description of the clinical findings. Note that several symptoms of Wernicke encephalopathy can mimic withdrawal (agitation, etc.). However, as noted in the question, this patient is still intoxicated.

QUICK QUIZ: WERNICKE ENCEPHALOPATHY

The triad of Wernicke encephalopathy includes all of the following EXCEPT:

- A) Ataxia
- B) Oculomotor dysfunction
- C) Incontinence
- D) Encephalopathy

The correct answer is "C." Wernicke encephalopathy may present with the classic triad of ataxia, encephalopathy (confusion), and oculomotor dysfunction (nystagmus, lateral rectus palsy, etc.). However, the majority of patients present with an incomplete syndrome and may be missing ophthalmoplegia, ataxia, or encephalopathy. If you choose "B," maybe you were thinking of normal pressure hydrocephalus, which presents with dementia, incontinence, and ataxia. For Wernicke encephalopathy, remember that the treatment is *high-dose* thiamine; 500 mg IV TID over 30 minutes for 2 days and then 250 mg IV (or IM) daily for 5 days.

CASE 25.3

A 28-year-old pregnant patient and her mother are presenting for a follow-up appointment. At the appointment today, the patient's mother shares that her daughter has been drinking alcohol during her pregnancy. The daughter is very annoyed when confronted with her use of alcohol and will not give specific information about it, but she does admit to drinking. She does not agree to quit during her pregnancy or to be referred for substance abuse evaluation. You discuss some of the effects alcohol might have on the developing fetus, including fetal alcohol syndrome (FAS).

Question 25.3.1 According to the National Institute on Alcohol Abuse and Alcoholism (NIAAA) consensus guidelines (2016), the diagnosis of FAS requires specific manifestations in three areas, including:

- A) At least two facial anomalies, retardation of growth \leq the 20th percentile, significant structural abnormalities on neuroimaging, and impulse control deficits
- B) At least two facial anomalies, retardation of growth \leq the 10th percentile, head circumference \leq 10th percentile, and significant global intellectual deficits
- C) At least three facial anomalies, retardation of growth \leq the 10th percentile, specific learning impairment, and confirmed alcohol use during pregnancy
- D) At least three facial anomalies, retardation of growth \leq the 10th percentile, head circumference \leq 20th percentile, and confirmed alcohol use during pregnancy

Answer 25.3.1 The correct answer is "B." The diagnosis of FAS (which is one form of fetal alcohol spectrum disorder) is a complex medical diagnostic process with no universally accepted set of diagnostic criteria. The NIAAA consensus guidelines, which were updated in 2016, were used for this answer and are abbreviated in "B." Major differences with the Department of Health and Human Services/CDC National Task Force on FAS Guidelines from 2004 will be pointed out. If all criteria are met in both guidelines, documented prenatal alcohol exposure is not needed, as this can be a stigmatizing or difficult answer to achieve at times. The diagnosis requires at least two (three in National Task Force Guidelines) facial anomalies, growth retardation (\leq 10th percentile), and CNS abnormalities (clear evidence of brain involvement and neurobehavioral impairments). For the National Task Force guidelines only one CNS abnormality (structural, neurologic, or functional) needs to be documented. The other options are incorrect. Other facial features and minor congenital abnormalities may occur but are not included in diagnostic criteria. See Figure 25-1.

HELPFUL (HOPEFULLY CLARIFYING) TIP: Fetal Alcohol Syndrome Diagnostic Criteria:

- A. *Characteristic Facial Anomalies:*
Short palpebral fissures, thin vermillion border, and smooth philtrum

FIGURE 25-1. Fetal alcohol syndrome. **(A)** At 2 1/2 years. **(B, C)** At 12 years. Note persistence of short palpebral fissures, epicanthal folds, flat midface, hypoplastic philtrum, and thin upper vermilion border. This individual also has the short, lean prepubertal stature characteristic of young males with fetal alcohol syndrome. (Reproduced from Streissguth AP, Clarren SK, Jones KL. Natural history of the fetal alcohol syndrome: A 10-year follow-up of eleven patients. *Lancet*. 1985;326:85–91, with permission from Elsevier.)

B. Growth Retardation:

Height and/or weight (adjusted for gestational age) \leq 10th percentile for age/sex

C. CNS Involvement:

1. Clear evidence of brain involvement:

- a. *Structural*—head circumference \leq 10th percentile or abnormalities on neuroimaging
- b. *Neurologic*—abnormal reflexes, abnormal tone, cranial nerve deficits, poor coordination or balance, visual-motor deficits, right-left confusion, or difficulty with motor sequencing

2. Neurobehavioral impairment (*Functional*):

- a. Significant global cognitive/intellectual deficits
- b. Significant developmental delay
- c. Functional deficits in one (three for National Task Force guidelines) domain(s):
 - Executive functioning deficits
 - Motor functioning delays
 - Problems with attention or hyperactivity
 - Social skills
 - Other sensory problems, memory deficits, etc.
- d. Significant impairment of self-regulation in at least one domain:
 - Mood or behavioral regulation impairment
 - Attention deficit
 - Impulse control

HELPFUL TIP:

Fetal alcohol spectrum disorders (FASD) is the leading preventable cause of birth defects and developmental disorders in the United States.

Question 25.3.2 Which of the following is the earliest that symptoms and signs of FAS may be detected after birth?

- A) Within 12 hours
- B) After the first week
- C) At 1 month
- D) At 3 months
- E) After 1 year

Answer 25.3.2 The correct answer is “A.” Soon after birth, the neonate may display symptoms of withdrawal, including tremulousness, inconsolability, vomiting, and poor feeding. The characteristic cluster of facial/physical malformations (listed above) is evident within 12 hours of birth, but is usually most pronounced between 8 months and 8 years of age. Other features, such as certain forms of CNS dysfunction, growth deficiency, joint and limb abnormalities, and heart defects, might not be noted until later in the child’s life. Given the wide range of disabilities and impairments, many fetal alcohol spectrum disorders are not recognized until later in childhood and are estimated to be underdiagnosed for a variety of reasons.

As you counsel your patient, you describe how FAS is just one form of FASD and even limited alcohol use during pregnancy can contribute to potential problems for her child.

Question 25.3.3 Which of the following conditions are considered a fetal alcohol spectrum disorder (FASD)?

- A) Alcohol-related neurodevelopmental disorder
- B) Partial fetal alcohol syndrome
- C) Neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE)
- D) Alcohol-related birth defects
- E) All of the above

Answer 25.3.3 The correct answer is “E.” Knowledge continues to grow regarding the subtler effects of maternal drinking, such as that seen with even “social” alcohol use. All of the above listed conditions are considered FASD, with various diagnostic criteria for each (some overlapping).

Question 25.3.4 In which stage of pregnancy does the teratogenic action of alcohol cause facial malformations?

- A) During conception
- B) During the third week of pregnancy
- C) During the late first trimester
- D) During the second trimester
- E) During the third trimester

Answer 25.3.4 The correct answer is “B.” Facial malformations occur with the use of alcohol during the third week. Organs and limbs appear most susceptible to the effects of alcohol during the embryonic phase, which is completed by the eighth week of conception, a time when most women are first confirming pregnancy. Alcohol exposure during any stage of development may affect brain development or function. Thus, there is no “safe time” for pregnant women to use alcohol.

You are able to convince this patient to reduce and eventually eliminate her use of alcohol; she delivers a healthy-appearing newborn who she names “Harley” after the motorcycle.

► **Objectives: Did you learn to ...**

- Identify problem drinking in a pregnant patient?
- Approach a patient with alcohol use in pregnancy?
- Describe the findings of fetal alcohol spectrum disorders, including fetal alcohol syndrome?

► CASE 25.4

A 60-year-old female presents to your office and is determined to stop smoking. She has a history of schizophrenia treated with clozapine (Clozaril) and a 43-year history of smoking up to two packs of cigarettes per day. She asks you what is available to help her stop. You tell her that nicotine replacement therapy (NRT), bupropion (Zyban), and varenicline (Chantix) are currently approved to aid patients who want to stop smoking.

Question 25.4.1 If you want to offer NRT that is easy to use, has few side effects, and provides steady blood levels of nicotine over the whole day, which do you choose?

- A) Nicotine patch
- B) Nicotine gum
- C) Nicotine nasal spray
- D) Nicotine inhaler
- E) E-cigarettes

Answer 25.4.1 The correct answer is “A.” There are benefits and drawbacks to each of the smoking cessation aids with five currently FDA-approved forms of NRT (patch, gum, nasal spray, inhaler, and lozenge). Combining a long-acting (patch) and a short-acting NRT product (e.g., gum) can increase cessation rates. For this question, the nicotine patch (“A”) provides the most continuous nicotine delivery among all NRT products and is the simplest NRT to use. The nicotine patch (and gum) are available without a prescription, while nicotine nasal spray and inhaler require a prescription. For a patient with a heavy, long smoking history, begin with the 21 mg patch and taper to the 7 mg patch, generally over a 10 to 12 week time frame, but longer durations can be used and NRT can continue until the patient feels stabilized as a “nonsmoker.” Some of the drawbacks of the patch include slower release of nicotine, the potential for skin irritation, insomnia, and vivid dreams. Some of these side effects can be reduced by having the patient rotate application sites daily (to avoid skin irritation) and removing the patch before bedtime. Nicotine gum (“B”) is an ion-exchange resin that releases nicotine for absorption through the buccal mucosa with only 30% bioavailability in the rest of the GI tract. Side effects include mouth and throat soreness, jaw fatigue, hiccups, and undesirable taste. There are advantages of nicotine gum: it involves an active coping mechanism (e.g., chewing, placing the gum in one’s mouth) and is more likely than the patch to delay weight gain. The nasal spray (“C”) delivers 0.5 mg nicotine per dose and is sprayed one to two times per hour for a maximum of 5 sprays per hour and 40 sprays per day. Most of the nicotine nasal spray side effects are attributable to its route of use—nasal and throat irritation, rhinorrhea, sneezing, etc. The oral inhaler (“D”) provides an active delivery of nicotine similar to the nasal inhaler, and its side effects are also a consequence of its route of delivery—throat irritation and coughing. E-cigarettes (“E”) create a vapor (not smoke) that simulates smoking. Like other nicotine replacement products, the amount of nicotine may be decreased over time.

HELPFUL TIP:

There are more than 460 different brands of e-cigarettes. Very little is known about their safety. While they don’t contain tobacco smoke, they do contain nicotine and other chemicals. E-cigarettes have a checkered track record when it comes to aiding smoking cessation versus being a gateway to nicotine addiction for younger users. There are studies to support their use, but just as many that suggest that they do not aid with smoking cessation.

Question 25.4.2 Which of the following is an absolute contraindication to varenicline (Chantix)?

- A) Coronary artery disease
- B) Severe psychiatric illness
- C) Seizure disorder
- D) Urinary incontinence
- E) None of the above

Answer 25.4.2 The correct answer is “E.” Previously, there was an FDA warning about the possibility of suicidal or homicidal ideation with varenicline. In 2016, the FDA removed the boxed warning about this, but the updated labeling still carries a warning of potential psychiatric adverse events. Patients with serious psychiatric illness may have a lower sustained quitting rate compared to those without psychiatric illness when treated with varenicline or bupropion, and the evidence for NRT in this population is unclear. The EAGLES trial demonstrated higher rate of neuropsychiatric symptoms with smokers with a psychiatric comorbidity, but rates were low in both groups and there was no statistically significant difference in neuropsychiatric symptoms among users of nicotine patch, varenicline, and bupropion for patients with and without a psychiatric disorder. A systematic review and meta-analysis in 2015 found no increased risk of suicide, suicidal ideation, depression, or death compared with placebo for those with and without a psychiatric disorder treated with varenicline. Additionally, varenicline is safe to use in CAD and epilepsy. Again, in the EAGLES trial, varenicline, bupropion, and NRT were all shown to be safe in patients with stable CAD.

Although this patient does not mind spending \$6 to \$7 per day on a pack of cigarettes (or more depending on where you live), she does not want to pay a lot for something to help her quit. You decide not to engage in a philosophical discussion about cognitive dissonance.

Question 25.4.3 Which smoking cessation aid is the most expensive?

- A) Nicotine patch
- B) Nicotine gum
- C) Nicotine nasal spray
- D) Nicotine inhaler
- E) Varenicline

Answer 25.4.3 The correct answer is “E.” The cash price of varenicline is approximately \$450 per month in 2019, which has increased from a price of about \$240 per month in 2013. Even at \$10 per pack, it is cheaper to continue smoking a pack per day (\$300) than purchasing a month of varenicline. Even if your patient is lucky enough to have this medication covered by her insurance, it is considered a tier 3 drug under many plans, which means high out-of-pocket co-pay costs. The nicotine products are less expensive in the range of \$60 to \$120 per month (or higher) depending on the product and your daily previous cigarette use. Some health insurance programs will support smoking cessation aids, but coverage and co-pays are variable.

“I tried those things, Doc, and nicotine didn’t work and varenicline made me shoot my boyfriend in the leg—but he had it coming. Isn’t there something else?”

Question 25.4.4 Which of the following medications might you also prescribe to aid this patient in smoking cessation?

- A) Naloxone
- B) Metoprolol
- C) Haloperidol
- D) Bupropion
- E) Fluoxetine

Answer 25.4.4 The correct answer is “D.” Bupropion is marketed as the antidepressant Wellbutrin and the smoking cessation aid Zyban. It reduces the symptoms of nicotine withdrawal by blocking dopamine in the brain’s reward center, and this mechanism is thought to result in reduced nicotine craving. Studies have shown that people who use bupropion doubled their chances of quitting smoking. Its effect appears to be additive to that of NRT. Its effect on smoking cessation is independent of its antidepressant effect, as shown by its equal efficacy in depressed and nondepressed patients. Several studies have demonstrated no significant risk of bupropion-induced psychosis in patients with schizophrenia when also treated with an antipsychotic (as our patient is). One of the advantages of bupropion is its ability to prevent the weight gain that occurs in most people when they stop smoking. Bupropion should be started at a dose of 150 mg daily for 3 days then increasing to 150 mg twice daily, if the patient is tolerating the drug. The patient should be advised to stop smoking during the second week of treatment. “E” is incorrect. There is no evidence that SSRIs are effective in smoking cessation.

HELPFUL TIP:

A 2014 Cochrane review found that nortriptyline has essentially the same success rate as bupropion. Nortriptyline is started at 25 mg daily for 3 days, then 50 mg until the 7th day when the dose is increased to 75 mg daily.

The mood in the examination room turns a shade bluer as your patient wonders whether, at age 60 and with an 86-pack-year history, there is even any reason to quit. “It’s too late for me,” she laments.

Question 25.4.5 How long does it take to reduce the risk of myocardial infarction by 50% after one stops smoking?

- A) 24 hours
- B) 6 months
- C) 1 year
- D) 10 years
- E) Infinity

Answer 25.4.5 The correct answer is “C.” Twenty minutes after quitting smoking, blood pressure and heart rate drops, and

the temperature of hands and feet increases to normal. After 24 hours, the risk of myocardial infarction (MI) begins to decrease. At 1 year, the chance of having an MI is cut in half. After 5 years, stroke risk is reduced to that of a nonsmoker. After 10 years, the risk of dying from lung cancer is about half that of a person who continues to smoke. After 15 years, the risk of coronary artery disease approaches that of a nonsmoker.

The mood in the examination room is heading into a deeper blue as your patient expresses concern that she will fail in this attempt to quit smoking, as she has in the past. “I’ll never do it,” she complains.

Question 25.4.6 On average, how many attempts to quit smoking are made before a person succeeds?

- A) 1
- B) 6
- C) 50
- D) 365

Answer 25.4.6 The correct answer is “B.” Historical data had shown that it takes an average of six attempts at quitting before success. A 2016 study published in *BMJ Open* by Chaiton et al. showed that previous data may grossly underestimate the number of attempts. Other organizations provide estimates of the number of quit attempts prior to meeting sustained success (American Cancer Society 8–10 attempts; CDC 8–11 attempts; Australian Cancer Society 12–14 attempts). Here’s the moral of the story: if at first your patient doesn’t succeed, try again and again and ... so on. As with many behavior changes, most patients don’t get it to stick on the first try.

HELPFUL (AND UNFORTUNATE) TIP:

None of these cessation aids have a great track record of success, but the significant health benefits of smoking cessation should make us continue to pursue smoking cessation with all of our patients. For quit rates, you can find numbers all over the board. Some studies have shown higher abstinence rates with varenicline than bupropion and NRT (usually shorter duration trials up to 6 months). However, a 2018 meta-analysis showed that NRT, bupropion, and varenicline all had sustained abstinence rates of around 20% at 1 year. Most studies demonstrate that behavioral support (counseling, text messaging, phone apps web-based services) can increase quit rates. Continue to urge all smokers to quit at every appointment since even brief advice has been shown to increase success rates.

This patient has been on clozapine (Clozaril) for control of her psychosis.

Question 25.4.7 The combination of clozapine and bupropion should be used with caution because:

- A) Both may lower the seizure threshold
- B) Both may cause hypertension

- C) Bupropion may interfere with the metabolism of clozapine
- D) Severe GI symptoms could occur
- E) A psychotic episode could be precipitated

Answer 25.4.7 The correct answer is “A.” Both drugs may lower the seizure threshold. Hypertension should not be a concern. Bupropion does not interfere with the metabolism of clozapine, cause severe GI symptoms, or precipitate psychotic episodes. There are case reports of bupropion-induced psychosis in patients without a known psychotic disorder, but as noted above, the risk for a psychotic episode for a patient with schizophrenia treated with bupropion and an antipsychotic is very low.

HELPFUL TIP:

Serum levels of clozapine may be decreased by tobacco use. Thus, smoking cessation can cause clozapine levels to rise within 24 hours. Patients should be monitored for adverse events related to higher serum clozapine levels, including sedation, hypersalivation, seizures, hypotension, akathisia, and other neurologic effects. A dose reduction of 30% to 50% may be required.

After all of your discussion, the patient wants to quit “cold turkey.” You gently explain that going from 40 cigarettes per day to zero might be hard on her, although quitting cold turkey improves the chance of success (*Ann Intern Med.* 2016;164(9):585–592).

Question 25.4.8 All of the following are symptoms of nicotine withdrawal EXCEPT:

- A) Increased appetite
- B) Dysphoria
- C) Tachycardia
- D) Insomnia
- E) Irritability

Answer 25.4.8 The correct answer is “C.” Nicotine withdrawal is actually associated with decreased heart rate. In addition to the above, trouble with concentration and restlessness are common symptoms.

HELPFUL TIP:

Cytisine (not to be confused with cysteine or cystine) is a herbal derivative that is effective in smoking cessation (placebo 2.4% vs. cytisine 8%). It is less expensive than varenicline—which is actually a derivative of cytisine (*N Engl J Med.* 2011;365:1193–1200). A more recent study has shown cytisine to be superior to NRT for continuous abstinence at 1 week, 2 months, and 6 months, but higher self-reported adverse events, primarily nausea/vomiting and sleep issues (*N Engl J Med.* 2014;371(25):2353–2362).

**HELPFUL TIP:**

Other measures that are effective in helping a patient quit are automated cell phone messages (*Lancet*. 2011;378(9785):49–55), intensive interaction (nurse phone calls, bed-side teaching after an MI, etc., *CMAJ*. 2009;180(13):1297–1303), and paying patients to quit (*N Engl J Med*. 2009;360(7):699–709). In addition, public policies such as taxes on cigarettes and banning smoking indoors have demonstrated effectiveness at increasing quitting rates.

► **Objectives: Did you learn to ...**

- Employ pharmacotherapy and nonpharmacologic interventions in the treatment of tobacco addiction?
- List the physiological advantages of smoking cessation at any age?
- Recognize signs and symptoms of nicotine withdrawal?

**QUICK QUIZ: ALL IN THE FAMILY**

Which of the following characteristics is NOT true of the children of alcoholics?

- A) They experience earlier onset of problem drinking
- B) They experience earlier pregnancies (well, not the males...)
- C) They have less stable family involvement
- D) They experience poor academic and social performance in school
- E) They have more antisocial behavior

The correct answer is “B.” There is no data to suggest early pregnancy as a characteristic. Twin, adoption, and half-sibling studies and studies of familial versus nonfamilial alcoholism indicate that children of alcoholics have four times the risk for developing alcoholism. They also have worse school performance, more antisocial behavior, and less stable family situations.

► **CASE 25.5**

A 35-year-old intoxicated female presents to your office requesting to be started on disulfiram (Antabuse). She is otherwise healthy and recently has begun to drink alcohol daily in response to the death of her sister. She wants to decrease her use but has been unsuccessful, has noticed she is needing to drink more to achieve the same effect, has missed a few family functions due to her alcohol use, and has experienced the need to drink in the morning to avoid “feeling bad.” Before this, she was a teetotaler (i.e., a nondrinker).

Question 25.5.1 As the patient meets criteria for an alcohol use disorder and is still drinking (as indicated by her intoxicated appearance in clinic today), you suggest an FDA-approved alternative to disulfiram. You recommend:

- A) Naltrexone
- B) Naloxone (Narcan)

- C) Nortriptyline
- D) Topiramate

Answer 25.5.1 The correct answer is “A.” Naltrexone is FDA approved for the treatment of alcohol use disorders. As an opioid antagonist, it blocks the euphoric effects of alcohol. It can be started while a patient is still using alcohol, thus not having to force abstinence (if the patient is not ready for that). Disulfiram (based on its mechanism of action) should only be used in already abstinent patients in order to maintain abstinence. Topiramate (“D,” Topamax) has been shown to decrease the craving for alcohol; however, it is not FDA approved for this indication. Nortriptyline (“C”) and naloxone (“B”) are not used to treat alcohol use disorders.

.....
She agrees to start naltrexone as she is very worried about her continued alcohol use. You start her on 25 mg per day and increase to the FDA-approved usual dose of 50 mg per day.

Question 25.5.2 Which of the following is NOT a common side effect of naltrexone?

- A) Nausea
- B) Headache
- C) Dizziness
- D) Insomnia
- E) Increased appetite

Answer 25.5.2 The correct answer is “E.” Nausea, headache, dizziness, and insomnia, along with a *decreased* appetite, syncope, and muscle pain/weakness are some of the more common adverse events with oral naltrexone. However, side effects generally subside with continued use (and should be separated from any alcohol withdrawal symptoms).

**HELPFUL TIP:**

Higher doses of naltrexone, up to 150 mg per day, have been used in alcohol use disorders, but there is no clear evidence that doses higher than 50 mg per day are more efficacious. Some patients experience liver enzyme elevation when treated with naltrexone—up to fivefold elevation, in fact. Thus, liver enzymes should be checked at baseline and periodically. Elevated liver enzymes can also be due to alcoholic liver injury, hepatitis B or C infection, or use of other hepatotoxic medications.

.....
She returns for follow-up in one week, noting that she has not been able to stop or reduce her drinking. Upon further questioning, she has not been taking the medication consistently and reports she is “not good at taking daily medication.”

Question 25.5.3 Given her issues with adherence, you consider other FDA-approved medications and decide to start the patient on:

- A) Acamprosate
- B) Disulfiram

- C) Long-acting naltrexone (Vivitrol)
- D) Baclofen

Answer 25.5.3 The correct answer is “C.” With any treatment of an alcohol or other substance use disorder, adherence can be a significant barrier to success. A depot preparation of naltrexone (Vivitrol) can be administered at a dose of 380 mg IM every 4 weeks. This can improve adherence with monthly administration and achieve a steady therapeutic medication level. Adverse events of the depot formulation are similar to oral naltrexone, with pain and inflammation at the injection site being unique to this formulation.

At a follow-up appointment 3 months later, she reports a successful reduction in her rate of heavy drinking, but given insurance changes, she is no longer able to afford depot naltrexone. At this point, as an alternative to naltrexone, you decide to prescribe acamprosate (Campral).

Question 25.5.4 Which of the following is/are true about acamprosate?

- A) The usual dose of acamprosate is 666 mg three times daily
- B) Acamprosate is no better than placebo in reducing heavy drinking days
- C) Most prominent adverse events include diarrhea, insomnia, pruritus, and anxiety
- D) Acamprosate increases GABA neurotransmission and has complex effects on glutamate neurotransmission at metabotropic-5 glutamate receptors, which is likely important for its treatment effects
- E) All of the above

Answer 25.5.4 The correct answer is “E.” All of the above are true. Multiple early meta-analyses had found acamprosate to reduce alcohol consumption, but evidence is mixed. European trials found that acamprosate increased abstinence rates at 6 months (with positive effects seen primarily for maintaining but not initiating abstinence). US and Australia trials have shown no increased alcohol-free days or time to first heavy drinking. As to “A,” maybe the drug company is in league with Satan.

Question 25.5.5 Which of the following is/are true about acamprosate?

- A) Patients receiving opioid maintenance therapy or opioids for pain will need higher levels of opioid medication
- B) It is contraindicated in those with liver impairment/liver failure
- C) Patients who require detoxification can be continued safely on acamprosate
- D) It is contraindicated in patients who are taking SSRIs
- E) All of the above

Answer 25.5.5 The correct answer is “C.” Acamprosate does not interact with benzodiazepines or other medications used in medical detoxification and thus can be continued safely

if a patient starts drinking and then requires detoxification. Acamprosate is not metabolized by the liver (excreted unchanged by the kidneys) and can be used safely even in patients with severe liver disease, whereas naltrexone and disulfiram are contraindicated. However, it is contraindicated in those with renal failure and requires dose adjustment for those with chronic kidney disease. Patients receiving opioids for acute or chronic pain or receiving opioid maintenance treatment can use acamprosate because it does not affect these medications. It is safe to take with SSRIs.

Your patient returns to clinic after a month and has not been able to successfully reduce her alcohol use. She feels residential treatment may be needed. She completes a 30-day program and transitions to an intense outpatient program and has achieved initial alcohol abstinence. Now that she has achieved abstinence, she again asks about disulfiram (Antabuse) as she heard people discussing this during her residential program. You discuss the aversive nature of the medication, but given clinical trials suggesting efficacy when taken routinely under supervised conditions, you agree to prescribe it.

Question 25.5.6 Disulfiram should not be administered until the patient has been abstinent from alcohol for how long?

- A) 4 hours
- B) 12 hours
- C) 24 hours
- D) 48 hours
- E) 72 hours

Answer 25.5.6 The correct answer is “B.” A minimum of 12 hours should have elapsed before giving disulfiram to avoid the disulfiram–alcohol reaction. Of course, this depends on how much they were drinking.

HELPFUL TIP:

Disulfiram is absorbed slowly from the GI tract and is eliminated slowly; therefore, **a patient should wait at least 1 week after stopping disulfiram before returning to drinking.**

Question 25.5.7 If the patient consumes alcohol while taking disulfiram, which of the following is most likely to occur?

- A) Respiratory depression
- B) Hypertension
- C) Nausea and vomiting
- D) Cardiovascular collapse
- E) The ability to time travel

Answer 25.5.7 The correct answer is “C.” Disulfiram inhibits aldehyde dehydrogenase preventing metabolism of acetaldehyde, which accumulates and causes flushing of the skin, nausea, vomiting, palpitations, hypotension, sweating, blurred

vision, and dizziness. Rarely, in more severe reactions, respiratory depression, cardiovascular collapse, convulsions, and death may occur. The severity of the reaction is typically dose-related and depends on the amount of alcohol ingested.

Question 25.5.8 Common side effects of disulfiram include which of the following?

- A) Hypotension
- B) Peripheral neuropathy
- C) Insomnia
- D) Nausea
- E) Depression

Answer 25.5.8 The correct answer is “B.” Peripheral neuropathy can be seen with disulfiram. Drowsiness, hepatotoxicity, rashes, hypertension, metallic after-taste, and optic neuritis may also occur with disulfiram use. These effects are independent of alcohol ingestion. Additionally, multiple cases of hepatitis have been reported with disulfiram, and baseline liver enzymes should be obtained prior to starting disulfiram and then approximately 2 weeks after initiation of treatment. Occasionally, a rash may occur early on. The rash can be treated with antihistamines and the drug can be continued.

HELPFUL TIP:

Other medications that have been used to treat alcohol use disorders include topiramate, baclofen, gabapentin, ondansetron, and SSRIs. Topiramate has the best data to support decreased alcohol use in alcohol dependence. Ondansetron has only shown effectiveness in early onset alcoholism (onset of problem drinking prior to 25 years old) or in those who have a specific genetic variant of the serotonin transporter (5-HTT) gene. SSRIs may reduce alcohol intake when alcohol use disorders and depression are both present. Nalmefene, an opioid antagonist, may have advantages over naltrexone, but is not available in the United States.

HELPFUL (AND UNFORTUNATE) TIP:

None of these drugs are particularly effective, but again the health and cost-related benefits of alcohol abstinence (or even reduced alcohol use) should continue to motivate us to work with our patients. Combining medications (such as naltrexone and acamprosate) had mixed results and did not appear more effective than either medication alone. The number needed to treat (NNT) to prevent a return to any drinking was 12 for acamprosate and 20 for oral naltrexone with a NNT to prevent a return to heavy drinking of 12 for naltrexone (acamprosate did not show reduced days of heavy drinking).

► **Objectives: Did you learn to ...**

- Describe the mechanisms of action of naltrexone, acamprosate, and disulfiram?

- Recognize side effects of naltrexone, acamprosate, and disulfiram?
- Describe the alcohol–disulfiram reaction?
- Choose between the various pharmacotherapies for alcohol use disorders?

► **CASE 25.6**

A 25-year-old comatose female presents to the ED with pinpoint pupils and respiratory depression.

Question 25.6.1 Which of the following is the most likely cause of coma?

- A) Blood alcohol level of 200 mg/dL
- B) Cocaine overdose
- C) Methadone overdose
- D) Benzodiazepine withdrawal
- E) Phencyclidine (PCP) intoxication

Answer 25.6.1 The correct answer is “C.” The classic “triad” of opioid overdose consists of respiratory depression, pinpoint pupils (miosis), and coma. Certain patients may have atypical presentations, and the triad may not always be present in opioid overdose. Miosis is particularly variable, often not being seen in those with meperidine overdoses; and co-ingestions, such as with sympathomimetics or anticholinergics, can also prevent miosis. A patient with a blood alcohol level of 200 mg/dL would likely be ataxic; but alcoholic coma typically occurs at blood levels >400 mg/dL and depends on the level of tolerance. Alcohol and PCP intoxication would more likely present with nystagmus and not constricted pupils. Stimulant overdose and benzodiazepine withdrawal would more likely present with psychomotor agitation and autonomic hyperactivity and not likely present with somnolence.

You treat her with naloxone and she wakes up (spitting mad, agitated, and in withdrawal).

Question 25.6.2 What is the minimum amount of time that you should observe a patient who has overdosed on methadone?

- A) 1 hour
- B) 4 hours
- C) 12 hours
- D) 36 hours
- E) 7 days

Answer 25.6.2 The correct answer is “D.” Methadone has a long half-life (variable, but up to 60 hours), and therefore a patient who has overdosed on methadone should be monitored for at least 36 to 48 hours. Since the half-life of naloxone is 30 to 90 minutes, it may take multiple doses of naloxone to treat a methadone overdose (a naloxone drip is sometimes used).

You discover that the patient has been on a methadone maintenance program, and you are not sure why she overdosed, as

her program reports she was stable with no evidence of opioid use. Her urine drug screen returns positive for opioids.

Question 25.6.3 What would be the next most appropriate course of action?

- A) Detoxify the patient off methadone as an outpatient
- B) Contact the authorities to have the patient arrested
- C) Contact the patient's methadone maintenance clinic for dose increase
- D) Notify the patient of her positive urine drug screen and let her know you are not surprised by the result, as methadone is metabolized to morphine
- E) Have the patient committed to a substance abuse treatment facility

Answer 25.6.3 The correct answer is "C." Based on the urine drug screen results, the patient likely overdosed on methadone and another opioid. Methadone does not have any active metabolites (thus, "D" is incorrect). The positive urine drug screen is evidence of other opioid use. Methadone can be detected in urine but requires special testing. Heroin and codeine are metabolized to morphine. It would appear that this patient has relapsed into opioid abuse, and her methadone dose may be too low for maintenance. The rest are incorrect. "A" would be dangerous. "B" is not necessary. "E" would be ineffective for a patient not interested in quitting (but is often used anyway as a desperate measure).

HELPFUL TIP:

High-dose methadone can lead to QT prolongation and torsades de pointes.

Question 25.6.4 Methadone is typically prescribed for opioid maintenance therapy:

- A) Once daily
- B) Twice daily
- C) Three times daily
- D) Three times weekly
- E) Once monthly

Answer 25.6.4 The correct answer is "A." Methadone has an elimination half-life of up to 60 hours (range 15–60 hours). Thus, once daily dosing is appropriate for the treatment of narcotic addiction. The advantage to once daily dosing is that the medication can be given under direct observation. Remember that it is given more frequently (two to three times daily) for pain control.

After regaining consciousness, the patient informs you that she is 20 weeks pregnant.

Question 25.6.5 Regarding pregnancy and usage of opioids, which of the following would most likely have the best outcome?

- A) Continuing the patient on methadone

- B) Withdrawing the patient from all opioids in the first trimester (too late for this one)
- C) Withdrawing the patient from all opioids in the second trimester
- D) Withdrawing the patient from all opioids in the third trimester

Answer 25.6.5 The correct answer is "A." Opioid withdrawal in a pregnant woman can cause fetal distress and low birth weight. Multiple organizations, including the American College of Obstetricians and Gynecologists, ASAM, and SAMHSA support use of methadone or buprenorphine as potential first-line medications for the treatment of opioid use disorder in pregnant women. Buprenorphine rather than methadone has been associated with a lower risk of pre-term birth, higher birth weight, and possibly less severe neonatal abstinence syndrome. It also can be administered from a physician's office, has a lower risk of overdose, fewer side effects, and fewer potential drug interactions. As successful pharmacotherapy depends on coordinated care, methadone may offer advantages of having to be dispensed daily at a registered opioid treatment center, allowing for more frequent contact for those who may need or want that. Some studies show higher retention rates in treatment for methadone, but others have shown no difference. However, these studies have also shown lower rates of opioid abuse during pregnancy among those on methadone. Whatever you choose, treating opioid use disorder during pregnancy has multiple advantages, including longer durations of maternal drug abstinence, better obstetrical care, reductions in fetal illicit drug exposure, and enhanced neonatal outcomes (e.g., increased fetal growth, reduced fetal mortality, and decreased risk of preeclampsia).

HELPFUL TIP:

Methadone use HAS been associated with greater treatment retention than buprenorphine in men and non-pregnant women. However, the difference was not large. The success of either medication depends on appropriate patient selection.

HELPFUL TIP:

Although it is generally recommended to prescribe buprenorphine with naloxone (Suboxone) in order to reduce intravenous misuse (also reducing risk of diversion), in the past pregnant patients were prescribed buprenorphine alone (without naloxone), given the relative lack of data on safety. This recommendation may be changing as more recent data have been reassuring in regards to using naloxone during pregnancy.

► **Objectives: Did you learn to ...**

- Recognize symptoms and signs of overdose with opioids and other illicit drugs?
- Use methadone for opioid use disorder?
- Treat a pregnant patient with opioid use disorder?

► CASE 25.7

A 40-year-old female is admitted through the ED, arriving via ambulance from a smaller hospital. The local physician called to report that her friends said that she had “shot up a lot of meth.” She has been confronted about using her son’s Adderall prescription on a regular basis. She appears frightened and anxious. She is uncommunicative, rocking back and forth on the examination table, and picking at her skin trying to remove bugs that only she can see. She becomes angry easily and lashes out at staff in the ED.

Question 25.7.1 A reasonable differential diagnosis for this patient would include which of the following?

- A) Schizophrenia
- B) Drug-induced psychosis
- C) PCP intoxication
- D) Hepatic encephalopathy
- E) Delirium tremens
- F) Methamphetamine intoxication
- G) All of the above

Answer 25.7.1 The correct answer is “G.” Although there is a history of both methamphetamine and amphetamine use, the other options should not be eliminated without further investigation. You do not have the full history and do not know if there is an underlying medical or psychiatric disorder. There also may be more than one substance involved (don’t be tricked by the “obvious” substance as polysubstance use is common).

The urine drug screen is positive for both methamphetamine and amphetamine. You admit the patient for further treatment.

Question 25.7.2 Which of the following does NOT address the needs of this patient during withdrawal?

- A) Provide a secure environment
- B) Provide regular meals and snacks
- C) Make sure the patient is awakened if she spends excess time sleeping
- D) Consider giving a benzodiazepine if the patient remains anxious
- E) Provide education as an intervention toward change

Answer 25.7.2 The correct answer is “C.” Amphetamine withdrawal requires sleep, adequate hydration, nutritious food, and a safe place until the unstable state of being has diminished. The patient should be allowed to sleep. Stimulant abusers often stay up for a week or more at a time and then “crash,” sleeping for days during withdrawal. Antipsychotic medications and benzodiazepines may be administered if needed for control of agitation or violence.

You send off for confirmatory testing which shows only methamphetamine use. Collateral history is obtained from her husband and he is now keeping and dispensing their son’s

Adderall. There is no reported psychiatric history, she is not on any other medication, and she does not drink alcohol. After recovering from withdrawal, she is discharged and enters an outpatient treatment program. Success! At least for now...

Question 25.7.3 The following are all symptoms of methamphetamine (and amphetamine) use EXCEPT:

- A) Tachycardia
- B) Hypertension
- C) Perspiration or chills
- D) Weight gain
- E) Psychomotor agitation

Answer 25.7.3 The correct answer is “D.” Weight loss, not weight gain, can be anticipated in a methamphetamine user (or amphetamine abuser). All of the other symptoms can be seen as a result of methamphetamine/amphetamine use. Other symptoms include increased energy, disrupted sleep patterns, mood changes, diaphoresis, increased sexuality, confusion, arrhythmia, seizure, tremors/myoclonus, or even coma in severe cases.

HELPFUL TIP:

Stimulant use can cause coronary artery occlusion and severe hypertension. Myocardial infarction with stimulant use should be treated like any other MI. Hypertension from stimulant intoxication is usually well controlled with benzodiazepines, which can also be used to manage any psychomotor agitation or anxiety. If refractory, consider intravenous medications, such as alpha-blockers or nitroprusside. Avoid beta-blockers (unless absolutely necessary) as this may result in unopposed alpha-adrenergic vasoconstriction and worsening of hypertension though outcome data are mixed and some clinicians will use combined alpha/beta blockers such as labetalol and carvedilol.

HELPFUL TIP:

Chronic methamphetamine use is associated with widespread dental caries and gingival disease that can result in loss of many, or even all, teeth. “Meth mouth,” as this is commonly called, is probably due to prolonged periods of poor dental hygiene, xerostomia, high calorie food and drink, and tooth grinding. Methamphetamine-induced psychosis is associated with paranoia, auditory/tactile/visual hallucinations (snakes coming out of dashboard), and persecutory delusions and appears to have a relatively long duration of psychosis and can recur even during periods of abstinence.

► Objectives: Did you learn to ...

- Recognize the signs and symptoms of methamphetamine intoxication?
- Appropriately treat a patient with methamphetamine intoxication and withdrawal?

► CASE 25.8

A 15-year-old male is brought into the ED by his neighbor who found the boy passed out in his backyard with multiple tubes of glue nearby. He had difficulty rousing the boy. Currently, the patient is lethargic with slurred speech and difficulty walking. When his parents arrive, they are shocked, as their son has been a “good kid.” They had no idea he was using any drugs. Of course, he bought lots of tubes of “model glue” but they never did see any completed models.

Question 25.8.1 The signs and symptoms of inhalant intoxication include all of the following EXCEPT:

- A) Dizziness
- B) Slurred speech
- C) Unsteady gait
- D) Tremor
- E) Dilated pupils

Answer 25.8.1 The correct answer is “E.” Nystagmus and blurred vision/diplopia can be seen in inhalant intoxication; whereas, dilated pupils are seen in anticholinergic toxicity and other drugs (e.g., sympathomimetics) but not with inhalants. According to DSM-5, other signs and symptoms of inhalant intoxication include: incoordination, lethargy, depressed reflexes, psychomotor retardation, generalized muscle weakness, stupor/coma, and euphoria. Alternatively, patients may also display belligerence and assaultive behavior. Judgment is impaired (probably before and after huffing). The smell of solvents or glue on breath, skin, or clothes, empty containers or rags, and “glue-sniffer’s rash” are also suggestive of inhalant use.

Question 25.8.2 Which of the following are considered inhalants used by abusers?

- A) Whipped cream aerosol
- B) Cleaning solvent
- C) Gasoline
- D) Spray paint
- E) All of the above

Answer 25.8.2 The correct answer is “E.” All of these products can be used as inhalants. Other products that are known to be inhaled for their intoxicating effects include household products containing hydrocarbons (butane, propane, benzene, toluene, halogenated hydrocarbons), nitrous oxide, and nitrites.

HELPFUL TIP:

The acute intoxicant effect of volatile hydrocarbons and nitrous oxide is produced within seconds of use and generally lasts 15 to 30 minutes. Inhalation of nitrites produces effects within seconds of inhalation, but its effects are very brief, lasting less than 5 minutes.

Question 25.8.3 All of the following can result from chronic solvent or hydrocarbon inhalation EXCEPT:

- A) Neurocognitive impairment and cerebellar dysfunction
- B) Generalized muscle weakness
- C) CNS microhemorrhages and secondary seizures
- D) Erythrocytosis
- E) Liver and renal damage

Answer 25.8.3 The correct answer is “D.” Solvents and hydrocarbons can cause all of the effects noted above except for erythrocytosis. In fact, bone marrow suppression can be a result of chronic inhalant use.

Question 25.8.4 Which of the following is FALSE in regard to inhalant use disorders?

- A) Male and female adolescents report similar rates of inhalant abuse
- B) Use peaks between seventh and ninth grade (age 13 to 15)
- C) Those with inhalant use disorders are more likely to have episodes of major depression, conduct disorder, and are at an increased risk of other substance use problems
- D) African American adolescents are at higher risk for an inhalant use disorder compared to the general adolescent population
- E) Poor school performance (dropping out of school), lower socioeconomic status, and being involved with criminal justice system are risk factors for inhalant use

Answer 25.8.4 The correct answer is “D.” African American youth have rates of inhalant use about half that of the general population. Unlike other substance use disorder, males and female adolescents report similar rates of inhalant use disorders. Inhalant users tend to be of lower socioeconomic status, younger age (13–15 years old), have difficulty in school, and have mental health and behavioral comorbidities.

HELPFUL TIP:

“Sniffing” is when fumes are inhaled directly from a source container. “Bagging” is when the substance is placed into a bag and then inhaled from the bag by placing over the mouth, nose, or head. “Huffing” is when the substance is placed on a rag and then inhaled with the rag placed over the nose and mouth. You got to know the lingo...

► **Objectives: Did you learn to ...**

- Identify some types of inhalants abused?
- Recognize the symptoms of inhalant use disorder?
- Describe the demographics of inhalant use disorder?

► CASE 25.9

A 40-year-old male who has been smoking marijuana daily for the past 20 years would like to quit his marijuana habit ... but he just cannot find the motivation. He wants to apply for

a new job, and a drug screen is part of the application process. He makes an appointment with you to discuss what he can expect when he quits and how long will it be until his drug screen is negative.

Question 25.9.1 All of the following are symptoms of cannabis intoxication EXCEPT:

- A) Euphoria
- B) Sensation of slowed time
- C) Increased mental alertness
- D) Increased appetite
- E) Dry mouth

Answer 25.9.1 The correct answer is “C.” Statistically speaking, over 40% of you will know this one from personal experience (you know who you are!). In fact, in 2017 almost 50% of US adults reported using marijuana some time in their lives. Cannabis intoxication decreases mental alertness, although it can reportedly enhance the senses. The DSM-5 criteria for cannabis intoxication include: (1) recent use of cannabis; (2) clinically significant problematic behavioral or psychological changes (impaired motor coordination, euphoria, anxiety, sensation of slowed time, impaired judgment, social withdrawal) that develop during, or shortly after, cannabis use; (3) two or more of the following signs: conjunctival injection, increased appetite, dry mouth, and tachycardia; (4) and the symptoms are not due to a general medical condition or another mental disorder. When inhaled, intoxication peaks after 10 to 30 minutes and lasts about 3 hours (these times vary by person, history of use, and THC content of cannabis). Of note, when ingested, peak effects can be delayed ranging from 30 minutes to 3 hours with effects lasting up to 12 hours.

HELPFUL TIP:

Recent (past year and past month) marijuana use has increased since 2002 among those 18 and older; prevalence among 12 to 17 year olds is actually lower than 2009 to 2014; and use for those older than 50 has significantly increased over the past decade. (Results from the 2016 National Survey on Drug Use and Health.)

Question 25.9.2 How long can marijuana (THC) be detected in the urine?

- A) 30 days if used regularly; 2 to 7 days if used occasionally
- B) 2 weeks
- C) 1 week for females; 2 weeks for males
- D) 24 to 48 hours
- E) Trick question! It cannot be detected in urine samples

Answer 25.9.2 The correct answer is “A.” This is the general rule. However, there is no simple answer to this question as detection times in urine are affected by a multitude of factors, including the threshold for the test, potency of marijuana used, frequency of use, route of ingestion (eating can make for slightly

longer detection than smoking), and a person’s physiological factors (e.g., metabolic rate, level of hydration). This patient will likely have to stop smoking marijuana for a minimum of 30 days before applying for the job, but this may be shorter or longer depending on those factors listed. Waiting longer (one study reported positive urine 77 days after use, which is definitely much longer than average) will assure his urine drug screen will be negative. The drug can be present in hair samples for an extended period of time, anywhere from 1 to 6 months (longer time if using body hair which grows slower than scalp hair). If a positive urine drug screen (for cannabis or any substance) is going to be used for legal or treatment purposes, it should be followed with a confirmatory test (e.g., gas chromatography/mass spectrometry).

Question 25.9.3 Which of these is NOT one of the touted benefits of cannabis?

- A) Pain reliever
- B) Anticonvulsant
- C) Antiemetic
- D) Appetite stimulator
- E) Antidepressant

Answer 25.9.3 The correct answer is “E.” In fact, the use of marijuana has a small increased risk for the development of depressive disorders. Cannabis has been used to treat pain, nausea, anorexia, seizures, glaucoma, etc. Despite the fact that nearly half of the states have passed laws allowing some sort of “medical marijuana” use, evidence for many of the touted medical benefits is scant or contradictory. The best evidence of benefit has been seen with chronic neuropathic pain (and these studies are small and of low quality), antiemetics for the treatment of chemotherapy-induced nausea, patient-reported multiple sclerosis spasticity symptoms, and certain pediatric seizure disorders (cannabidiol).

HELPFUL TIP:

There are several FDA-approved cannabinoid-based medications currently on the market and perhaps more to come. **Marinol** (dronabinol) and **Syndros** (liquified dronabinol) are approved for anorexia/weight loss in patients with AIDS and chemotherapy-related nausea/vomiting who have failed other treatments. **Cesamet** (nabilone) is approved for chemotherapy-related nausea/vomiting in patients who have failed other treatments. **Epidiolex** (cannabidiol) is approved for seizures associated with Lennox–Gastaut syndrome and Dravet syndrome. This medication is different than the others as it is the first plant-derived cannabinoid medication. **Sativex** (Δ -9-tetrahydrocannabinol and cannabidiol) is an oromucosal spray approved for use in the United Kingdom, Canada, EU, New Zealand, and other countries (but not approved in the United States currently) as a treatment for spasticity due to multiple sclerosis. It is also plant-derived.

**HELPFUL TIP:**

An association between cannabis use and the development of schizophrenia or another psychotic disorder is supported by data from multiple systematic reviews and appears to be dose-dependent (highest risk among the most frequent users) and moderated by genetic factors.

► **Objectives: Did you learn to ...**

- Recognize the signs and symptoms of cannabis intoxication?
- Evaluate what positive marijuana urine drug screens mean?
- Recognize possible medicinal benefits of marijuana?

**QUICK QUIZ: DUDE, WHAT WAS IN THAT WEED?**

A 20-year-old male is brought by the police into the ED because of severe agitation after smoking what he thought was marijuana. He exhibits tachycardia, vomiting, paranoia, visual hallucinations, and may have had a seizure.

Which of the following substances is most likely causing his symptoms?

- A) Marijuana
- B) Heroin
- C) Methamphetamine
- D) Synthetic cannabinoid ("spice")
- E) Nicotine

The correct answer is "D." Synthetic cannabinoids (also known as "K2," "spice," "chill x," and many others) are analogs of natural cannabinoids, which have been chemically synthesized. They are typically more potent than natural marijuana. They are often marketed as "incense" or "herbal remedies." They can be added to other herbals and smoked, can be ingested in teas, or insufflated (such as adding to and burning incense). Clinical effects are similar to natural marijuana (tachycardia, conjunctival injection, euphoria, altered perception, sedation, and ataxia). However, there is an increased risk of more serious effects including hypertension, mood dysregulation/agitation, severe anxiety/panic attacks, paranoia, hallucinations, rhabdomyolysis, and seizures. Treatment is typically supportive measures with calming environment and benzodiazepines as needed. Clinical effects occur soon after inhalation/insufflation and can last several hours to days. There are no fatal overdoses linked to marijuana alone, *but overdoses and deaths associated with synthetic cannabinoids are increasing*. Given that chemical analogs used in synthetic cannabinoids are constantly changing and increasing to avoid regulation, additional toxic effects and life-threatening symptoms may result.

**HELPFUL TIP:**

A few words on other substances, which are becoming increasingly popular and are often difficult to detect on standard urine drug screens.

MDMA (3,4-methylenedioxymethamphetamine; also known as "ecstasy," "molly," "E," and "X") is a synthetic compound with both hallucinogenic (mescaline-like) and stimulant (amphetamine-like) properties. It produces sensations of euphoria, intimacy, and disinhibition. It can cause nausea, diaphoresis, blurry vision, tachycardia, and bruxism (which is why candy pacifiers are popular with MDMA users). MDMA can cause seizures, liver disease, hyponatremia, and hyperthermia among more severe effects. Treatment focuses on supportive care (stabilization of airway, breathing, circulation), treatment with IV benzodiazepines (for hypertension or psychomotor agitation), and cooling techniques if needed for hyperthermia. MDMA is typically ingested orally with peak effects occurring within 2 hours (usually less) after ingestion and lasting 3 to 6 hours. "Molly" refers to drugs that are supposed to be the pure crystal form of MDMA as ecstasy can have other additives, including caffeine, methamphetamine, cocaine, etc.

Synthetic cathinones (also known as "bath salts," "khat," "vanilla sky," "white lightning," "cloud nine," and others) are synthetic stimulant compounds analogous to a naturally occurring substance found in the leaves of *Catha edulis* (khat or qat). Symptoms of intoxication/toxicity are sympathomimetic, similar to amphetamine, including tachycardia, hypertension, mydriasis, hyperthermia, aggression, agitation, memory deficits, hallucination, and paranoia. More severe complications include hepatic failure, acute kidney injury, arrhythmia, rhabdomyolysis, and electrolytic abnormalities. Treatment is typically supportive measures with IV fluids, benzodiazepines for agitation, calming environment, and/or temporary use of low-dose antipsychotics for psychoses. Bath salts can be ingested, smoked, snorted, or injected. Cathinone appears to peak about 1 hour after oral ingestion with effects lasting variable lengths, given widely varying half-lives between different chemicals.

GHB (gamma-hydroxybutyric acid; also known as "grievous bodily harm," "Georgia home boy," "liquid ecstasy," and others) is a short-acting drug that produces both sedation and stimulation (which may cycle rapidly). Patients may be bradycardic and near apneic but when stimulated may become agitated and violent. Confusion, dizziness, and drowsiness are common with low oral doses, but effects are variable (even in the same person at different times). Risks of acute toxicity are high based on abrupt onset of action, narrow safety margin, and unpredictability of effects. Treatment is supportive care, sedation for agitation, monitoring for possible airway support, and treating injuries they may have sustained. GHB is primarily available in a liquid form, which is odorless and clear. Effects with an oral dose typically peak within 30 to 60 minutes and typical effects last 2 to 4 hours. GHB is also known as the "date rape drug" as it has been used in sexual assaults. Sodium oxybate (sodium salt of GHB) is also known as Xyrem, a medication approved for narcolepsy.

Salvia (also known as "magic mint," "diviner's sage," and others) is a naturally occurring herb from the mint family in Mexico (*Salvia divinorum*), structurally unrelated to any other hallucinogen. The herb is typically smoked but can be

chewed and absorbed from the buccal mucosa or ingested in a tea. The active ingredient is salvinorin A, which binds as a κ -opioid receptor agonist. Desired effects are similar to ketamine, LSD, and cannabis, including intense, short hallucinations, altered visual perception, and a “modified perception of external reality.” Adverse effects include: anxiety, depersonalization, dysphoria, confusion, headaches, drowsiness, tachycardia, and hypertension. Since salvinorin A does not bind to μ -opioid receptors, respiratory depression is not typically seen (unlike with opioids). Treatment for salvia toxicity is supportive with calming environments and benzodiazepines as needed. When smoked, it generally produces a rapid, hallucinogenic effect, altered reality, and mood changes normally appearing within seconds lasting 10 to 30 minutes. Hallucinations and mood changes can be present for more than 2 hours depending on dose and route of administration (shorter when smoked.)

PCP (phencyclidine; also called “angel dust”) is a dissociative anesthetic that has hallucinogenic properties. PCP intoxication is characterized by agitation, impulsiveness, nystagmus, hypertension, tachycardia, numbness, ataxia, and perceptual distortions. Intoxication begins 5 minutes after use and peaks in 30 minutes. PCP-induced psychosis is the most common PCP-induced disorder and may mimic a schizophrenic psychotic episode, and antipsychotic medication is sometimes needed (if benzodiazepines are insufficient). PCP may be added to other drugs unbeknownst to the user.

Kratom (*Mitragyna speciosa*) is a tropical tree native to Southeast Asia that has stimulant-like effects (at low doses) and opioid-like effects (at higher doses). The FDA has not found any legitimate medical use for kratom, but it is not currently banned in the United States (although certain states have made it illegal). Most users consume kratom as a pill, capsule, or extract, but leaves can be chewed, smoked, or brewed in tea. Effects usually begin within 5 to 10 minutes of ingestion and last for 2 to 5 hours.

Remember the abuse of caffeine (legally available in powder form over the internet) and the toxicity of nicotine (from ingestion of products meant for a vaporizer) when presented with a patient abusing drugs.

QUICK QUIZ: QUICK COUNSELING

Brief intervention for alcohol problems is one of the most clinically effective and cost-effective preventive services from among those recommended by the USPSTF.

All of the following are components for conducting brief interventions EXCEPT:

- A) Ask about use and give feedback on screening results
- B) State recommendations about safe drinking levels and offer advice about change
- C) Assess the patient's readiness to change

- D) Negotiate goals and strategies for change
- E) Follow-up in a year or two to see how changes are progressing

The correct answer (and the thing to avoid) is “E.” Hopefully, this one wasn't too hard as we wanted to introduce the concept of brief interventions. Follow-up should be arranged much sooner than 1 year. The “5 A's” method for brief interventions has substantial research support for its utility in alcohol use disorders across a variety of settings and can be incorporated with motivational strategies in a step-by-step process. The “5 A's” approach is a brief, goal-directed way to more effectively address substance use with patients. Altogether, the “5 A's” may take 1 to 5 minutes, depending on a provider's clinical setting and roles. These components include **A**sking about use, **A**dvising to cut down/quit, **A**ssessing willingness to quit, **A**ssisting with strategies for abstinence, and **A**rranging follow-up. The 5 A's approach is not the only model for brief interventions for alcohol use disorders with many approaches having been used successfully. Although duration of contact has not been shown to be an important determinant of effectiveness, delivering a clear, consistent message to your patient with whom you have an established relationship is an important part of any method.

HELPFUL TIP:

As part of any behavioral intervention, it is important to recognize a patient's readiness to change. Tailoring your interventions toward a patient's stage of readiness to change is more effective (and less frustrating) than taking a “one size fits all” approach to counseling. The five stages of change are: precontemplation, contemplation, determination/preparation, action, and maintenance.

Clinical Pearls

- Ask all adults about tobacco use, advise them to stop using tobacco, and provide behavioral interventions and offer pharmacotherapy (if not contraindicated) for tobacco cessation.
- Do not administer intravenous multivitamins to patients with alcohol use disorders and/or withdrawal. Oral multivitamins are sufficient for the majority of patients. IV thiamine may be indicated in those suspected of having Wernicke encephalopathy.
- Provide education and counseling to school-age children and adolescents regarding tobacco, alcohol, and illicit drug use.
- Screen all adults for alcohol misuse and provide persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce alcohol misuse.
- Screen all pregnant women for tobacco use and alcohol misuse. Provide counseling and resources to reduce misuse. Fetal alcohol syndrome is the leading cause of intellectual disability in the United States.

Ethics

Mark A. Graber and Nicholas H. Kluesner

▶ CASE 26.1

A 54-year-old married female, Charlene, has insulin-dependent diabetes and has seen you for her care for the last 7 years. In the last year, she has developed diabetic retinopathy and neuropathy. To your great frustration, Charlene continues to resist the recommended lifestyle changes required to control her diabetes.

She is a casual, friendly woman known as the “candy lady” in her neighborhood where she lives with her husband of 30 years. She loves children and volunteers at the local elementary school, where she is well known for a quick smile, a reassuring hug, and a piece of candy in her large, full pockets. In fact, she is noted during most of her appointments to be munching on M&M’s—her favorite candy. She has had dietary consults and many education-oriented doctor appointments but says, “I know I shouldn’t eat the way I do, but I just don’t have the heart to change who I am, even if it does help my eyes and legs. Who I am is about what I eat and do.”

You wonder about Charlene’s capacity for decision-making, given her frank noncompliance with care, even in the setting of serious complications from her diabetes.

Question 26.1.1 All of the following variables are necessary in decision-making capacity (DMC) EXCEPT:

- A) Ability to communicate a choice
- B) Voluntary choice (e.g., absence of coercion)
- C) Understanding of the variables involved in the decision
- D) Ability to appreciate the personal impact of choices
- E) Family agreement that the patient is competent

Answer 26.1.1 The correct answer is “E.” All of the other options are considered important for determining decision-making capacity (DMC). Certainly family concerns need to be addressed, but family agreement has nothing to do with determining a patient’s DMC. One additional necessary element for respecting DMC is freedom from coercion or other external threats to a person’s right to self-determination (autonomy). In this regard, coordinating family agreement to pressure the

patient into changing their decisions could be undermining the patient’s autonomy.

Question 26.1.2 Which of the following is TRUE about DMC?

- A) Patients who have been found legally incompetent do not have DMC
- B) A patient’s DMC may vary according to the circumstances of the situation
- C) A minor’s DMC is not clinically relevant since there is a surrogate who bears the responsibility for decision-making
- D) DMC should not be evaluated in cases in which the patient makes a conventional, recommended choice
- E) Patients with psychiatric disease, who are involuntarily committed to a treatment facility do not have DMC

Answer 26.1.2 The correct answer is “B.” DMC is largely considered on a sliding-scale, rather than an “all-or-none” distinction, since the threshold for reaching DMC can vary widely from case to case or setting to setting. *Even patients who have been declared legally incompetent or who have been legally and involuntarily committed may still have a measure of DMC* (for example, meal choices, etc.). Moral theory typically urges clinicians to consider the wishes and reasoning of their patients as morally and clinically relevant, regardless of the placement of a legal guardian or the state as a surrogate decision-maker. DMC may ultimately be overridden in certain kinds of legal circumstances, but it **should not be done lightly** as it suggests a fundamental denial of patient autonomy.

Just as no legal determination removes our responsibility to respect a patient’s autonomy, no particular diagnosis does either. As such, many patients with psychiatric illness still have the right to make choices, even with diagnoses such as schizophrenia. Additionally, making unconventional choices can sometimes be a marker that DMC is not intact, but does not automatically lead to this conclusion (a classic example would be an adult Jehovah’s Witness patient who refuses a blood transfusion; while this is an unconventional choice, DMC may be intact). Finally, though minors technically cannot make many healthcare choices, their wishes should be taken into consideration as they are often able

to articulate a preference. In minors, this is termed “assent,” rather than consent. Children may not be able to understand enough to consent on their own but they can “assent” to (or protest) a particular plan of treatment.

Charlene continues to have a slow decline over time but remains in good spirits despite the complications of her uncontrolled diabetes. One day her husband brings her to the emergency department. He had found her in the bathroom, unconscious, and called an ambulance. She has had a stroke and remains unresponsive and is on a ventilator in the ICU. Her prognosis is poor.

Question 26.1.3 What are appropriate considerations for making a treatment decision about end-of-life care for Charlene?

- A) Oral statements to her husband about her end-of-life care
- B) Her husband’s wishes for her care as designated proxy healthcare decision-maker
- C) Written advance directives
- D) Oral statements to her physician about her end-of-life care
- E) All of the above

Answer 26.1.3 The correct answer is “E.” Written advance directives are considered the most binding, since they are the patient’s own declaration of their preferences, although all of these considerations are relevant in making end-of-life decisions since all of them could inform the family and treating medical team on what the patient would have wanted given her critical illness. Since the family is likely also grieving about her poor prognosis, emotions could cloud their recollection of her previously informally expressed wishes. This underscores why anticipatory discussions and advance directives can be profoundly helpful.

Question 26.1.4 Which of the following statements can be used to describe medical futility?

- A) No worthwhile goals of care can be achieved
- B) The likelihood of success is negligible (any intervention would be “futile”)
- C) The patient’s quality of life is unacceptably burdensome
- D) All of the above

Answer 26.1.4 The correct answer is “D.” All of the above meanings have been explicitly or implicitly drawn into discussions about medical futility. Because of its variable interpretations and explanations, many theorists have objected to the use of the term “futility” as a justification for decisions and urge clinicians to be precise when “futility” is used as an argument to withhold care (e.g., the patient has metastatic lung cancer including to the brain, has been resuscitated two times already, may be resuscitated for this particular cardiac arrest but will never regain consciousness, will likely arrest again within the next 8 hours due to the underlying disease, and will never be able to be weaned successfully from a ventilator). Another definition of “futility” is trying to make it through this book without vast quantities of caffeine.

After discussion with her husband, you decide to discontinue ventilation. Charlene dies.

Question 26.1.5 This intervention is appropriately considered:

- A) Active, involuntary euthanasia
- B) Physician-assisted suicide
- C) Withholding medical intervention
- D) The principle of double effect
- E) Withdrawing medical intervention (passive euthanasia)

Answer 26.1.5 The correct answer is “E.” While the answer might seem intuitive to you, many persons (including physicians) do not recognize the differences between these various interventions. Active euthanasia (“A”) is when the physician both supplies the means of death and is the final human agent in the events leading to the patient’s death (e.g., the physician administers the lethal drug). Whether or not active euthanasia is voluntary, involuntary, or nonvoluntary depends on the DMC of the patient and their consent to the process. Assisted suicide (“B”) occurs when the physician provides the means of death but the patient carries out the act, such as taking an overdose of phenobarbital. Withholding medical intervention (“C”) means not initiating care for a disease state so that the disease itself results in death (e.g., not placing a gastric tube for artificial feeding in a patient with end-stage dementia). Withdrawing medical intervention (“E”) means discontinuing an intervention that has already been used, although the disease state itself results in death with the intervention’s discontinuation. Both of these (“C” and “E”) are forms of passive euthanasia, where withdrawing life-sustaining treatment, or not starting it, leads to death. The principle of double effect (“D”) is an ethical theory that suggests that if there is an unintended but anticipated bad consequence (e.g., earlier death) while pursuing an intended purpose (e.g., pain relief), there is diminished moral responsibility for the unintended outcome. This principle is sometimes used to justify the use of high-dose opiates or sedatives in patients with intractable pain or dyspnea, even when the unintended effect is respiratory depression and death.

Question 26.1.6 Which of the following is TRUE about the role of law in life-sustaining interventions?

- A) Courts must be involved in decisions *after* a patient has been declared to not have capacity
- B) Life-sustaining treatment may be withheld only if patients are terminally ill or permanently unconscious
- C) Physicians may face criminal charges for providing appropriate palliative care and not treating the underlying disease
- D) The most prudent legal advice is to continue treatment in medically futile cases
- E) The law presents few barriers to physicians withholding life-sustaining interventions

Answer 26.1.6 The correct answer is “E.” Sometimes physicians inappropriately provide treatment to patients who have made their end-of-life choices clear and have stated that they do not want

prolongation of life. Respecting the patient's prior wishes will **not** result in legal liability for the physician, but the converse is not true; *one can be legally liable for treating a patient who does not want treatment* (e.g., transfusing a Jehovah's Witness patient who refused transfusion). While they are exceedingly rare, there are case reports of "wrongful life" malpractice suits against providers who ignored advanced directives to withhold life-sustaining treatment. There is still a risk-management, and likely professional and moral preference to "err on the side of life" when there is ambiguity about the patient's advance directives. While state laws vary, generally speaking "A" is incorrect, since surrogates for the patient have the authority to make decisions after the patient is declared not to have capacity. This may be a relative, a healthcare provider, or court-appointed surrogate. "B" is also incorrect as treatment may be withheld at any time at the request of a competent patient.

► **Objectives: Did you learn to ...**

- Evaluate a patient's DMC?
- Recognize how DMC may vary based on the patient and the clinical setting?
- Identify some ethical issues in end-of-life care?
- Describe medical futility and understand its importance in making ethical decisions?

HELPFUL TIP:

Do "noncompliant" patients make you frustrated and angry? Just internalize the principle of patient autonomy. We can make suggestions, but it is up to the patient to decide how to act on our advice. In fact, it is their **right** to do so. Understand this and you will have a lot less heartburn.

QUICK QUIZ: AN ETHICAL DILEMMA

You are seeing George, a 30-year-old, HIV-positive male, for routine care and to assess his HIV status. During your conversation, he mentions that he is in a new relationship—a relationship that he hopes will become long term. They use condoms "some of the time", but have unprotected sex on a regular basis when there is no condom available. When you ask him whether or not he has disclosed his HIV status to his partner, he states that he has not done so and will not do so because of the fear his partner will leave him. He also forbids you to contact his partner to notify her of his HIV status.

Your response in this situation is to:

- Attempt to convince George to notify his partner of his HIV status
- Depending on your state, contact the health department and have them follow up on the patient's sexual contacts
- Contact the partner directly and let him/her know of George's HIV status
- Maintain strict confidentiality and do not warn George's partner nor report his HIV status regardless of the situation
- A, B, and C

The correct answer is "E." "A" is clearly correct. Anything we can do to convince George that it is critical he notify his partner of his HIV status (short of coercion) should be done. George should be aware that in some states it is a crime not to disclose known HIV-positive status to a sexual partner. "B" is correct but may vary by state. As of this writing, all 50 states and most territories have confidential, name-based reporting for HIV. However, patients can still be tested anonymously which precludes reporting and can circumvent reporting laws. For this same reason, "D" is incorrect. There are mandatory reporter laws on the books. "C" is also correct. Although this is somewhat controversial and there are conflicting duties (the patient's autonomy and confidentiality vs. the duty to warn the partner), we have a duty to protect the patient's partner. This can be clearly apparent in mental health, as in cases of a direct threat to a known individual, where there is a duty to warn the individual—known as the Tarasoff Rule after a court ruling on such a case. One such clear-cut example would be if George were threatening to shoot his partner and storms out of the office with a gun. While this is a more immediate example, the same principle holds. Clearly, we must not take the breaking of patient confidentiality lightly. And, we must inform the patient of our course of action. You may want to set a time frame for George to notify his partner with the understanding that if he does not do so, you must.

There are clear limits to this duty to protect other individuals. For example, if all we know is that George is HIV positive and have no knowledge of his partner(s), we cannot publicize George's HIV status in the local press in order to "protect the public." This would be too profound of a violation of the patient's confidentiality and privacy, without any concrete, individual benefits. But if we have a specific name of an ongoing sexual partner, we have a duty to warn that individual which competes with our duty to maintain confidentiality with George.

► **CASE 26.2**

Robert, a 27-year-old married nurse from your hospital, is referred to your emergency department for an urgent evaluation by his supervisor. In the past 2 weeks, he has been noted to be increasingly distressed while at work, with occasional tearfulness, distractibility, and irritability.

During the initial assessment, Robert reveals that there is a specific reason that he has been so preoccupied. He indicates that 2 weeks ago he was jailed for operating a vehicle while intoxicated and that he feels ashamed. He is afraid that his coworkers have read about it in the newspaper, although no one on his floor has indicated that this is the case. This is his first legal infraction of any kind and he describes it as humiliating.

On further questioning, Robert indicates that he uses alcohol regularly. While it has not overtly affected his work as far as he can tell, it has caused significant marital strife. He reports that his pattern is to stop by the bar on the way home from work to "relax and let go of the hospital stuff that I worry about." He typically drinks three beers and then drives home,

where he continues to drink beer throughout the evening. He notes that his wife and kids complain that he is emotionally absent and even irritable with them, but he says that his family simply doesn't understand the stress of the workplace and his need to "forget about it for a few hours." He and his wife have started arguing lately about his alcohol use, especially since the driving charge. He takes special exception to her stating that he is an "alcoholic."

As you take the history, Robert begins to be more guarded in his responses and more restricted in his affect. Suddenly, he blurts out, "I don't think I'm an alcoholic, but I don't want you to put anything in my record about any of this stuff! And I want you to tell my supervisor that there are some personal problems going on at home and that I'll be fine in a few days."

Question 26.2.1 Which of the following statements is TRUE about your obligation with regard to documentation in the chart?

- A) You are obligated to document the visit as it occurred so far as the medical facts are concerned, including the concern about alcohol abuse
- B) You can enter incorrect information into the chart in order to protect the patient
- C) You are under no obligation to document anything said and can withhold information from the chart at the patient's request
- D) Hospital administration or legal counsel should be involved if information is going to be purposefully left out of the chart
- E) You can lie in the medical record ... we're pretty sure perjury, liable, and slander don't apply to doctors

Answer 26.2.1 The correct answer is "A." The ethical principles of beneficence, nonmaleficence, and justice drive the decision here. A patient may legitimately ask for nonactive medical problems (e.g., distant history of sexual abuse) to be withheld from current documentation of an active problem (e.g., allergic rhinitis—by the way, kudos on your detailed history-taking). However, a patient **cannot** legitimately ask to have information withheld from the record if that information is pertinent to an ongoing condition currently being evaluated and treated. In this case, Robert is receiving care simply by virtue of being seen in the emergency department and disclosing the chief complaint and its associated variables. It is important for you to be forthcoming in explaining why the information may not be withheld from the medical record and also in reassuring him that irrelevant medical information will be omitted from the record if he feels that this is necessary. For example, the specifics of the argument with a wife need not be detailed beyond the comment that there is nonviolent marital conflict over the patient's alcohol use—important because it supports an alcohol abuse disorder. Furthermore, the patient can be reassured that many institutions have specific policies on managing sensitive medical information and there may be a formal mechanism for increasing the security of the patient's medical record.

Question 26.2.2 Why is protection of confidentiality important in medical practice?

- A) It shows respect for patient autonomy
- B) It helps prevent stigmatization and discrimination against patients based on private medical issues
- C) It helps solidify trust within the physician–patient relationship
- D) It helps establish a boundary between the physician–patient relationship and the rest of the medical system
- E) All of the above

Answer 26.2.2 The correct answer is "E." The physician–patient relationship is a long-honored tradition in medicine that is increasingly fragile in a medical system with numerous competing obligations. Nevertheless, it is prudent to remember the aspect of the Hippocratic Oath, which states, "What I may see or hear in the course of the treatment ... which on no account one must spread abroad, I will keep to myself, holding such things shameful to be spoken about." This is not only important to the tradition of medicine itself but also to the physician–patient relationship. There is no doubt that loss of confidentiality may cause harm to the patient when others are in possession of confidential medical information. Such harms may be as overt as denying insurance coverage for certain genetic conditions or as subtle as devaluing a person waiting to see the psychiatrist. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) codified confidentiality and disclosure of protected health information to respect individual privacy.

Question 26.2.3 Which of the following are legally protected exceptions to the rule of maintaining patient confidentiality?

- A) Reporting tuberculosis to public officials without patient consent
- B) Warning a third party at risk of imminent and serious bodily harm from the patient without patient consent
- C) Reporting a patient's alcohol abuse to a work supervisor without the patient's consent
- D) A and B
- E) All of the above

Answer 26.2.3 The correct answer is "D." Under current national and state laws, physicians are mandatory reporters of some infectious diseases, of intent to harm another, and of child / dependent-adult abuse. In most other cases, provision of protected health information without the patient's written consent is not legally protected, although there may be cases in which it is felt to be morally justifiable. Physicians need to weigh violations of patient confidentiality very carefully, even when legally sanctioned. Ethicists typically agree that if a physician is going to compromise a patient's confidentiality for an overwhelming moral obligation, the patient needs to be notified out of respect for his/her autonomy. In many situations in which a physician hopes to communicate confidential information to a third party even when the patient is unwilling, a process of education and negotiation with the patient occurs such that respect for autonomy is acknowledged while simultaneously making the patient aware of competing moral obligations.

**HELPFUL TIP:**

Having a faxed, e-mailed, or mailed report containing a patient's confidential medical information misdirected to an unintended recipient is *not* legally protected. Be cautious about transmission of patient information.

Question 26.2.4 Which of the following interferes with protecting patient confidentiality in the medical structure?

- A) Involvement of managed care organizations in patient care and medical payments
- B) Electronic records and transmissions
- C) Group practices and/or teaching hospitals with multiple care providers
- D) A and B
- E) All of the above

Answer 26.2.4 The correct answer is "E." While individual physicians and patients continue to prize the tradition of respect for confidentiality, the multiple players in healthcare make it nearly impossible to restrict all information to the dyad of physician and patient. Insurance companies will not provide payment without, at least, information about the diagnosis, and notably, insurance companies are not legally bound by the same codes of conduct that apply to physicians regarding patient privacy. Electronic records and transmissions by e-mail, cellular phones, faxes, and other means are much more easily accessed by the curious or unintended recipients who have no reason to have confidential information. Open waiting rooms and multiple providers of care mean that larger and larger numbers of the community are aware that a patient is being seen in certain clinics for certain purposes. Once information is in written form, it is more difficult to control who might, either now or in the future, have access to the details of the report. For this reason, some physicians try to err on documenting only that which is considered absolutely necessary to patient care, although the distinction between the "absolutely necessary" and unnecessary can be a difficult line to draw in the sand, especially without the ability to appreciate how multiple variables may play out in the patient's future medical care.

Back to the patient at hand ... Robert is asking you to be deliberately deceptive with the supervisor. You disagree with this.

Question 26.2.5 Which of the following is FALSE?

- A) Trust in the physician-patient relationship depends on allowing the patient to make such a directive about communication with outside persons
- B) A physician who establishes a precedent for deception may be expected to practice deception in a future situation in which the harms greatly outweigh the benefits
- C) A physician who deceives may undermine general trust in the profession
- D) All of the above

Answer 26.2.5 The correct answer is "A." Another way of phrasing the question is, "What drives a physician to be honest even when what the patient really wants is not honesty?" Will the patient trust you more if you are deceptive for him? Will this help him (aside from allowing him to keep his job)?

The physician-patient relationship is generally not considered an adequate reason to lie to a third party about the nature of a patient's illness and treatment. There has been concern that a physician who deceives a third party, even in the immediate interest of the patient's confidentiality or other concerns, establishes himself or herself as a physician who may not be trustworthy in other matters. A patient may not consider this at the time a deception is requested. These kinds of ripple effects from the decisions of an individual physician can affect the profession in general, ultimately producing fears that physicians will take the self-serving path rather than the higher moral ground.

You tell Robert that he has alcohol dependence and then provide education about the diagnosis and treatment options. You recommend outpatient treatment in Alcoholics Anonymous (AA) and a chemical dependency program. Robert agrees, more for the sake of his family stability rather than because of any true insight into the severity of his problem. You then arrange for follow-up with one of your partners (you've been selected as a contestant on the next *Survivor* and get to escape to a tropical island).

At the next appointment, Robert meets his new physician, Dr. Pincus. At this appointment, Robert indicates that he did attend two AA meetings but was very uncomfortable with the aspect of the 12-step program that requires acknowledging a "higher power." Robert indicates that he is an atheist and secular humanist, believing that the locus of self-control comes from within the individual human spirit. He has refused to continue in AA due to his rejection of its theistic foundation. He has had no further legal problems and reports that work is still going fine, with diminished irritability once he resolved in his mind that his coworkers were unaware of his previous driving violation. However, he continues to drink six to nine alcoholic beverages per night and admits that he occasionally needs a shot of whisky in the morning to "make sure I don't lose it with all the work stress" (this is where his self-control theory really comes together). He also works a night shift about once per week and does use approximately the same amount of alcohol before beginning the night shift, although he denies being intoxicated while on the job on these nights ("My tolerance is high and six beers are no big deal"). He doesn't think this is a problem because "things are quiet at night and everyone just helps each other keep the patients comfortable." He reports that his family is satisfied with the decrease in consumption and that he considers the matter of alcohol abuse resolved.

Dr. Pincus has had her own problems with alcohol in the past. She has had a rocky course over the past many years but found AA to be very helpful. She has become very active in her Jewish synagogue and community, where she receives support and is accountable to her friends. Her own alcohol

history has been marked by difficulty with alcohol bingeing, such that when she starts to drink, she drinks to intoxication. Only with aggressive honesty at a professional-group AA, as well as a substance abuse protocol through the state board of medical examiners, does she feel that she's been able to remain completely abstinent for the last 4 years.

Dr. Pincus is considering revealing to Robert some of her own struggles as a healthcare professional with a substance abuse disorder. She believes that this will help him reevaluate the role of AA in sobriety and the importance of very tight control of alcohol consumption to prevent relapsing illness.

Question 26.2.6 Self-disclosure is best described as involving the ethical issues of:

- A) Deception and nondisclosure
- B) Privacy and boundaries
- C) Informed consent
- D) Impaired colleagues
- E) Autonomy

Answer 26.2.6 The correct answer is "B." There are explicit and implicit boundaries that exist between a physician's private experiences and the physician-patient relationship. One of these boundaries has to do with preventing physician needs and private matters from encroaching into the visit in a way that is not therapeutic to the patient and does not respect the physician's boundaries. While it would appear that Dr. Pincus has therapeutic reasons—for Robert, not for herself—for crossing the boundary of self-disclosure, both physician motivation for self-disclosure and the immediate and potential effects of the self-disclosure need to be weighed very seriously before private matters are revealed. If there is even a potential of harm, crossing the boundary in this way should be considered a violation of professional norms.

Question 26.2.7 How could Dr. Pincus appropriately respond to Robert's refusal to participate in AA on the basis of his religious impulse?

- A) "AA is still shown the best intervention for preventing relapsing alcohol use. I hope you can go and get something out of it without acknowledging your acceptance of the 'higher power' explicitly"
- B) "AA has important group support from others who understand how difficult it is to stop using alcohol. It is not meant to be religious, but rather a community of care"
- C) "I have found both AA and a theistic world-view to be very helpful in understanding my own powerlessness to control some of my behaviors. Would it be helpful to you to hear more about this?"
- D) "I understand how the religious aspect of AA is inconsistent with your own philosophy. Would you be willing to investigate nonreligious group meetings for alcohol abusers?"

Answer 26.2.7 The correct answer is "D." AA is an example of a prescribed treatment that involves an active theological component. AA's first step involves acknowledgment of a higher power, traditionally invoking a specific monotheistic

conception of the divine as a necessity to surrendering the illusion of control. In the interest of respecting a patient's religious rights in a diverse community, and of optimizing treatment options, it would be disrespectful and ineffective to have the patient participate in AA, while ignoring the first step of the program and the foundational philosophy of AA. While there are fewer studies about the efficacy of nonreligious alcohol treatment groups, it is appropriate to respect Robert's beliefs by investigating nonreligious alternatives. As to option "A," the Cochrane database concludes, "No experimental studies unequivocally demonstrated the effectiveness of AA."

Whether or not self-disclosure of one's own religious beliefs is appropriate is an important question. As mentioned in the discussion in the question above, it is very important for the physician to measure the intent of the disclosure. Also, physicians need to be exquisitely sensitive to the power differential that exists between a physician and a patient such that strong individual viewpoints might become threatening or coercive in the physician-patient relationship. In certain religious traditions, sharing one's faith is an important step, demonstrating courage and integrity; nevertheless, physicians should be strongly cautioned to pay heed to the virtue of practical wisdom and the unique circumstances of the medical relationship that makes proselytizing most often inappropriate. A better strategy, if a physician feels that a patient might be seeking additional spiritual or philosophical direction, is to ask open-ended questions and then make an appropriate referral to pastoral care or a spiritual counselor who will be sensitive to the issues the patient has raised as relevant.

Question 26.2.8 Which of the following is true about intervening with an "impaired colleague," like Robert?

- A) Impairment should be reported only to a state licensing board if the colleague's patients are placed at known and documentable risk
- B) Because alcohol abuse is a confidential matter, it is inappropriate for a treating physician to report a colleague's impairment to a licensing board
- C) Removing a colleague from direct patient care and increasing supervision during patient care are reasonable first-step interventions for a colleague who is actively engaged in substance treatment (e.g., a report has already been made)
- D) It is preferable to contact a state licensing board directly as opposed to discussing the matter with the patient or institutional administration. This protects both the reporter and the colleague from unnecessary negative repercussions

Answer 26.2.8 The correct answer is "C." Legal statutes on reporting impaired colleagues vary from state to state, with some state laws making physicians mandatory reporters of impaired physician colleagues, while others simply recommend reporting. Furthermore, state laws are even less prescriptive with regard to nonphysician health professionals with impairments. Any impairment should be treated seriously, preferably with support from the institution's administration. It is imperative to protect patients from harm. While reporting the impaired colleague may result in anger and disappointment

from the colleague or even supervisors who are reluctant to tackle such a difficult question, physicians should consider the needs of vulnerable patients and the patients' rights to adequate care.

Confidentiality adds an additional ethical dimension when an impaired colleague reveals his or her impairment to his treating physician. In an effort to respect patient autonomy, physicians will often urge impaired colleagues to report themselves as well as voluntarily engage in treatment protocols. Many states have less-restrictive policies for treatment and monitoring for impaired colleagues who self-report. If a physician intends to report her patient's impairment without the consent of the patient, the physician is obligated to be truthful with the colleague about her intentions and rationale for reporting.

Question 26.2.9 A colleague may be impaired in her practice by all of the following EXCEPT:

- A) Substance use
- B) Major depression
- C) Dementia
- D) Deficits knowledge
- E) Barely passing the board examination

Answer 26.2.9 The correct answer is "E." Well, "barely passed," is what is needed to achieve certification. All of the others, whether acute or chronic, may impair a health professional's ability to practice, but none of these automatically imply global impairment in medical practice. Each has its own implications for a colleague's medical practice. Special attention should be given to the colleague's actual and possible consequences in practice, given her specific job requirements and compensatory skills/supports, while assessing the presence and degree of impairment. One might say that dementia is OK in physicians working for insurance companies (or at least it seems so!).

► **Objectives: Did you learn to ...**

- Identify what items are required for inclusion in the medical record?
- Recognize the importance of patient confidentiality and understand when confidentiality might be broken in order to fulfill other ethical obligations?
- Recognize obstacles to protecting patient confidentiality?
- Describe the importance of individual and societal trust in individual physicians and the medical profession as a whole?
- Describe the ethical principles involved in self-disclosure?
- Identify an impaired colleague and determine how to best intervene?

► **CASE 26.3**

Anne is a 19-year-old single female presenting for her first prenatal visit. She is G1P0, and roughly 10 weeks gestation by last menstrual period. She is new to your practice. Anne has had no medical care at this facility and no physician appointments since childhood. In recollecting the past medical history, Anne reveals that she has had several first-degree

female relatives who have been diagnosed with breast and/or ovarian cancer: her mother, two maternal aunts, and a maternal grandmother. A great aunt also died young of unknown causes. Anne is unsure of the workup that they had, but there was significant morbidity and mortality as a result of the illnesses. It was as if God were playing with a cosmic grenade launcher when it accidentally went off and blasted her family apart. "Oh, well. Genetic roulette," she says. Anne only recently became aware of this family history when her mother and aunts were diagnosed. When you ask if she has discussed genetic risks for breast cancer, Anne looks at you blankly and replies, "No."

Anne has been in a stable relationship with her boyfriend, Jordan, for 2 years. They cohabit and are engaged, but have not set a wedding date. Anne has completed high school and works in telemarketing while applying to art schools. The pregnancy was not planned, but she and Jordan are thrilled, even if a little nervous, about having a baby.

Being an extraordinarily astute clinician, you are concerned about BRCA1 and 2 genes. In families with a high incidence of breast and ovarian cancer, mutations in BRCA1 are associated with an 85% lifetime risk of developing breast cancer and a 50% risk of ovarian cancer.

You wonder if this is the best time to bring up genetic concerns with Anne, given Anne's concurrent transition with an unplanned pregnancy.

Question 26.3.1 Which of the following is/are true about disclosure?

- A) Nondisclosure is not justifiable due to fears that a patient will be distressed by the information, unless disclosure might cause death (e.g., suicide at hearing a diagnosis of cancer)
- B) Regardless of the consequences, nondisclosure could be considered deception and would be morally wrong on the basis of this intrinsic feature
- C) Disclosure is important because it respects patient autonomy and optimizes a patient's ability to make an informed choice
- D) Nondisclosure may be a sign of paternalism rather than beneficence
- E) All of the above

Answer 26.3.1 The correct answer is "E." There are a variety of moral theories which comment on whether or not deception or nondisclosure is morally appropriate. Most theorists rely on the principle of respect for patient autonomy, such that a person who has incomplete information is not able to act freely in making a choice for herself. "Consequentialism" is also a commonly used moral theory, suggesting that it is not the intrinsic nature of the act itself but the consequences that follow which determines whether the act is good or evil (as in "the end justifies the means"). In virtue ethics, by comparison, the nature and motivation of the act are very important as a reflection of the physician's character and habits. In virtue ethics, deception is morally blameworthy because it is comparable to lying. In virtue ethics, motivation is also an important issue to judge the goodness of the action.

Question 26.3.2 Which of the following is FALSE about testing for genetic conditions?

- A) Informed consent for genetic testing should be taken more seriously and formally than other kinds of blood testing, such as obtaining a CBC
- B) Physicians should ask patients what they would do with the different possible outcomes of the genetic test before the test is performed
- C) Physicians should make a recommendation regarding genetic testing guided by evidence-based medicine and the patient's specific narrative and values
- D) Physicians should urge patients to disclose positive results to relatives or spouses if the information is pertinent medically or emotionally to these third parties
- E) Physicians should never disclose genetic information to a third party without the consent of the patient

Answer 26.3.2 The correct answer is "E." Genetic testing differs from other blood tests because of multiple actual and potential risks, including personal effects on the patient and her family, as well as discrimination by employers or insurers. There is a shortage of formally trained genetic counselors, and patients rely on their physicians to not only help guide their decision-making about whether or not to perform the test, but also what to do with the information obtained. Because such testing has profound medical and/or psychosocial effects on the patient and family, a discussion about disclosure should happen both before and after the test is obtained.

Confidentiality is important for many reasons, not only in establishing and maintaining a good physician–patient relationship and respecting patient autonomy but also because of the potential discrimination and misuses of genetic information in today's culture. However, when the risk of harm to another related person is high and the patient refuses to disclose important genetic information, there may be adequate cause to break confidentiality in order to prevent serious harm to the third party; therefore, "E" is a false statement. For example, if a female patient has a genetic test that shows an X-linked trait that is lethal at approximately age 5 years in any male offspring, it would be immoral to withhold this information from the patient's reproductive age sister.

You decide to disclose the possibility of genetic risk factors to Anne at the first prenatal visit and also discuss the risk of passing genes to the fetus. Anne seems overwhelmed and asks to bring Jordan to the next visit to discuss this further. When Anne returns with her fiancé, you discuss your concerns about the BRCA1 and 2 genes and why Anne's family history is suspicious. Jordan says, "I think you should be tested right away, Anne. This would totally change our future." Anne replies: "What are you saying? Will you leave me if I have the gene? I can't raise this baby by myself!"

Question 26.3.3 Which of the following statements are appropriate to consider in promoting the patient's best interests?

- A) Patients can be a vulnerable population
- B) Physicians have expertise that patients lack
- C) Patients rely on their physicians
- D) Physicians and patients often agree on what constitutes a patient's best interests, although they may differ in the way they plan to meet those interests
- E) All of the above

Answer 26.3.3 The correct answer is "E." The nature of a relationship between a physician and a patient may have as many permutations as there are individuals. However, it is important to appreciate the position of the patient and the need that has pushed her to seek care. Patients are vulnerable in many ways, and the vulnerability is enhanced by limited access to technological and scientific information. When external variables, such as Jordan's comment and Anne's response, come into play, physicians should pay attention to this narrative and take some responsibility for establishing and maintaining a supportive network even outside of the office. This is particularly important as physicians give patients information about difficult choices. While physicians and patients may often be able to negotiate a mutually acceptable alternative, an active dialogue is important. Supporters and advocates who are familiar with the patient's values and wishes can be an important adjunct to medical decision-making, as long as there is no material or psychological conflict of interests. Physicians should not adopt a completely hands-off policy in decision-making; rather, physicians should pay attention to supporting the patient with real options and evidence-based variables in a noncoercive, empowering relationship.

.....

Anne decides not to have the test, but to have an elective abortion "just in case I passed on a gene to the baby." For the sake of argument, you are philosophically opposed to elective abortions in this scenario, but you would consider abortion an appropriate intervention if the fetus tests positive for the gene by chorionic villus sampling.

Question 26.3.4 What is the best ethical option for you at this point?

- A) Explain that you are personally uncomfortable with abortion, but in deference to Anne's legal rights, you will make a referral to another physician who is willing to provide the elective abortion
- B) Refuse to perform or make a referral for the abortion
- C) Refer to a "pro-life" counseling agency
- D) Tell Anne, for reasons that you do not feel comfortable disclosing, you will no longer be able to care for her
- E) Perform the elective abortion, despite personal convictions, out of respect for the law and patient autonomy

Answer 26.3.4 The correct answer is “A.” Abortion is a fiercely contentious topic in the United States. Under the 1973 *Roe v. Wade* decision and in subsequent rulings such as *Planned Parenthood v. Casey*, the Supreme Court has affirmed a woman’s legal right to abort a fetus. Physicians have responsibilities that should transcend views about a physician’s own moral values, such as ensuring that informed consent is practiced and that the patient has medical care available. Informed consent requires a physician to provide the necessary information about the various medical choices available and to assess the patient’s emotional needs. Coercion and failure to disclose clinically relevant information is inappropriate; for example, a referral to a pro-life group without informing the patient of the counseling center’s perspective (when known) is a form of manipulation and failure to disclose. Abandoning the patient (“D”) without a simple explanation is disrespectful, although the physician should be careful not to coerce her in other ways while revealing personal values/beliefs.

Three years later, Anne is seen in a new clinic. She had the abortion. Anne is now an art student and is married to Jordan. Since her last clinic visit, Anne has had a prophylactic mastectomy following a positive test for the BRCA1 gene. She has also had an elective tubal ligation. Anne wants to consider in vitro fertilization (IVF) and has a friend, Jessica, who is willing to donate ova. They put 18 embryos into cold storage, using Jessica’s ova and Jordan’s sperm. Anne has 6 embryos implanted, with the result of two fetuses that are carried to term. Anne decides that she does not want any more children and contacts the lab to discard the remaining embryos, eliminating storage costs. The lab agrees and sells the embryos to a private lab, where stem cell research is under way.

Question 26.3.5 What is NOT true about stored tissue samples?

- A) The embryos are considered Anne’s property only as long as she claims them
- B) Samples used for research purposes are potentially identifiable by third parties as belonging to Jessica and Jordan
- C) Tissue samples may be used only for their initial intended purpose, after which time they must be destroyed
- D) Third parties, such as research labs, upon discovering genetic anomalies in tissue samples, have no legal obligation to find and inform Anne, Jordan, and/or Jessica
- E) Embryos sold to a private lab may be used to establish germ lines via destruction of the embryo

Answer 26.3.5 The correct answer is “C.” At the time of publication, there is ongoing discussion about how to regulate use of tissue samples. While it might seem that this is an ethical question far removed from the purview of the family physician, patients in family practice clinics are very frequently targeted for various research protocols due to their regular follow-up and easy accessibility.

Patients donating tissue samples often give little thought to what happens to those tissues after they are obtained. In many cases, tissues are banked indefinitely after the initial research is conducted, with various identifiers linked to the tissue potentially including the donor’s gender, geographic location, educational level, family history, or other private information (e.g., *The Immortal Life of Henrietta Lacks*). While efforts are made to respect the privacy of the donor, there are ways to track down the donor using even the limited identification information associated with the stored sample. Such means are especially facilitated by the wide availability of personal information via the Internet.

Tissue samples may be collected for one purpose, but later used for another. Tissue samples are very important in research and are often the limiting factor for studies, but should informed consent include asking donors for permission for each and every lab test run on the tissue sample? At what point, if any, does the tissue sample become the sole property of the lab? In the example of embryos, discarded embryos are sometimes sold to private labs; parents using IVF technology are often unaware that such embryos may be used to establish a stem cell line from which genetically identical embryos can be created using nuclear transfers. Such stem cell lines are highly lucrative for research purposes, and there has been discussion, for example, of whether parents should be compensated in some manner when a lab sells their discarded embryos or a research facility develops a product using the embryonic stem cells.

HELPFUL TIP:

Family physicians should continue to serve as advocates for their patients. You can do so by investigating the policies and procedures of research groups prior to recommending them to patients and by taking some responsibility for the informed consent process when patients are volunteering to participate in research.

► Objectives: Did you learn to ...

- Describe the ethical issues regarding disclosure?
- Appreciate the many competing interests involved in genetic testing?
- Identify patient and physician factors that affect the patient–physician relationship?
- Find an ethical and acceptable way to disagree with a patient and continue to assure that patient’s healthcare?

► CASE 26.4

John is a 32-year-old newly practicing physician in your group. As friends on social media, you see his posts from time to time, typically about his family or sharing the latest current events in medicine. On one occasion, however, you notice a posting to a medical group discussing a “hypothetical” clinical case that clearly seems to be a recent real diagnostic dilemma he faced. He has, of course, de-identified the patient, but the

clinical context (recurrent asthma attacks at public sporting events) is important as he seems to be crowdsourcing input on how to distinguish true bronchoconstriction from social anxiety.

Question 26.4.1 Which of the following could pose problems for your colleague's social media activity?

- A) De-identification of the patient's information may not be sufficient to protect the patient's privacy
- B) Crowdsourcing can result in unreliable and unverifiable information
- C) Any publically available dialogue may be held to a higher standard as a physician in terms of the potential to violate confidentiality
- D) There may be relevant guidelines or rules that your partner has broken
- E) All of the above

Answer 26.4.1 The correct answer is "E." All of the above are true. In addition to the patient's name and other identifiable demographics, the circumstances, time, location, and other public records (e.g., police or news reports) could converge to threaten a patient's confidentiality. Additional caution and restrictions are needed to respect patient privacy on social media "A." Crowdsourcing, "B," occurs when a question is posed to a large group in hopes of generating more clinical insight, can indeed provide a diversity of opinions and perspectives but with unreliable and unverifiable references. Consensus in this platform can falsely reassure a provider. Physicians are de facto held to a higher standard of public discourse than the general public, with tangible consequences (e.g., state medical board investigations) for inappropriate behavior "C." Most hospitals and healthcare organizations have social media policies which this provider may be inadvertently violating; additionally, many medical societies are generating best practices and recommendations in this regard too.

► **Objective: Did you learn to ...**

- Describe the ethical issues regarding social media use?

► **CASE 26.5**

Jane is a 30-year-old female, newly married, and not typically a patient of your practice. As your sister, she calls you while at work reporting 3 days of dysuria, typical for her previous experience of UTIs. She expresses frustration about urgent care wait times, ER costs, and unavailability of her primary care provider, which is why she's asking if you will call-in a prescription for treatment.

Question 26.5.1 All of the following would be concerns you respond to your sister with EXCEPT:

- A) You do not typically call in prescriptions for patients, so wouldn't want to for her
- B) You are concerned that your personal relationship may limit both of your comforts in discussing critical information to treat this case appropriately

- C) The guiding AMA ethics strongly discourages this practice
- D) Without appropriate testing and follow-up established, starting an empiric treatment could cause her harm
- E) All of the above would be concerns to express

Answer 26.5.1 The correct answer is "A." While calling in such prescriptions for your patients may be part of your typical practice, there are several compelling reasons to object to this request of a family member. While state administrative rules governing the Board of Medicine may vary, the guiding principles from the AMA in this regard are clear. *Treating family members is fraught with problems.* Most notably is the limited comfort and interrogation of potentially sensitive information such as sexual/behavioral history and potentially relevant but previously unknown medical comorbidities. Physical examination is often sorely limited when involving family members for similar reasons. Furthermore, because of the blurring of personal and professional boundaries, this can introduce a slippery slope where one called-in prescription develops into enabling deleterious healthcare utilization (e.g., missing the opportunity for her primary care provider to track health maintenance and screening exams). Of additional legal and logistical concern is the under-documentation of such encounters.

Question 26.5.2 Under what circumstances may it be appropriate to engage in such treatment of family members?

- A) When the patient's primary physician refuses to provide a prescription for a medicine your family member requests (e.g., Xanax for anxiety)
- B) When no other provider is reasonably available due to the isolated, rural community (e.g., nearest primary clinic is 30 miles away and your aging aunt doesn't drive out of town)
- C) The trivially innocuous request on the part of the family member (e.g., left BP medication at home while out of town traveling for the weekend)
- D) There is a minor, urgent need of the family member (e.g., needs sutures removed)
- E) B, C, and D

Answer 26.5.2 The correct answer is "E." The rural family provider may find himself/herself in a unique circumstance of limited alternative resources for patients in the community to utilize. This can create a legitimate logistical exception to the ethical concerns surrounding treatment of family members "B." It is prudent to anticipate how these relationships should be managed in the healthcare setting, setting up referral alternatives should there be such a conflict.

In addition to this, there may be appropriately innocuous circumstances that can be considered ethically appropriate (Answers "C" and "D"). Documentation of such medical encounters—be them with family or otherwise—should be approached in a consistent way. Particular concern should be paid to controlled substances (e.g., mental health and pain medications) as these often have further legal restrictions. It would also be entirely appropriate, and supported by the AMA Code of Ethics to answer "none of these" as permissible, at least

in part because of the risk of such inconsequential encounters escalating to serious problems.

► **Objectives: Did you learn to ...**

- Describe the ethical issues regarding treatment of family members?
- Identify under which circumstances, if any, it *may* be appropriate to provide care for a family member?

Clinical Pearls

- An impaired medical professional must not be ignored. Physicians are bound by ethics and state laws to protect patients and society by identifying, assisting, and reporting impaired medical professionals.
- Ask patients about advanced directives periodically at outpatient visits and with every hospital admission. Discuss living will, durable power of attorney for healthcare, resuscitation wishes, and specific interventions (e.g., feeding tube use) in the appropriate setting.
- Each patient and each clinical question must be assessed individually to determine if a patient has decision-making capacity in that particular circumstance. The same patient may be able to decide not to follow a medically indicated diet, but be incapable of deciding his own disposition after hospitalization.
- Engage patients in shared decision-making regarding screening and diagnostic tests as well as medical procedures and treatments.
- Physicians must act in an ethical manner in order to maintain individual trust in the physician as well as societal trust in the profession.

- Recognize that patients have a right to noncompliance. While it is the physician's responsibility to provide the best care recommendations for a patient, the patient may refuse to follow the advice if other priorities (e.g., money, comfort, avoidance of drug side effects) outrank health in the patient's determination.
- Take great care in the transmission of patient information. Having a faxed, e-mailed, or mailed report containing a patient's confidential medical information misdirected to an unintended recipient is *not* legally protected.
- Use caution when using social media as physicians are de facto held to a higher standard of public discourse than the general public, with tangible consequences for inappropriate behavior.
- Recognize the multiple problems associated with treatment of family members. Follow the AMA Code of Ethics which highly discourages this practice.

End-of-Life Care

27

Juan R. Pagan-Ferrer

► CASE 27.1

A 75-year-old man is admitted to the hospital for a heart failure exacerbation. This is his second admission for heart failure within the last 6 months. His nurse asks if he is an appropriate candidate for hospice care.

Question 27.1.1 Which of the following would qualify your patient for the Medicare hospice benefit?

- A) His cardiac ejection fraction is 20%, and he is dyspneic with moderate exertion (NYHA class II heart failure)
- B) He agrees to a do-not-resuscitate (DNR) status in the event of cardiorespiratory failure
- C) He needs assistance with ambulation
- D) His implanted cardiac defibrillator (ICD) has fired once in the past year
- E) He has experienced escalating cardiac hospitalizations despite optimal medical management

Answer 27.1.1 The correct answer is “E.” If your patient has a terminal disease with declining function, worsening symptoms, worsening laboratory tests, or escalating hospitalizations, he or she probably qualifies for hospice. “A,” a low cardiac ejection fraction (typically <20%), is a recommended criterion for heart disease–related hospice care **but must be accompanied by dyspnea at rest** (class IV heart failure). “B” is incorrect. Despite popular belief, a hospice patient need not agree to a DNR status; however, hospice agencies are permitted to have different admission criteria and some require a DNR status for admission. Check with your local hospice agencies. Regardless, you should have a frank discussion with the patient about the role of aggressive resuscitation and the goals of hospice care. “C” is also incorrect. While a decline in functional status is a strong indication of worsening prognosis, it is not automatically a criterion. Most patients with heart failure need assistance with at least four activities of daily living (ADLs) before having a prognosis of death within 6 months. “D” is incorrect. Patients with ICDs are eligible for hospice, and whether or not it has fired does not impact enrollment decisions. It is important to talk about the ICD, ideally before

a patient approaches the final weeks/days of life. Many patients choose to have it disabled once they enroll in hospice. If an ICD is not disabled, it is important that the hospice staff be aware of it and know what to do as it will fire when the patient dies, which can be distressing for both the patient and the family.

HELPFUL TIP:

As opposed to an ICD, a pacemaker does not cause distress (shocks) during the dying process; however, if the patient’s usual cardiac rhythm is completely dependent on the pacemaker, then the pacemaker is considered to be life-prolonging.

HELPFUL TIP:

Although prognosis may be the most difficult task a physician faces, an attempt at prognosis in patients with a terminal illness may help them. Asking the simple question, “Would you be surprised if this patient died in the next year?” serves as a good screening tool and has been shown to be a reasonably accurate way to predict who might benefit from a hospice referral.

Your heart failure patient is currently on maximal medical management with an ACE inhibitor, beta-blocker, loop diuretic, aldosterone antagonist, long-acting nitrate, hydralazine, and a dual chamber ICD. He wants to discuss the management of his cardiac therapies in relation to hospice.

Question 27.1.2 Which statement is true about cardiac therapies for patients with heart failure in hospice?

- A) Hospice will not enroll patients on intravenous inotropic support (such as dobutamine or milrinone infusions)
- B) Oral cardiac medications like beta-blockers and diuretics should be stopped because they are unlikely to provide any benefit to quality of life

- C) A fluid restriction is no longer relevant once a patient enrolls in hospice
- D) Hospice will not enroll patients who have not deactivated their ICD
- E) None of the above

Answer 27.1.2 The correct answer is “E.” Many of the therapies for patients with advanced heart failure provide symptomatic relief and improve quality of life. Just as you would do with any other advanced illness, a thorough evaluation of each medication and intervention should occur with the goal of determining if that intervention will contribute to your patient’s overall goals. Physicians need to negotiate the balance between benefit and burden of each individual therapy. Although often a surprise to physicians, “A” is incorrect. A patient can have continuous inotropic infusion and still be enrolled in hospice. Some heart failure patients are dependent on inotropes and require them to maintain a certain level of quality of life, and they are willing to accept the trade-offs of having a continuous infusion to maintain that quality of life. Be aware that inotrope infusions do not prolong survival (in fact they shorten survival compared to no inotropes). The burden of inotrope infusions includes: cost, risk of line infections, and increased risk for arrhythmia.

Hospice agencies are required to provide treatment to manage symptoms related to the terminal condition and many hospice agencies utilize formularies in order to control cost. Some hospice agencies have formularies that will allow the use of inotropes for management of dyspnea, fatigue, etc., while others will specify that the symptoms be controlled with other agents such as opioids.

“B” is incorrect. There is so much more to palliative care than giving morphine for shortness of breath in heart failure! Continuing cardiac therapies may allow a patient to maintain their cardiac functional status and prevent pulmonary congestion and should never be discontinued just because a patient enrolls in hospice. With that being said, there are times when the patient’s goals support the discontinuation of these medications. “C” is incorrect because as noted above, every decision comes with both a benefit and a burden, which need to be weighed. Some level of fluid restriction may help with breathing and pulmonary congestion and should be balanced against the discomfort of restricting intake. On the other hand, there is no evidence that sodium restriction is helpful in CHF (*JAMA Intern Med.* 2018;178(12):1693–1700). Individualize the decision. “D” is incorrect because it is not a requirement for an ICD to be deactivated. However, the incidence of arrhythmia can be high in this population, and ICD shocks near the time of death can be very distressing to the patient and the family and should be discussed.

HELPFUL TIP:

If you’ve seen one hospice agency, you’ve seen one hospice agency. Hospices often have different formularies, different available ancillary services (e.g., music therapy, pet therapy, massage), and different policies in what they cover for symptom management (e.g., chemotherapy, radiation, blood transfusions). It can be helpful to know what services your local hospice covers.

You think that your patient may be appropriate for hospice and decide that a palliative medicine consult might be useful to address his goals of care, review symptom management, and discuss hospice.

Question 27.1.3 Which statement accurately reflects how palliative medicine is different from hospice?

- A) Only palliative medicine affirms life and attempts to help patients live as fully as possible
- B) Palliative medicine offers treatments including aggressive medical treatments such as radiation therapy, intravenous (IV) fluids, or interventional radiologic procedures, while hospice does not
- C) Palliative medicine is performed by a physician only, while hospice care involves an entire team of providers
- D) Palliative care can be offered at any time during a life-limiting illness, even if a patient is still actively seeking a cure
- E) Palliative medicine consults are billed under Medicare Part B while hospice care is reimbursed through the Medicare Part H

Answer 27.1.3 The correct answer is “D.” Palliative care is specialized medical care for people with serious illnesses that focuses on providing patients with relief from the symptoms, pain, and stress of the serious illness—whatever the diagnosis. The goal is to improve quality of life for both the patient and the family. Palliative care is provided by a team of doctors, nurses, and other specialists who work with a patient’s primary team to provide an extra layer of support. Palliative care is appropriate at any time in a serious illness and can be provided together with curative treatment. Hospice care is a type of palliative care, which occurs during the final months of someone’s life when cure is no longer possible or no longer consistent with the patient’s goals. “A” is incorrect because both hospice and palliative care strive to make life meaningful and comfortable for patients. “B” is incorrect. Since the goal of both hospice and palliative care is to prevent and relieve suffering, any of these modalities may be used if appropriate. In fact, **any intervention** can be considered palliative if the intention is to relieve distressing symptoms associated with the fatal disease (such as a hip-pinning for pain control after a pathologic fracture). There are no restrictions prohibiting a hospice agency from providing “aggressive” interventions designed to relieve pain and suffering. “C” is incorrect because both hospice and palliative medicine are built on the concept of a team providing care to the patient and family. Hospice care usually (but not always) is directed by the primary physician. “E” is incorrect because Medicare Part A covers both palliative medicine services (typically billed as inpatient consult services) **and** hospice benefits, and there is no such thing as Medicare Part H—yet!

Question 27.1.4 Which of the following is TRUE regarding the Medicare hospice benefit?

- A) The Medicare hospice benefit requires all care related to the primary admitting illness to be covered by the hospice agency, including physician fees, as long as the hospice program does not employ the physician

- B) The hospice benefit, similar to the Medicare home care benefit, requires that the patient be homebound
- C) Respite care within an acute hospital setting is provided for up to 5 days every 6 months
- D) Hospice entry requires that the patient cannot live alone (must have an on-site primary caregiver)
- E) A flat per diem rate is paid to the licensed hospice program regardless of the level of services provided

Answer 27.1.4 The correct answer is “A.” The Medicare hospice benefit requires all care related to the primary admitting illness to be covered by the hospice agency. Think of it as capitated care. However, Medicare affords individual hospice agencies wide latitude in determining what modalities they use to treat the symptoms of a particular illness. For example, one agency might allow blood transfusions for the relief of dyspnea, while another agency only covers the use of medications such as morphine or lorazepam for dyspnea. If necessary for acute symptom management, Medicare also covers acute hospitalizations related to the primary illness. “B” is incorrect. A hospice patient does not need to be homebound. The Medicare hospice benefit provides respite care which can occur as frequently as needed, making “C” incorrect. Respite admissions can last up to five nights at a time. The respite care needs to be provided in a setting where there is a registered nurse available continuously, and the patient must come from a home setting (including assisted living). This can be used if the caregiver is unable to care for the patient for a variety of reasons. “D” is incorrect because Medicare does not require that the patient have a primary caregiver in the home to receive the hospice benefit; however, an individual hospice agency may require a primary caregiver be identified before enrolling a patient. “E” is incorrect because Medicare pays the hospice organization a stratified per diem rate depending on the level of care the patient requires.

After meeting with the palliative care team, your patient’s family inquires more about hospice care. They ask what other services are covered.

Question 27.1.5 The Medicare hospice benefit includes coverage for all of the following expenses EXCEPT:

- A) Medications related to symptom management
- B) Social work visits
- C) Home health aide services
- D) Room and board for a patient living in a nursing home
- E) Bereavement services

Answer 27.1.5 The correct answer is “D.” All of the other options listed are services covered under the Medicare hospice benefit. A patient living in a nursing home is eligible for hospice care, but the cost of room and board for the nursing home is not paid by the hospice benefit. In some special circumstances, nursing home care will be paid for a short duration (e.g., when a hospice patient uses the five-night respite care benefit or if the patient is admitted to a nursing home for management of a distressing symptom that cannot be controlled in the home setting).

A few months go by and your patient has again been hospitalized. You now believe that he has fewer than 6 months to live. The local hospice medical director reviews the case and agrees. The patient is dyspneic at rest, requires 24-hour oxygen by nasal cannula, and his cardiac ejection fraction has decreased to 15%. He wishes to avoid further hospitalization and has elected to have a DNR status. His family wants to know what you can do when he becomes severely dyspneic.

Question 27.1.6 Which of the following is appropriate palliative treatment of severe dyspnea in this patient?

- A) Intubation and ventilation
- B) Morphine
- C) Scopolamine
- D) Buspirone
- E) Hyperventilating into a paper bag

Answer 27.1.6 The correct answer is “B.” Morphine and other opioid analgesics are indicated for palliation of dyspnea in cardiac failure. Despite concerns about opioids worsening respiratory function in end-stage heart failure, studies have concluded that oral morphine improves dyspnea in this patient population and does not cause respiratory failure or hasten death. This is supported by recommendations from the American College of Cardiology and the American Heart Association. If morphine or other therapies for shortness of breath were to shorten life, the ethical principle of “double effect” would be applicable. The double effect principle states that as long as the intention of a therapy is to reach a good outcome (such as improve pain and alleviate suffering), then even if the unintended consequences result in a negative outcome (e.g., shortening life), the intervention is permissible. The key here is intention. If you choose “A,” your patient’s ghost will be back to haunt you. This patient has chosen a far less aggressive stance toward life-prolonging measures, and his wishes should be honored. “C” is incorrect. Scopolamine is used to reduce oropharyngeal secretions (resulting in sonorous respirations) but is not likely to relieve dyspnea in this patient. In addition, scopolamine is highly anticholinergic and crosses the blood–brain barrier, which can result in delirium and should be used with caution in an awake and alert patient. Glycopyrrrolate is a better choice to control secretions in a patient who is alert and awake. “D” is incorrect. While anxiety and dyspnea often occur together and exacerbate each other, buspirone (BuSpar) is a weak anxiolytic and has no direct effect on dyspnea. Low-dose lorazepam would be a reasonable alternative if you felt his dyspnea was complicated by anxiety. And “E” is just plain wrong—although still not as bad a choice as “A.”

Consider diuretics to relieve dyspnea in heart failure patients in hospice. Oftentimes we are guilty of forgetting to treat the underlying illness when someone is in hospice, reaching for morphine first. Are there signs of volume overload (e.g., elevated JVD, diffuse crackles, profound edema)? Diuretic therapy may reduce pulmonary congestion and relieve dyspnea, and the benefits and burdens should be weighed. The burdens that need to be considered include: patient’s bed bound status, risk for

incontinence decreasing quality of life, patient's agreement with using a bladder catheter, renal function, etc.

HELPFUL TIP:

Benzodiazepines may be used in combination with opioids for added relief of dyspnea and anxiety. The patient should be monitored for excessive sedation and respiratory depression.

► Objectives: Did you learn to ...

- Identify appropriate patients for end-of-life care, particularly for the Medicare hospice benefit?
- Describe the features of the Medicare hospice benefit?
- Treat patients with dyspnea related to end-stage cardiac disease?

QUICK QUIZ: MORE THAN A LITTLE HEADACHE

A 30-year-old male patient you have known for several years was diagnosed with metastatic melanoma several months ago. He presents now with intermittent, severe headaches associated with nausea. A head CT scan performed last week showed three metastatic foci with surrounding edema. He currently takes maximum doses of acetaminophen and large doses of morphine.

What is the best initial treatment option to help relieve his headache and nausea?

- A) Neurosurgical intervention
- B) Dexamethasone
- C) Sumatriptan
- D) Ibuprofen
- E) Increased morphine doses

The correct answer is "B." Corticosteroids are the preferred therapy for headaches due to increased intracranial pressure from edema, as is presumably the case here. Whole brain or stereotactic radiation therapy, alone or in combination with corticosteroids, may also be used as palliative therapy for multiple brain metastases. "A" is incorrect because neurosurgical consultation should be reserved for patients who fail other interventions or who present with rapidly worsening symptoms. "C" and "D" are incorrect. Sumatriptan and ibuprofen should not be used to treat increased intracranial pressure. "E," increased morphine doses, may be required, but corticosteroids are typically used first.

QUICK QUIZ: EARLY PALLIATIVE CARE

A 74-year-old woman presents to your clinic with a new diagnosis of non-small-cell lung cancer found during an evaluation for hip pain that revealed diffuse bony metastases on x-ray. She inquires about ways to improve her quality of life in addition to the care recommended by her oncologist. You recall reading the

landmark study (a study that every primary care and palliative care physician should know—and if you don't know you should read it cover-to-cover several times) by Temel et al., regarding the introduction of early palliative care in patients with metastatic non-small-cell lung cancer.

Which of the following is NOT true about the outcomes for the patients that received early palliative care compared to those that received standard oncologic care?

- A) Introduction of early palliative care improved patients' quality of life
- B) Introduction of early palliative care improved patients' mood
- C) Introduction of early palliative care shortened the median survival
- D) Introduction of early palliative care resulted in fewer aggressive therapies at the end-of-life

The correct answer is "C." Introduction of early palliative care was shown to **increase** median survival from 8.9 months to 11.6 months, and this occurred despite the intervention group patients receiving fewer aggressive interventions at the end-of-life. Both "A" and "B" are incorrect answers (but true statements) because this study showed that both quality of life and mood were improved when early palliative care was introduced to the standard oncologic care in this patient population. "D" is incorrect (but again a true statement) because 33% of patients who received early palliative care received "aggressive care" (chemotherapy within 2 weeks of death, no hospice care, and/or admission to hospice 3 days or less before death) as compared to 54% of patients in the standard care group. The Temel study applies to a very specific patient population—patients with metastatic non-small-cell lung cancer; however, multiple studies in other settings (mostly with cancer diagnoses) have now shown that including palliative care earlier in treatment of very serious illness may reduce cost, shorten length of stay, and improve quality of life.

► CASE 27.2

A 74-year-old female was diagnosed with adenocarcinoma of the colon 3 years prior to beginning hospice care. She has known metastases to her liver and pelvis. She complains of a cramping pain in her abdomen and a "deep pain" in her groin. She is currently receiving morphine 10 mg PO every 4 hours (except when asleep) and acetaminophen 650 mg PO TID. She says that her pain is 4 out of 10 on a numeric pain scale. Her past medical history includes hemorrhage secondary to a gastric ulcer 4 years ago (*Helicobacter pylori* negative on biopsy).

Question 27.2.1 Which of the following strategies is the best next step for improving this patient's pain control?

- A) Start gabapentin to treat the neuropathic aspect of her pain
- B) Add a strong nonsteroidal anti-inflammatory drug (NSAID) such as ketorolac (Toradol) to her current regimen

- C) Add scheduled tramadol to try to decrease her morphine use
- D) Start a long-acting morphine (e.g., MS Contin) at a dose 20% higher than her current morphine use
- E) Maximize the dose of acetaminophen to 1,000 mg every 4 hours

Answer 27.2.1 The correct answer is “D.” The patient is taking short-acting opioids around the clock, which can lead to “chasing the pain” (not to be confused with “chasing the dragon,” which is inhaling heroin smoke, which leads to a leukoencephalopathy ... you never know ... it could be on the test!). Patients often receive much better pain control when they are maintained on a long-acting opioid. It is common practice to increase the dose of opioids by 15% to 25% when a patient’s pain is only partially controlled. It is then recommended to have the breakthrough dose equivalent to 10% of her 24-hour use. “A” is incorrect as her pain is better described as visceral or somatic rather than neuropathic. Gabapentin is an acceptable choice for neuropathic pain but is not likely to be effective for this patient. “B” is incorrect. Ketorolac is the NSAID with the highest rate of renal disease and gastrointestinal (GI) bleeds and is contraindicated in a patient who has had a GI bleed. If you were to add an NSAID, ibuprofen would be a better choice, and GI protection with a proton pump inhibitor would be advisable for this patient. “C” is incorrect. Tramadol is a weak mu-receptor agonist, possessing some norepinephrine and serotonin reuptake inhibition and is much less efficacious than morphine. Tramadol is not likely to benefit a patient with severe pain from cancer and metastases. Tramadol also has a number of troubling side effects such as an increased risk of seizures and serotonin syndrome. “E” is incorrect because the current recommended daily maximum dose of acetaminophen for elderly patients is 3,000 mg (don’t blame us ... blame the FDA), and the frequency suggested in “E” would far exceed this amount.

When determining what medications are appropriate for treating pain, it helps to know what type of pain the patient has.

Question 27.2.2 Cancer is known to cause which type(s) of pain?

- A) Neuropathic pain
- B) Visceral pain
- C) Soft tissue/bony pain
- D) Pain from increased intracranial pressure
- E) All of the above are types of pain

Answer 27.2.2 The correct answer is “E.” Physiologic pain is separated into four categories: soft tissue or bony pain (also called somatic pain), neuropathic pain, visceral pain, and the pain of increased intracranial pressure. An example of somatic pain is the musculoskeletal pain (e.g., sports injuries and fractures) that everyone experiences at some point. Neuropathic pain is generally described as burning and results from nerve damage, inflammation, or compression. Visceral pain comes

from distention of an organ capsule (e.g., liver enlargement from metastases and colicky pain from the colon). Depending on where a metastasis or primary tumor is located, it may cause somatic pain (e.g., bone tumors), neuropathic pain (e.g., Pancoast tumor), visceral pain (e.g., peritoneal carcinomatosis), or a headache from increased intracranial pressure.

HELPFUL TIP:

Avoid using meperidine (Demerol). It has toxic metabolites that may cause agitation and seizures. Meperidine can also interact with a number of drugs to cause serotonin syndrome.

You decide to increase her morphine dose.

Question 27.2.3 Which of the following statements is TRUE?

- A) Intravenous morphine is 10 times more potent than oral morphine
- B) Naloxone should be given if a hospice patient near death demonstrates confusion, decreased responsiveness, a slowed respiratory rate or cool extremities
- C) Patients exhibiting a local rash or intense pruritus at the site of intravenous morphine administration must be considered allergic and given an alternate opioid
- D) Tolerance to morphine does not occur in patients with cancer, so any increased analgesic need is due solely to uncontrolled pain
- E) Renal and hepatic insufficiency both contribute to the accumulation of morphine and its metabolites

Answer 27.2.3 The correct answer is “E.” “A” is incorrect. Intravenous (IV) morphine is about three times as potent as oral morphine. “B” is incorrect. Patients who are within several days or hours of death often exhibit pallor, peripheral vasoconstriction, apneic episodes, and obtundation as part of the physiologic process of dying. Counseling the family and patient is preferable to administering naloxone, which can cause abrupt opioid withdrawal and significant distress and discomfort to the patient (again, don’t make her ghost haunt you). “C” is also incorrect. Local histamine release is a known effect of IV morphine administration. Histamine-mediated skin changes proximal to the IV infusion site of morphine do not represent a contraindication to future morphine use. In fact, antihistamines (e.g., diphenhydramine) can be used to counter morphine-related histamine effects, such as rash, itching, and hypotension. But again, if you choose to use an antihistamine with anticholinergic activity you need to monitor for delirium, constipation, etc. “D” is incorrect. All patients can develop tolerance to the effects of morphine. Of course, in patients with terminal cancer, increasing opioid requirements are often entirely due to increasing pain. And even if your dying patient develops morphine tolerance, you still need to treat the pain. Finally, “E” is correct. Patients with renal and hepatic insufficiency can accumulate metabolites of morphine, some of which are helpful in pain control and others of which may have an anti-analgesic effect.

These patients often need **lower** doses of opioids. If a patient is actively dying and has evidence of renal failure, opioid doses can often be decreased significantly without a worsening of pain control. Fentanyl and methadone are considered the safest opioids in renal failure although methadone use is complicated by its long half-life.

HELPFUL TIP:

Start patients on a regimen to prevent constipation when initiating opioids. Think about the bowel regimen each time you increase the opioid dose. It will save you and your patient a lot of grief in the long run.

HELPFUL TIP:

For patients whose pain cannot be controlled with typical treatments, consider ketamine or lidocaine infusions, both which have been shown to be beneficial in refractory pain.

Question 27.2.4 Which of the following statements is **NOT** accurate regarding the appropriate use of opioids in end-of-life situations?

- A) At times, delirium can be improved with opioid dosage reduction and/or the addition of opioid-sparing analgesics (e.g., acetaminophen)
- B) If oral morphine cannot be swallowed, then either an enteral feeding tube or a parenteral route (IM/IV/subcutaneous) must be used
- C) Dosage conversion from one opioid to another is affected by the type of opioid used and the route of administration
- D) Transdermal opioid delivery products are expensive, have a slow onset of action, and have erratic absorption
- E) There is no pre-established ceiling dosage for opioids, and you may increase the opioid dose until adverse side effects occur

Answer 27.2.4 The correct answer (and the false statement) is “B.” Concentrated oral morphine solutions (20 mg/mL) can be given in small amounts to patients who are unable to swallow. While it was previously thought that morphine elixir worked by absorption through the buccal mucosa, it is now believed to trickle down the throat to be absorbed through the gastric mucosa. Fentanyl is the only opioid absorbed via the buccal mucosa (thus, the fentanyl lollipops and lozenges). A secret that drug companies do not want you to know is that you can avoid the expense of fentanyl lollipops by using fentanyl IV solution orally for control of breakthrough pain. “A” is true. Delirium is a common and disturbing finding toward the end of life, and it is sometimes precipitated or exaggerated by opioids. On the flip side, untreated pain can cause delirium, and the delirium may improve when opioid doses are escalated. In these situations, it can be helpful to rotate opioids because the lack of cross-tolerance means that the dose can often be decreased while maintaining the same level of pain control. Acetaminophen is

the safest opioid-sparing analgesic, and its adjuvant action may allow for opioid dosage reduction without a loss of overall analgesia. In the appropriate patient, NSAIDs may also be used.

“C” is true. When a patient chronically taking one opioid switches to another, a dose adjustment calculation must be made. You cannot switch milligram for milligram. Also, some authorities recommend that after the calculation, you slightly reduce the dose of the new opioid due to incomplete cross-tolerance (refer to opioid dose conversion charts available in numerous pharmaceutical texts and handbooks). “D” is true. The transdermal fentanyl patches, though convenient, have fluctuating bioavailability over the three days that each patch is worn, and breakthrough doses of an alternative opioid should be available. Fentanyl is also fat-soluble and absorption/bioavailability is decreased in thin and/or cachectic patients. The fentanyl patches are expensive and initially have a slow onset until a steady state is achieved. For this reason, a fentanyl patch should never be used alone as an initial treatment of acute pain. In fact, if you want to avoid a lawsuit, a fentanyl patch should never be used as the first method to treat pain in an “opioid-naïve” patient. “E” is true. Because of the extraordinarily wide dosage range of opioids, the ceiling dosage cannot be calculated or assumed. Rather, analgesic requirements allow for continual increase unless adverse side effects clearly undermine the use of the drug.

HELPFUL TIP:

There is no consistent relationship between blood levels of morphine and analgesic effects. This is because of tolerance, metabolism difference, individual variability in drug effect, etc. Thus, there is no single “right” dose. You should titrate morphine to the desired effect while watching for side effects.

You increase the morphine dose considerably over a 2-week period and your patient begins having escalating pain and muscle twitching.

Question 27.2.5 Which statement is true about opioid-induced hyperalgesia (OIH)?

- A) Patients with OIH always become delirious
- B) When a patient has OIH, the pain improves when the opioid dose is increased
- C) The pain in OIH is described as a worsening of the original pain being treated
- D) OIH needs to be differentiated from worsening underlying disease

Answer 27.2.5 The correct answer is “D.” Before we presume that a patient has OIH, we need to ensure that the increase in pain is not due to further disease progression. We also need to consider increased pain resulting from increased activity or other exacerbation (such as trips to x-ray or radiation therapy). Additional features that can help distinguish OIH from increased pain include: the development of muscle twitching,

presence of allodynia (pain elicited from ordinarily nonpainful stimuli, such as stroking skin with cotton—although this can occur with neuropathic pain syndromes as well), and development of seizures or delirium. However, not all patients with OIH become delirious, making “A” incorrect. The key feature of OIH is that the pain increases as the dose of the opioid is increased and will decrease when the dose is decreased. Hence “B” is incorrect as we would expect the pain to worsen as the opioid dose is increased. We are not certain why OIH occurs, but several mechanisms have been proposed. Switching to a medication with NMDA antagonism could prove helpful (such as methadone or ketamine). However, OIH can still occur in patients new to opioids and on low doses. “C” is incorrect as well. OIH typically produces diffuse pain, less defined in quality and extending beyond the preexisting pain distribution.

You are concerned about OIH and you decide to rotate to methadone.

Question 27.2.6 Which of the following statements is FALSE regarding the use of methadone?

- A) Methadone can be legally prescribed for pain and addiction by a physician with a current schedule II DEA license
- B) Methadone is more easily absorbed by those with bowel problems than is sustained-release morphine
- C) The half-life of methadone is 22 hours
- D) Methadone may be used as a long-acting, chronic opioid for pain control, similar to extended-release morphine products.
- E) Methadone is primarily excreted in the stool and thus drug dosages do not need to be modified in those with mild-to-moderate renal disease

Answer 27.2.6 The correct answer (and false statement) is “A.” Methadone **can** be prescribed for pain control by physicians with a schedule II DEA license but **cannot** be prescribed for addiction or opioid withdrawal without a special license. “B,” “C,” and “D” are true. Methadone has a long half-life, and sustained-release preparations are not needed. Sustained-release morphine may pass unabsorbed in patients with short gut or dysfunctional gut, whereas methadone would be absorbed. “E” is also true. Methadone is primarily excreted into the GI tract. Patients with liver disease should have doses adjusted. However, those with renal disease may tolerate “normal” doses since renal excretion is a minor part of methadone elimination.

HELPFUL TIP:

When it comes to switching or dosing opioids, there are several useful tips: (1) don't forget to account for incomplete cross-tolerance when switching classes of opioids—reduce the dose of the new opioid by 30% to 50%; (2) when opioids are not helping, increase the dose by 50%; essentially, treat opioids like you would treat a loop diuretic—if 60 mg of IV furosemide does not work, you wouldn't try 61 mg (or at least we hope

not!), but rather go to 90 or 120 mg; (3) for an opioid-naïve patient who is starting a patient-controlled analgesia (PCA) pump, begin with as-needed (PRN only) dosing frequently, such as every 10 minutes, without a continuous (“basal”) infusion.

HELPFUL TIP:

Methadone is the only **long-acting** opioid that comes in a liquid form and can be given buccally or in an enteral tube. Methadone can be dosed every 8 to 12 hours with many patients requiring every 8 hour dosing for pain. Although often touted as a good choice for neuropathic pain, data suggests that methadone is no better for neuropathic pain than are other opioids. Remember that methadone prolongs the QT in high doses and can cause torsades de pointes.

Your nurse calls you about your patient and reports that her pain level has been rising, and despite significant increases in both basal and breakthrough opioid therapy, the patient's pain is uncontrolled. The nurse asks you if there is something else that can be added to the opioids as an adjunctive treatment for pain. For no explicable reason, you cannot get gabapentin out of your head—even though you know it's probably useless for this patient.

Question 27.2.7 Which of the following is TRUE regarding the use of the gabapentin?

- A) Gabapentin is hepatically cleared and dose adjustment is needed in patients with liver disease
- B) The primary utility of gabapentin is in neuropathic pain
- C) Gabapentin primarily works via the μ -opioid receptors
- D) The most common side effects of gabapentin are supraventricular arrhythmias (thus limiting its utility in heart failure patients)
- E) If a patient does not respond to gabapentin, she will also not respond to pregabalin

Answer 27.2.7 The correct answer is “B.” Gabapentin has proven to be a marginally effective (NNT = 7) therapy for a number of diseases that manifest with neuropathic pain, including postherpetic neuralgia, diabetic neuropathy, and cancer-related neuropathic pain. “A” is incorrect because gabapentin is excreted unchanged through the kidneys—a plus for patients with working kidneys on multiple drugs. Why do we like drugs that are not hepatically cleared? They do not interact in any of the cytochrome P450 pathways and therefore have few drug–drug interactions. “C” is incorrect. The mechanism of gabapentin is complex and not fully understood, but we are fairly certain that it does not work through the μ -opioid receptors. “D” is incorrect. The most common side effect of gabapentin is its effect on cognition, causing dizziness and somnolence. Gabapentin can also cause edema, which can be problematic for patients with heart failure. “E” is incorrect. Although gabapentin and

pregabalin are thought to have the same mechanism of action, it appears that some patients will respond to one but not the other. Another important distinction between gabapentin and pregabalin is the time needed to titrate to an effective dose. With gabapentin we typically start at 100 to 300 mg and escalate the dose over the course of weeks up to 3,600 mg divided three times a day; alternatively, pregabalin starts at 75 mg daily and reaches a max dose of 300 mg BID within a week of initiation.

HELPFUL TIP:

An opioid-naïve patient should never be started on a fentanyl patch. A patient needs to be taking an oral morphine equivalent of at least 25 mg in 24 hours before the lowest dose (12.5 mcg) fentanyl patch can be applied.

As time goes on, the patient has other concerns, including constipation, weight loss of 20 pounds over 2 months, sleeplessness, nausea, and anxiety. In addition, she expresses how her loss of functional abilities is a hardship for her and her adult daughter who serves as her primary caregiver. Her guilt for losing her health is a continual source of frustration and anger.

Question 27.2.8 What is true regarding her social and emotional pain?

- A) It will not affect the patient's analgesic requirements
- B) It will likely complicate treatment adherence
- C) Active treatment of emotional sources of pain should only occur after the physical source has been addressed and treated
- D) Prophylactic antidepressants in patients within 6 months of death decrease the probability of developing depression

Answer 27.2.8 The correct answer is "B." Adherence, always an issue, is especially compromised in those dying patients whose social, spiritual, and emotional problems are not effectively addressed. Similarly, analgesic control of somatic pain is complicated when social, emotional, and spiritual sources of pain exacerbate the patient's response to and perception of somatic pain. Concurrent treatment of all sources of pain is necessary. Antidepressant therapy in dying patients who do not have clinical depression offers no prophylaxis against the development of depression.

You estimate your patient's life expectancy to be 2 months or less. Her frailty has progressed to the point where she is bed-bound and utterly dependent for all of her ADLs. You have made some adjustments, and she is now on stable doses of the following medications:

- Hydromorphone (Dilaudid) 20 mg PO Q 4 hours
- Acetaminophen 1,000 mg PO TID
- Sorbitol 30 mL PO TID
- Metoclopramide 20 mg PO TID

You want to optimize her medications.

Question 27.2.9 Which of the following is the most appropriate medication adjustment to make at this time?

- A) Hydromorphone → scheduled **controlled**-release morphine
- B) Hydromorphone → scheduled **immediate**-release morphine
- C) Hydromorphone → scheduled **controlled**-release morphine and **immediate**-release morphine as needed
- D) Acetaminophen → **immediate**-release morphine
- E) Acetaminophen → nortriptyline

Answer 27.2.9 The correct answer is "C." A patient who has reached a stable dose of short-acting opioid, such as hydromorphone, should subsequently be switched to a long-acting opioid agent. An immediate-release medication should be available for acute "breakthrough" pain. There is no reason to change the acetaminophen. Nortriptyline is sometimes useful as an adjuvant medication and is particularly helpful when treating neuropathic pain.

The hospice nurse calls you. Your patient is at home and has become restless with slow respirations (6/min) along with paroxysmal coughing and gagging with a large amount of secretions.

Question 27.2.10 The following are all appropriate orders for this patient EXCEPT:

- A) Obtain subcutaneous access through placement of a subcutaneous button or butterfly needle
- B) Lorazepam 1 to 2 mg PO or SL every hour PRN
- C) Glycopyrrolate 2 mg PO or SL every 4 hours PRN
- D) Midazolam 0.4 to 4 mg SC every hour PRN
- E) Naloxone 2 mg SC every 2 hours PRN

Answer 27.2.10 The correct answer is "E." Naloxone is a potent opioid receptor antagonist. Although the sudden change in the patient's status could be partly due to opioid accumulation, the risks of naloxone antagonism are great and include severe pain, cardiac arrhythmias, and seizures (and again, you don't want that ghost haunting you). Withholding or reducing the next dose of opioids is a safer approach. A subcutaneous infusion pump ("A") may allow effective administration of medications and fluids in patients who cannot tolerate oral administration. The use of hydration at the end of life is controversial. Withholding fluids and nutrition has strong merit, but the evidence is not compelling enough to declare that fluid infusion is futile and possibly harmful in this setting. In addition, dehydration is a common cause of delirium at the end of life, and her confusion may improve with gentle hydration. It is more important to review the patient's goals and only administer fluids if consistent with her goals. Glycopyrrolate ("C") has been shown to decrease oral/pulmonary secretions that lead to the "death rattle" in the final days and hours of life. Such treatment benefits the patient and her grieving family and friends. "B" and "D" may also be useful. Benzodiazepines have the potential to reduce anxiety, agitation, and insomnia; however, any benzodiazepine can worsen confusion and cause delirium. Benzodiazepines with an extended half-life (e.g., diazepam and

chlordiazepoxide) should generally be avoided because of the potential for toxic accumulation.

► **Objectives: Did you learn to ...**

- Define major physiologic pain categories?
- Describe the pharmacology of pain control?
- Prescribe opioid pain medications and adjuvant therapies for pain?
- Identify emotional, social, and spiritual symptoms and recognize how they can affect pain management?

QUICK QUIZ: THE SUBCUTANEOUS ROUTE

Regarding the subcutaneous administration of fluids and medications, which of the following is true?

- A) Not more than 500 cc of saline per day can be given by hypodermoclysis (subcutaneous administration)
- B) Only medication with low lipid solubility can be delivered via subcutaneous administration
- C) Most drugs used in end-of-life care can be given subcutaneously
- D) In general, subcutaneous administration dosage conversion is closer to oral dosage than to IV dosage

The correct answer is “C.” The subcutaneous route can be quite effective. Adverse events such as local irritation, pulmonary edema, and local edema are less frequent with subcutaneous administration when compared with IV administration. In general, most drugs used in end-of-life care can be given subcutaneously. “A” is incorrect. Evidence demonstrates that up to 3,000 cc of crystalloid solution can be given subcutaneously in a 24-hour period with limited adverse effects. Experience suggests that even greater volumes can be given. “B” is incorrect. Lipid solubility is not a clinically relevant aspect of bioavailability during subcutaneous administration. “D” is also not true. Subcutaneous doses are generally very close to, but lower than, the IV dose of a drug. As with IV administration, the onset of action is more rapid than with enteral dosing.

► **CASE 27.3**

You assume care for the 84-year-old father of one of your patients. He has severe dementia, which has caused him to require nursing home care for the last 5 years. He has stable heart failure due to ischemic cardiomyopathy. He requires full assistance to eat, with the staff members spending an hour at each meal. He has lost 20 lbs in the last 6 months (BMI now is 21 kg/m²). A facility nurse calls you worried about his weight.

Question 27.3.1 What would be the best intervention for weight gain in this patient?

- A) Megestrol
- B) Nutritional supplements

- C) Dronabinol
- D) Mirtazapine
- E) Feeding tube

Answer 27.3.1 The correct answer is “B.” The most effective means to maintain weight in elderly patients with dementia is hand feeding and providing favorite foods (yes, ice cream with every meal is OK!) and frequent offerings. Hand feeding is expensive and often problematic in nursing homes with limited staff. Nutritional supplements have been shown to be modestly effective in promoting weight gain in elderly patients with dementia. Other important considerations related to nutrition in dementia patients is being aware of effective ways to decrease aspiration risk, including sitting upright, eating small portions, use of thickened liquids, and hand feeding. “A,” megestrol (Megace), is minimally effective in improving appetite and increasing weight in patients with cancer cachexia and weight loss related to HIV/AIDS, but there is sparse evidence for use in geriatric patients. Trials are of short duration (1–2 months) using widely varying amounts of megestrol (240–1,600 mg/day), and the weight gained is typically fluid and not muscle mass. With such poor evidence for benefit but well-known side effects, there is no role for megestrol in this setting. In fact, there is no role for hormones or steroids in the treatment of weight loss in the elderly patient with dementia. “B,” dronabinol, is a synthetic derivative of cannabis (known to cause “the munchies”... we’ve heard). It increases appetite and improves nausea, but again the studies are small and exploratory in nature and focused mainly on patients with HIV/AIDS and cancer. Additionally, dronabinol has CNS side effects in the elderly. “D” is incorrect. If the patient were depressed and losing weight as a result, mirtazapine might be a reasonable choice since it may stimulate appetite. However, mirtazapine has not been shown to boost appetite in nondepressed subjects (and like the SSRIs, does not improve depression in the demented elderly anyway). Some antidepressants, such as SSRIs and bupropion, are associated with **weight loss**. Finally, a feeding tube (“E”) is invasive with numerous side effects (cellulitis, leakage, and increased fecal incontinence which can contribute to bed sores). While enteric tube feeds may improve caloric intake, they do not extend life, increase weight, improve functional status, or reduce the incidence of pressure sores or aspiration in dementia patients (exceptions to this are ALS and gastrointestinal cancers with proximal obstruction with a good functional status). Tube feeding is associated with agitation, greater use of physical and chemical restraints, and also greater healthcare use due to tube-related complications.

HELPFUL TIP:

Remind and reinforce to families that dementia is a terminal illness and that our current understanding is that tube feeding is unlikely to alter the course of the illness.

Your nutrition shakes are not doing the trick. The patient continues to lose weight. To further stage his dementia, you attempt a Folstein Mini Mental Status Exam, but he cannot

participate. The nurse reports that he needs assistance with all ADLs, he is incontinent, and he is unable to speak more than six intelligible words (and although you remember a couple of post-call days when you were in the same condition, you say nothing). The nursing staff asks you if the patient is appropriate for hospice care.

Question 27.3.2 Which of the following is TRUE?

- A) The life trajectory of terminally demented patients is unclear. Wait until his cardiac disease worsens
- B) He does not yet meet Medicare hospice benefit criteria for dementia
- C) A history from the nursing staff or family regarding the rate of his functional loss is the best predictor of death
- D) The nursing home staff can provide all of the end-of-life services provided by hospice, so hospice is not needed
- E) Presence of a stage 2 pressure ulcer and aspiration risk is sufficient for referral to hospice

Answer 27.3.2 The correct answer is “C.” Predicting death in patients with dementing illness is difficult which is why it is one of most underutilized diagnoses for referral to hospice care. In fact, dementia has the greatest variability among hospice diagnoses when it comes to predicting survival. However, waiting until a more predictable organ system failure occurs is not a reason for delaying a hospice referral, which makes “A” incorrect. “B” is incorrect because he *does* meet criteria for hospice enrollment. The National Hospice and Palliative Care Organization (NHPCO) hospice guidelines for eligibility in dementia include three components: (1) demonstrating severity of dementia (e.g., an inability to walk or dress or bathe without assistance, urinary/fecal incontinence, or inability to speak six different intelligible words per day); (2) evidence of a severe comorbid condition within the past 6 months (e.g., aspiration pneumonia, pyelonephritis, sepsis, stage ≥ 3 decubitus ulcer, or fever despite antibiotics); (3) inability to maintain fluid/caloric intake (by demonstrating weight loss $>10\%$ in 6 months or albumin <2.5 g/dL). “E” is incorrect. Aspiration risk and stage 2 pressure ulcers alone are not sufficient for referral to hospice. If the patient had stage 3 or 4 pressure ulcers, he would likely meet NHPCO hospice criteria for severe dementia. It is the extrapolation of the patient’s loss of basic functions over time that best predicts death, as in “C.” “D” is incorrect because while most nursing homes routinely care for dying patients without the assistance of hospice, they are typically not able to offer the full range of services or the end-of-life expertise that hospice offers.

.....

Your patient develops nausea and vomiting and on examination you feel a large abdominal mass. He is still having bowel movements, which are positive for occult blood. You inform the family that you suspect he has colon cancer, and they elect for no further evaluation but want his symptoms aggressively managed.

Question 27.3.3 Which of the following drugs is the best initial choice for treatment of this patient’s nausea and vomiting?

- A) Octreotide
- B) Metoclopramide
- C) Diphenhydramine
- D) Ondansetron (Zofran)
- E) Aprepitant (Emend)

Answer 27.3.3 The correct answer is “D.” “B” is not correct. Using a pro-peristaltic agent in a patient who may have an obstruction is not a good idea in general. Also, metoclopramide has central antidopaminergic properties and can cause confusion and extrapyramidal side effects. By understanding the pathophysiology of nausea and targeting antiemetics to specific receptors, therapy can be optimized and side effects minimized. An easy way to remember the causes of vomiting is to use the “VOMIT” mnemonic. In Table 27-1, pathophysiologic mechanisms causing nausea are described using the letters of the mnemonic. Blockade of these receptors allows rational, focused therapy.

Using Table 27-1, another reasonable alternative would be promethazine, although promethazine is not a great antiemetic. “A” is incorrect. Octreotide works by slowing the GI track, and its main use is found in patients with nausea and vomiting due to malignancy-related intestinal obstruction. However, it does not rapidly treat nausea and is not easily administered (usually continuous IV infusion, but it can be given subcutaneously or intramuscularly). “C” is incorrect because diphenhydramine alone is a weak antiemetic, mostly used for motion sickness, and it can cause confusion, particularly in the elderly. Aprepitant (Emend) is a neurokinin receptor antagonist that is most effective when used **with** serotonin receptor antagonists such as ondansetron; its primary use is in the management of chemotherapy-induced nausea, and it is very expensive.

HELPFUL TIP:

When treating chemotherapy-induced nausea, add something to their current regimen. Do not just drop one medication and add another. This is counterintuitive but is considered the approach of choice.

.....

The patient’s nausea is ultimately controlled with scheduled low-dose promethazine and ondansetron (Hey, look! Two drugs instead of a large dose of one!). He is continuing to lose weight and has been coughing after eating. He spikes a fever and you suspect he has developed aspiration pneumonia.

Question 27.3.4 Which is true regarding the use of antibiotics for pneumonia in patients with end-stage dementia?

- A) Antibiotic use is considered the standard of care and should be initiated without discussing with the family
- B) Antibiotics might prolong patients’ lives but treatment comes with significant risks that need to be weighed

TABLE 27-1 CAUSES AND TREATMENT OF NAUSEA AND EMESIS

Type of Nausea	Receptors Causing Nausea	Useful Drug Classes	Examples of Drugs of Choice
V estibular	Cholinergic Histaminic	Anticholinergic Antihistaminic	Scopolamine Promethazine
O bststruction (caused by constipation)	Cholinergic Histaminic 5-HT ₃	Stimulate myenteric plexus	Senna products Prunes
M ysMotility	Cholinergic Histaminic 5-HT ₃	Prokinetics to stimulate 5-HT ₄ receptors	Metoclopramide
I nfection, Inflammation	Cholinergic Histaminic 5-HT ₃	Anticholinergic Antihistaminic	Promethazine
T Toxins (stimulating the CTZ in the brain, i.e., opioids)	Dopamine 2 5-HT ₃	Antidopaminergic 5-HT ₃ antagonist	Prochlorperazine Haloperidol Ondansetron

5-HT₃, 5-hydroxytryptamine (serotonin); CTZ, chemoreceptor trigger zone.

- C) Antibiotics given in a controlled setting such as a nursing home, where compliance can be ensured, lead to less antibiotic resistance
- D) Parenteral antibiotics are more successful at treating aspiration pneumonia in patients with dementia, compared with oral antibiotics

Answer 27.3.4 The correct answer is “B.” While antibiotics may prolong life in patients with dementia, they do so with the cost of increasing discomfort, making “B” the correct answer. The previous prevailing belief of carte blanche use of antibiotics is being challenged. Currently, antibiotic use is very common in nursing homes, and a majority of nursing home residents will receive antibiotics in the 2 weeks before their death. Most of those antibiotics will be given intravenously, which increases patient discomfort. But more importantly, patients are often admitted to a hospital, placing demented patients at risk for delirium, restraints, and exposure to hospital-acquired organisms. The reason we emphasize “might prolong” patients’ lives is that the literature shows that in the extremes of advanced dementia plus another advanced illness (such as bacteremia), antibiotics may not provide improved survival. In fact, in patients with advanced dementia, infections often characterize the final stage of their illness. “A” is incorrect because antibiotic use in patients with dementia (specifically in patients with dementia who are hospice appropriate) should always be discussed with the surrogate decision maker, and antibiotic use should be based on an informed choice and the patient’s wishes/goals. “C” is incorrect because nursing homes have been shown to harbor drug-resistant bacteria, likely due in part to the frequent use of antibiotics in these patients. Oral antibiotics have been shown to be as effective as other more invasive administration routes in patients with dementia, making “D” incorrect.

The patient is enrolled in hospice and 3 weeks later you are called by a nurse reporting an acute condition change. You go to see the patient and he is unresponsive, breathing is labored, and his feet are mottled.

Question 27.3.5 All of the following can be signs of impending death EXCEPT:

- A) Cheyne–Stokes breathing
- B) Fever
- C) Cyanosis and mottling
- D) Aldosterone escape phenomenon with increased urinary output
- E) Talking to someone who is already dead (and not via medium at Coney Island)

Answer 27.3.5 The correct answer is “D.” Most dying patients have a decrease in urinary output prior to death. The other options describe changes that are commonly seen in patients who are actively dying. Respiratory changes in the active dying phase include Cheyne–Stokes breathing, terminal secretions (the “death rattle”), and periods of apnea. Dying is often accompanied by decreased circulation, which can result in cool extremities and mottling (the skin turning blue and patchy particularly in the fingers and toes). It is not uncommon for a dying patient to have a fever in the last 24 to 48 hours of life, typically thought to be secondary to aspiration pneumonia or another serious infection. It is not uncommon for someone who is dying to talk about going on a journey or talk about seeing someone who is dead. This is typically believed to be part of the normal dying process and in the absence of other symptoms should not be confused with delirium or psychosis.

**HELPFUL TIP:**

Delirium is very common (up to 85%) in the last few days of life. If the symptoms are distressing to the patient or family, it is best treated with an antipsychotic such as haloperidol.

You need to call the son to tell him of his father's decline.

Question 27.3.6 Which of the following should you say when giving the son an update?

- A) "There have been some changes in your father's condition. I think you should go to see him. Call me if you have any questions after you have seen your dad"
- B) "Good news, your dad will soon be out of his misery and released from this mortal world"
- C) "I'm afraid I have some bad news for you regarding your dad. Would you like to talk over the phone or meet at my office later today to discuss it?"
- D) "Your dad is dying. If you want to see him alive again you had better go today"
- E) Don't call at all. Ask the nurse to inform the son of his father's condition while you duck out quietly

Answer 27.3.6 The correct answer is "C." It gives a "warning shot" and allows the person receiving the bad news some control by allowing him to determine how and where he wants to receive the bad news. "A" avoids giving the bad news at all. "B" is inappropriately flippant and uses euphemisms. "D" is inappropriately blunt and sounds awful—and if it doesn't sound awful to you, it's probably time to take an online psychopathy test. "E" avoids having the discussion at all and is only appropriate if you will be unable to reach the son in a timely fashion. Besides, you will be forever after known to the nurses as "Dr. Wuss." A common format for giving bad news is to use the SPIKES six-step protocol in Table 27-2.

**HELPFUL TIP:**

When giving bad news, do not use phrases such as, "I'm afraid there is nothing more we can do for you." This leaves patients and family feeling abandoned. It is better to be more specific to say, "I am afraid that I don't have any treatments that will cure your cancer, but there is still a lot I can offer to help improve your quality of life." This assures the patient and the family that there is still something to be done and that you will not abandon them.

Breaking bad news is difficult in person and can be more difficult over the phone.

Question 27.3.7 Which suggestion below is NOT recommended when breaking bad news over the phone?

TABLE 27-2 A MNEMONIC FOR GIVING BAD NEWS

S Setting. An inappropriate setting can make it difficult to give bad news effectively. Make sure the physical setting is as conducive as possible by trying to ensure privacy, involving significant others, sitting down, connecting with the patient (eye contact, hand holding), ensuring enough time, and minimizing interruptions.

P Patient's perception. Ask what the patient's (or family's) knowledge and understanding of the current medical illness is.

I Invitation. Ask what information the patient wants to receive. Some patients do not want to hear bad news themselves, and in this case it can be helpful to ask if there is someone else with whom you should speak.

K Knowledge. Give the medical facts in a straightforward manner using vocabulary and language appropriate to the patient's level. Avoid medical jargon and do not be excessively blunt (i.e., avoid saying things such as "you have very bad cancer and unless you do something, you will die"). Give the information in small chunks and frequently assess what the patient has understood. When possible, start off with a warning shot (i.e., "Unfortunately, I have some bad news for you").

E Exploring/empathy/emotion. A patient's emotional reaction can vary and is often hard for a physician to experience. An empathetic response can be helpful. This can be fostered by allowing silence after breaking the bad news and watching and listening for the emotion. When you have identified the emotion, it can be helpful to name it and determine what caused it. Then make an empathetic statement such as "I'm sorry. I know this isn't what you wanted to hear."

S Strategy/summary. After the emotions have been addressed, it is helpful to review what has been said and agree on a plan. Consider asking the patient if he wants to discuss treatment options at this time or wait until a future meeting. Receiving bad news can be overwhelming, and patients often forget the details of what is said. It is important to have clear, well-defined, timely follow-up such as "Go home and talk with your family, I will see you (and your family) back tomorrow at 9 AM, and we can discuss specific treatment options and answer questions at that time."

Data from Baile WF, et al. SPIKES-A six-step protocol for delivering bad news: application to the patient with cancer. *Oncologist*. 2000;5:302–311.

- A) Take time to prepare what you are going to say and find a quiet place to make the call
- B) If no one answers the phone, it is acceptable to leave a message or voicemail detailing the bad news
- C) Identify yourself and avoid answering any direct questions until you are sure of the identity of the person to whom you are talking
- D) Ask if the person is alone
- E) Speak clearly and slowly, allow time for questions; be empathetic

Answer 27.3.7 The correct answer is "B." When breaking bad news over the phone, steps similar to breaking bad news in person should be used. You should obtain the full name, address, and phone number(s) of the person(s) you are calling. If you are not calling the patient, try to establish from the chart and nursing staff the relationship of the contact to the patient. In

addition, it can be helpful to write down the key information you need and review what you will say and find a quiet area with a phone. Don't delay in making the call. When you do call, clearly identify yourself and ensure you are able to speak with the person closest to the patient (ideally, the healthcare proxy or the contact person indicated in the chart). Avoid responding to any direct question until you have verified the identity of the person to whom you are speaking, in order to avoid violating the patient's right to privacy. Ask if the contact person is alone. Do not give death notification to minor children. If you do not have a prior relationship with the person you are speaking to, ask what they know about the patient's condition. Provide a warning shot. Never deliver the news of death to an answering machine or voicemail. Instead, leave specific contact information. Allow time for questions; be empathetic and ask if you can contact anyone for them. Assess their emotional reaction and arrange follow-up as indicated.

HELPFUL TIP:

When you need to inform a family that a patient has died, words like "dead" or "died" should be used; avoid euphemisms such as "expired," "passed away," or "didn't make it" (also, "kicked the bucket," "bit the bullet," "bought the farm," and so on), which can be misinterpreted.

► Objectives: Did you learn to ...

- Generate a management plan for a patient with weight loss due to a terminal disease?
- Describe criteria for hospice admission in patients with severe dementia?
- Identify and treat causes of nausea and vomiting at the end of life?
- Identify signs of the active dying process?
- Recognize the proper steps for breaking bad news?

Clinical Pearls

- Avoid meperidine. Other opioid analgesics are preferred.
- Do not delay palliative care assessment in a patient with a serious, life-limiting illness, even if that patient is planning to seek curative therapy. Patients with an early palliative approach live longer and have a higher quality of life.
- Do not leave an implanted cardiac defibrillator (ICD) active without assessing the patient and family's goals of care. In a patient with a terminal illness who is DNR, it is logically consistent to deactivate the ICD, and this option should be discussed with the patient/family.
- Do not start an opioid-naïve patient on a fentanyl patch.
- Opioid analgesics, morphine in particular, relieve respiratory distress in dying patients.
- Start a bowel regimen whenever starting opioid analgesics.
- The addition of a benzodiazepine to an opioid reduces anxiety and breathlessness, but respiratory rate and mental status must be carefully monitored.

- Titrate opioid analgesics to an effect rather than a particular dose or blood level.
- Use equianalgesic reference charts and account for incomplete cross-tolerance when switching from one opioid to another.

Evidence-Based Medicine

28

Mark A. Graber

Yeah, we don't like numbers either. But they are at the end of the chapter for those of you who want to learn 2×2 tables, etc. We do like evidence-based medicine (EBM) though, and it will be on the examination. So here goes...

Table 28-1 is here for reference. You may want to refer to it as you work your way through the chapter.

► CASE 28.1

Research published in *World's Best Medical Journal* studied screening for lung cancer using a new method. The researchers reported that patients who had lung cancer detected via screening lived longer after diagnosis than people who were diagnosed with lung cancer but not screened.

Question 28.1.1 Which is true?

- A) This shows that screening is effective at prolonging survival
- B) This may be an example of lead-time bias
- C) This may be an example of verification bias
- D) Well-respected medical journals (and board review books) are always right

Answer 28.1.1 The correct answer is "B." This may be an example of lead-time bias, which is not to be confused with length-time bias (see Table 28-2). Screening is intended to diagnose disease earlier, hopefully allowing for interventions that prevent or slow the progression of the disease. Without screening, the disease may be discovered only after symptoms develop when it may be too late to intervene. Screening, however, can also give the appearance of longer survival even though no additional life has been gained. This is called "lead-time bias." Here's another example. Mr. X has the test, is diagnosed with disease, receives treatment, and dies 5 years later. Mr. Y is in the control group, develops symptoms at year 4 of the study and dies 1 year after that. They have both lived for 5 years after being randomized to screening or no screening. Mr. X and Mr. Y both die at age 65 of the same disease. Did Mr. X have more survival time or just more "disease time"? This lead-time bias may be avoided by

TABLE 28-1 USEFUL EQUATIONS

Sensitivity: True Positives/(true positives + false negatives)

Specificity: True Negatives/(true negatives + false positives)

False Positive Rate: $1 - \text{specificity}$

False Negative Rate: $1 - \text{sensitivity}$

Positive Predictive Value: True Positive/(true positive + false positive)

Negative Predictive Value: True Negative/(true negative + false negative)

using age-specific mortality rates rather than survival time from diagnosis. "C," verification bias, occurs when you are looking at a new diagnostic modality, and patients with a negative test result (for the new test) are not evaluated with the gold standard test. For example, verification bias could occur in a study where people with a negative cardiac stress test do not proceed to a cardiac catheterization. This underestimates the prevalence of disease in the population studied (some of those with a negative exercise test will certainly have disease ... we just haven't checked for it). It also overestimates the value of the stress test (seemingly, all patients with cardiac disease were picked up by the stress test ... but only because we didn't look far enough). See Table 28-2 for more types of bias found in studies.

As part of a quality control study, the hemoglobin A_{1c} values of patients with diabetes at two clinics are compared. In a study of 4,000 patients, it is found that the mean hemoglobin A_{1c} value in group 1 is 7.4% and the mean hemoglobin A_{1c} value in group 2 is 7.6%. The authors did the correct statistical test and found a *p*-value of 0.04 for this comparison.

Question 28.1.2 Based on this information, you conclude:

- A) Group 1 is significantly different from group 2. Reject the null hypothesis

TABLE 28-2 SOME COMMON TYPES OF BIASES/ PROBLEMS SEEN IN STUDIES

Type of Bias	Effect
Confirmation Bias	This occurs when you only look for data that supports your contention and ignore any information to the contrary (i.e., if I believe that the Internet is full of sociopaths, I could confirm that by reading comments under videos posted on related websites and ignoring everything else that would suggest otherwise).
Confounders (Confounding variables)	This occurs when two or more factors are associated with the outcome and only the one being studied is accounted for (i.e., research shows that 9 out of 10 Cubs fans have annoying behavior, but 9 out of 10 Cubs fans are also drunk when the annoying behavior occurs; if we do not account for the confounding variable [drunkenness], we may incorrectly assume that being a Cubs fan <i>causes</i> annoying behavior ... which can't possibly be true ... can it?).
Length time bias (not lead time)	This occurs because screening tests are more likely to find slow-growing tumors rather than those that are rapidly growing. This can bias results in favor of screening because more slow-growing cancers with a good prognosis will be found with a screening test.
Selection bias	This occurs when subjects selected for the study do not represent the entire population you might see clinically. For example, they may be sicker or less sick than the patients in your practice or they may be excluded from the study for another reason. For example, let's say we are doing a study on renal failure. If all patients with diabetes are excluded, we will not be able to apply the results to our patients many of whom have renal failure and coexisting diabetes. This is avoided by having large, representative samples with few exclusion criteria.
Spectrum bias	This occurs if a study is skewed toward a particular group of patients, for example, those with an NSTEMI. If you study NSTEMI patients, you cannot apply your results to patients with other related conditions, such as a STEMI or unstable angina. Spectrum bias is common in studies; often the patients studied at a tertiary care institution differ in the severity of illness than those in primary care practices (who in general tend to have less severe disease).
Performance bias	This occurs when one group of subjects in an experiment gets more attention from researchers (e.g., control group gets more frequent visits, more education, etc.) or one group of subjects changes their behavior in response to the experiment (e.g., control group exercises more, eats better, etc.). An example of this is estrogen for heart disease. Case-control studies suggested estrogen was cardio-protective, but it didn't pan out in randomized, controlled trials. Thus, the positive effect was due to something else; maybe the women on estrogen exercised more, maybe they had better diets, maybe they smoked less and were more interested in their health overall. Randomized, blinded trials protect against this bias—especially, the blinding part.

- B) Group 1 is not significantly different from group 2. Don't reject the null hypothesis
- C) Group 1 is not significantly different from group 2. Reject the null hypothesis
- D) Group 1 is significantly different from group 2. Don't reject the null hypothesis

Answer 28.1.2 The correct answer is “A.” To answer this question, you have to know what the usual cutoff for significance is for a p -value, and you also have to know what a null hypothesis is. A null hypothesis is the hypothesis that there is no significant difference between two groups being compared or that the observed difference is likely to have occurred by chance alone rather than due to a variable. By setting up null hypotheses in this way, we can then search for proof that the null hypothesis is incorrect. Tests of significance are a method of looking for evidence that a null hypothesis is incorrect. The p -value gives you the probability that the results of the study occurred by chance alone. A p -value of 0.04 means that if the study results were untrue, we would expect to see these results only 4% of the time by chance alone and not related to the study intervention. By convention, a p -value of 0.05 or smaller is considered statistically significant. Thus, when you have a p -value ≤ 0.05 , you have evidence that the null hypothesis is false and can therefore be rejected.

**HELPFUL TIP:**

A type I error occurs when a difference is found when in reality the two groups are the same. The p -value provides you with the probability of a type I error. For example, a p -value of 0.05 is considered statistically significant. But what this means, however, is that 5% of the time, the same conclusion would be produced by chance alone. By contrast, a p -value of 0.005 means that there is only a 0.5% chance that the conclusion is mistaken and occurred by chance. The lower the p -value, the lower the chance of a type I error.

**HELPFUL TIP:**

A type II error occurs when a study fails to show a difference where one exists. This may occur because there are not enough subjects in a study or when there is measurement error. For example, in a (real) study of lorazepam versus diazepam for seizures, twice as many patients had their seizures stop with lorazepam. However, the conclusion of the study was that there was no difference between the two drugs. This is only because there were not enough subjects for this to reach statistical significance. Including another 100 subjects may have made this reach statistical significance. Remember this by “Type II error is too few subjects.”

► **Objectives: Did you learn to ...**

- Recognize forms of bias in research studies?
- Define p -value and null hypothesis?

- Describe the significance of p -value and type I error?
- Recognize a type II error?

► CASE 28.2

Being the compulsive physician that you are, you are spending your Saturday morning relaxing by reading your journals (we know who you are; you can't fool us... why else would you be working through the EBM chapter?). You notice a study of particular interest on type 2 diabetes, using a novel drug called Shugabegone (not a real drug), and note that the data were analyzed in two ways. The first method used was an "intention to treat" analysis. The second method was by a "per-protocol" analysis. Hmm, you think. The per-protocol data sure makes you want to start prescribing Shugabegone for your patients with diabetes.

Question 28.2.1 Which of the following applies to a per-protocol analysis?

- It provides an objective description of how a new therapy will work in our patient population
- It is more statistically stringent when compared to an intention-to-treat analysis
- It allows the study authors to manipulate the outcome to make it look better than it is
- You are wrong, Dr. Graber. I am not reading this chapter

Answer 28.2.1 The correct answer is "C." Per-protocol analysis allows the authors to make the outcome look better than it is. To understand why, we must know the difference between an "intention to treat" analysis and a "per-protocol analysis." A per-protocol analysis allows the authors to manipulate the results, usually in favor of the study drug. Here is an example: "Of all of the patients who were enrolled in this study, those who took the drug at least 75% of the time were included in the final analysis." There is a problem here. Many of our patients will not take all of their medicine. Maybe they forgot to take it. Maybe it had side effects that were intolerable. If we only analyze the patients who took all of their medication, the drug will look better in the per-protocol analysis than it will in our clinical practice where adherence to a regimen is less than complete. You will see this in many papers. In some papers, there is a "wash-in period" where everyone is given the medication and only those who tolerate it for 2 weeks (for example) continue to the main trial. The results here will not be representative of our patients, many of whom may not tolerate the medication. In summary, per-protocol analysis = bad.

An intention to treat analysis analyzes *all* study patients in the group to which they were originally assigned. In this case (to continue the hypothetical study above), the authors do not care if the patients took the drug 75% of the time. Even if they *never* took the drug but were assigned to the treatment group, they are analyzed in the treatment group. Many of these patients likely would be treatment failures making the overall results look worse. However, the results will be more applicable to our patient population, many of whom will not

take their medications properly. In summary, intention to treat analysis = good.

"OK," you think. "I'll pay attention to the intention to treat analysis." So, you next look at the inclusion and exclusion criteria. In this diabetes drug study, the exclusion criteria include renal disease, a history of heart failure, coronary artery disease, and peripheral vascular disease.

Question 28.2.2 From this we can conclude:

- The patients in this study are so finely selected that the results *cannot* be applied to our general clinic population
- The results should be generalizable to our general clinic population given the fact that the medication worked so well in this study
- This is an example of "selection bias"
- A and C
- B and C

Answer 28.2.2 The correct answer is "D." We cannot apply these results to our general clinic patients. Think about it: how many of your diabetic patients have no renal disease, no history of CHF, and no history of CAD/PVD? Not too many. Many of our patients with diabetes have at least some renal disease (proteinuria). You always need to look at the inclusion and exclusion criteria of a trial before you can determine if the trial is applicable to your patients. This is called "selection bias"; only select patients are entered into the study.

There is also a phenomenon called "spectrum bias." In the case of spectrum bias, the patients in the study are different than our patients; they may be sicker or not as sick. Case in point: glycoprotein IIB/IIIA inhibitors for acute coronary syndrome (ACS). The initial studies looked at patients going for cardiac catheterization; and it appeared there was a small benefit here. But the drug companies then generalized from these sick patients to say that all patients with ACS should have glycoprotein IIB/IIIA inhibitors. You can't do this. Most of our "ACS" admissions turn out not to have ACS, and they will get better regardless of what we do. They certainly don't need glycoprotein IIB/IIIA inhibitors. And, thankfully, these drugs have fallen out of favor.

HELPFUL TIP:

Subgroup analyses (you know, the "our drug worked in left-handed women over 60" pitch) can only be used to generate a hypothesis. This is called the "derivation set." Before accepting it into practice, a second study of that subgroup, called the "validation set" must be done. This is always true. Don't let them tell you otherwise.

► **Objectives: Did you learn to ...**

- Describe an intention to treat analysis and its value for applying study results?
- Recognize the effect of inclusion and exclusion criteria on the application of study results?

QUICK QUIZ: FEELING SENSITIVE ABOUT SOMETHING SPECIFIC?

Which of the following statements is true?

- A) Specificity is the most important test characteristic when trying to find a very dangerous disease
- B) As sensitivity increases, specificity decreases
- C) Specificity need not be considered as long as a test is sensitive enough
- D) As sensitivity increases, specificity increases

The correct answer is “B.” As sensitivity increases, specificity decreases. This makes intuitive sense. The more cases you detect, the more false positives you will have. We can have a sensitivity of 100% if, for example, we say that everyone with WBCs in their blood and a cough has pneumonia. We will pick up everyone with the disease (very sensitive), but also a lot of patients without the disease (poor specificity... everyone has at least one, lonely, white cell running around). Ideally, we would like to have a diagnostic test with both high sensitivity and high specificity. In reality, there is an inherent trade-off between sensitivity and specificity—as sensitivity increases, specificity decreases and vice versa. “A” is incorrect. Generally, *when it is very dangerous not to detect a disease, it is important to have a highly sensitive test (one that will find “all” cases)* with an acceptable specificity. “C” is incorrect. This is why both an ELISA and a Western blot may be done when trying to detect HIV. The ELISA is very sensitive (will pick up the great majority of HIV cases), but is not very specific (will categorize a lot of patients who do not have the disease as positive). The Western blot is more specific and will filter the true positives from the false positives found on the screening test (the ELISA).

QUICK QUIZ: ALL THAT GLITTERS ...

You are having a meaningful discussion with an industry representative (yeah, right). OK, let’s recalibrate. You are being sold a package of goods by an industry representative. She says that if their test for Dreaded Disease is positive, the likelihood ratio of the disease being present is 3.

Your response to this is:

- A) “Great! The disease is three times more likely to be present if the test is positive”
- B) “Not so great! A likelihood ratio of 3 is pretty much worthless in differentiating between those who are ill and those who are not”
- C) “What is this likelihood ratio stuff anyway?”
- D) “What happened to my free lunch?”

The correct answer is “B.” In a situation in which the pretest probability of a disease is between 30% and 70%, a likelihood ratio can meaningfully reduce the possibility of disease presence only if it is <0.1 . In a situation in which the pretest probability of

a disease is between 30% and 70%, a likelihood ratio can meaningfully increase the possibility of disease presence only if it is over 10. So, a likelihood ratio of 3 is more or less useless. Draw some lines on this and you will see what we mean (Fig. 28-1).

CASE 28.3

One common and debilitating complication of diabetes is neuropathy. In a (fictional) study by Tooth E. Fairie et al., one group had routine therapy and an experimental group had intensive therapy for their diabetic neuropathy. In the first group, those assigned to routine therapy, 10% of patients developed neuropathy. In the second group, those assigned to intensive therapy, 2% of patients developed neuropathy.

Question 28.3.1 Using the data above, how many patients with diabetes need to be treated with intensive therapy to prevent the development of one case of neuropathy?

- A) 10
- B) 11
- C) 8
- D) 12.5
- E) 25.5

FIGURE 28-1. Reproduced from the Centre for Evidence-Based Medicine. Available at: <http://www.cebm.net>.

Answer 28.3.1 The correct answer is “D.” The question is really asking, “What is the number needed to treat (NNT)?” The NNT is the number of patients who need to be treated to prevent one adverse outcome. In this question, the absolute risk reduction is 8% (10% in control group vs. 2% in the treated group). To calculate this, we need to know a few other terms:

$$\begin{aligned}\text{ARR} &= \text{Absolute Risk Reduction} \\ &= \text{control group event rate (CER)} \\ &\quad - \text{experimental group event rate (EER)}.\end{aligned}$$

$$\text{NNT} = 1 / \text{ARR (in percent)}$$

Using the values given above, $\text{ARR} = 10\% - 2\% = 8\%$ and $\text{NNT} = 1/0.08 = 12.5$.

The anti-clotting properties of aspirin are well described. In a (fictional) trial studying the long-term outcome of stroke patients by Haywood Jabuzzoff et al., 1% of patients on long-term aspirin therapy developed new onset of strokes and 50% of patients without aspirin therapy developed new strokes.

Question 28.3.2 Using the data above, how many stroke patients need to be treated with aspirin therapy to prevent one new stroke (what is the NNT)?

- A) 2
- B) 8
- C) 10
- D) 12
- E) 25

Answer 28.3.2 The correct answer is “A.” Again, the NNT is the number of patients who need to be treated to prevent one adverse outcome. $\text{NNT} = 1/\text{ARR}$, where $\text{ARR} = \text{CER} - \text{EER}$. Using the values given above, $50\% - 1\% = 49\% = \text{ARR}$ and $\text{NNT} = 1/0.49 = 2$ (well, really close to 2).

In a (fictional) pharmaceutical study by Anita Hand et al., Group A is the placebo group and Group B is the group that received the actual new drug. Data were gathered on Groups A and B and confidence intervals (CI) were calculated. Side effect rates were calculated as a percentage of each group.

Question 28.3.3 Using the 95% CI, which of the following group comparisons are statistically significantly different?

- A) Group A CI 30% to 46% and Group B CI 44% to 88%
- B) Group A CI 10% to 30% and Group B CI 44% to 88%
- C) Group A CI 0.1% to 0.3% and Group B CI 0.2% to 0.4%
- D) Group A CI 88% to 90% and Group B CI 88% to 90%
- E) None of the above is statistically significant

Answer 28.3.3 The correct answer is “B.” The CI is a range of possible high to low values of data. The true mean is likely to

be in the specified range. In general, the larger the study group, the narrower the CI. When you have a large study, you are more likely to get closer to the true value.

“B” is correct because when comparing the CI between two groups, there is no overlap. When there is an overlap of CI, as in the other options, the groups have no statistically significant difference. For example, in answer “A” the true mean value of Group A could lie anywhere between 30% and 46% (it could be 45%), and the true mean value of Group B could lie anywhere between 44% and 88% (it could also be 45%); therefore, the groups have no statistically significant difference.

HELPFUL TIP:

Confidence intervals are usually given as “CI 95%,” meaning that there is a 95% probability that the true mean value will be within the CI. When looking at CI for relative risk (RR), relative benefit, odds ratio, etc., remember that if the CI 95% crosses “1,” there is no difference between the groups. Thus, a RR of 4.2, CI 95% of 0.8 to 10 is consistent with a 0.8 times risk or a 10 times risk. However, since the CI 95% crosses “1,” there is no real difference between the groups.

HELPFUL TIP:

Confidence intervals are useful when determining the magnitude of a treatment effect. For example, if a RR has CI 95% of 1.2 to 1.4, this means there is a small difference (0.2–0.4 times) between the two groups, even though it is statistically significant. Remember, something that is statistically significant may not be clinically significant. On the other hand, if the RR has a CI 95% of 10 to 20, this is a major difference between the groups. This means that one group has a 10 to 20 times greater risk (or benefit depending on what is being studied) than does the other group.

In a (fictional) clinical trial testing a new provider order entry (POE) technology at Big Important University Hospital, relative and absolute risk reduction is discussed. A group of family medicine residents at the hospital was allowed to give verbal orders during their intern year and averaged seven medication errors per year. In the residents’ second year, POE was instituted (in which physicians were required to enter orders, and alerts to medication errors were given before finalization of orders), and the group’s medication errors dropped to an average of four per year.

Question 28.3.4 Which of the following is true?

- A) The RR reduction is 43% and the absolute risk reduction is three in medication errors
- B) The RR reduction is 57% and the absolute risk reduction is three in medication errors
- C) The RR reduction is 43% and the absolute risk reduction is four in medication errors

- D) The RR reduction is 57% and the absolute risk reduction is four in medication errors
 E) POE has ruined medicine. I quit! Boo-hoo!

Answer 28.3.4 The correct answer is “A.” POE compared with no POE (the control group) resulted in a 43% relative decrease in the risk of a medication error—from seven to four errors per year ($3/7 = 43\%$). The difference in the number of medication errors before and after POE is three errors ($7 - 4 = 3$), which is the absolute reduction in the risk of a medication error. Now, think about this from a pharmaceutical or medical device representative’s point of view. Would you say (a) “We reduced errors by 3 per year,” or would you say (b) “We reduced errors by 43% per year!”? That’s how you sell a study.

► **Objectives: Did you learn to ...**

- Calculate number needed to treat?
- Differentiate between absolute and relative risk reduction?
- Use confidence intervals to determine statistical significance?

► **CASE 28.4**

Mr. Handsome Q. Drugrep has come to tell you all about Happy Lucky Golden Drug (HLGD) that is newly indicated for the treatment of the Dreadful Yucks. As a primary care doctor, you are concerned about better treatment of this disease. Current standard treatment involves ChemoRADical Pharmacotherapy (CRAP). Cure rates with CRAP are only about 10%. Mr. Drugrep has a study that shows HLGD has a 12% cure rate versus placebo. He’s very excited and expects HLGD to be the new standard of care.

Question 28.4.1 To his argument, you appropriately respond:

- A) “Wow. HLGD is clearly superior to CRAP”
 B) “Hmm. HLGD is statistically no different from CRAP”
 C) “Wow. HLGD is clearly superior to placebo”
 D) “Do you have free samples of HLGD? Where’s lunch?”
 E) “I need more information before I can make an informed decision”

Answer 28.4.1 The correct answer is “E.” You need more information. Before coming to market, a drug manufacturer must demonstrate safety and efficacy of a drug. The new drug may or may not be compared with another currently available treatment. Without a study comparing HLGD to CRAP, you cannot say anything about how these drugs compare, even if HLGD looks better versus placebo. In addition, “C” is incorrect because the placebo results have not been given.

You ask Mr. Drugrep for more information. He proudly tells you the drug study involved 10,000 subjects with the Dreadful Yucks, randomly assigned to placebo (5,000) or HLGD (5,000). All of the subjects completed the trial. At the

end of 1 year, 400 subjects on placebo (8%) were cured and 600 subjects on HLGD (12%) were cured.

Question 28.4.2 He correctly tells you that:

- A) The NNT is 10,000
 B) The number needed to harm (NNH) is 10,000
 C) The relative benefit of HLGD versus placebo is 50% greater cure rate
 D) The absolute benefit of HLGD versus placebo is 50% greater cure rate

Answer 28.4.2 The correct answer is “C.” When looking at drug studies, benefit is often stated as “relative benefit” or relative risk reduction. In this question, 600/5,000 patients benefit from HLGD and 400/5,000 benefit from placebo; thus, 200 more patients are cured with HLGD, $200/400 = 0.5 = 50\%$ relative benefit of the drug vs. placebo. The absolute benefit is only 4% (12% cure with HLGD vs. 8% cure with placebo). For the NNT in this example, think about the previously given equation: $NNT = 1/ARR$, where $ARR = CER - EER$. The control group, the placebo, had a risk reduction of 8% (92% still had disease); and the experiment group had a risk reduction of 12% (88% still had disease). So, the $ARR = 12\% - 8\% = 4\%$, and $NNT = 1/0.04 = 25$. NNH cannot be calculated with the information available since the adverse event rate is not provided.

In real life, there are often more dramatic examples of how relative and absolute risks differ. It may be stated that there is a 50% reduction in complications of diabetes using Drug A versus placebo. However, when translated into patients, this could be 1/1,000 complications of diabetes in the drug group versus 2/1,000 complications of diabetes in the placebo group. This is a 50% relative decrease in adverse outcomes but in fact may be clinically meaningless. The absolute risk reduction is 1/1,000 or 0.1%! This ploy is often used to make drug studies look good. Thus, anytime you are looking at a new drug, ask for the absolute risk reduction and the NNT and the NNH. Forget the relative risk reduction and the *p*-values.

Mr. Drugrep tells you that the adverse event rate for HLGD is only 1%. Aren’t you impressed? But he frowns a little when you want to know the NNH.

Question 28.4.3 To calculate NNH, you ask him for:

- A) The types of adverse events that occurred in the treatment group
 B) The percentage of adverse events that occurred in the control group
 C) The percentage of adverse events with standard treatment
 D) The cure rate in the treatment group

Answer 28.4.3 The correct answer is “B.” Adverse effects of a drug will often be reported as an absolute number, and here it is given as 1%. So, the conclusion you are given by the pharmaceutical industry may be 50% reduction in disease and only a 1% risk of side effects of the drug. Both of these statements are true, but it’s an “apples and oranges” comparison. We prefer

comparing apples-to-apples (or corn-to-corn in Iowa). In order to directly compare benefits and harms, we need to know the NNT and the NNH.

Let's say that when you ask Mr. Drugrep, he tells you that the adverse event rate in the placebo group was 0.5%. Here's the calculation: $NNH = 1/ARI$, where ARI (absolute risk increase) = risk in experiment group – risk in control group.

Using the numbers in this question: $ARI = 1 - 0.5 = 0.5$; $NNH = 1/0.5 = 2$.

So, for HLGD, the NNT is 25 and the NNH is 2. By the way, the adverse event in question is disfiguring, painful ear hair growth. You will have to treat 25 patients with HLGD to cure one case of the Dreadful Yucks; but with every two patients you treat, one will have an adverse event. Demand NNT and NNH: how many patients who take the drug will benefit and how many will be harmed?

► **Objectives: Did you learn to ...**

- Employ CI in the analysis of data?
- Analyze data using risk reduction and relative benefit?
- Understand the importance of absolute risk reduction, NNH, and NNT when clinically applying data from a study?

► CASE 28.5

Mounting paperwork and electronic medical record hassles have played a role in your decision to make a career change. You have found a nice academic job with a research focus—minimal patient care, 10 weeks of vacation, no paperwork. The only downside is that you get paid peanuts—literally, you get 100 lbs of peanuts per month. Your work centers on reducing the risk of stroke in patients who have survived one stroke.

Question 28.5.1 This is an example of which category of prevention?

- A) Primary prevention
- B) Secondary prevention
- C) Tertiary prevention
- D) Quaternary prevention

Answer 28.5.1 The correct answer is “C.” The idea behind primary prevention, a big interest in primary care, is to prevent a disease from occurring at all by removing its cause (i.e., influenza vaccine to prevent illness from influenza). Primary prevention may occur in the healthcare setting but is often in the domain of public health. Secondary prevention detects disease at an early stage so that intervention can prevent progression (i.e., Pap smears detecting dysplasia prior to cancer declaring itself or treating elevated cholesterol prior to vascular events). Your new job will be to study tertiary prevention: the reduction in complications and mortality due to disease after it is recognized. The line between secondary and tertiary prevention can be blurry: some would consider preventing another stroke “secondary” prevention and preventing stroke complications (e.g., muscle atrophy and pressure ulcer) “tertiary” prevention. There is no such thing as quaternary prevention.

In between day-trading and coffee breaks, you plan to study two groups of patients (A and B) to see if variable XYZ makes any difference in death or recurrent stroke. There is no randomization and there are no interventions. You are just reviewing records to see how each group did. Subjects in Group A had a stroke and then had another stroke or died a year later. Subjects in Group B had a stroke but were alive with no recurrent stroke at the time of the study. You assess the presence of XYZ in each group.

Question 28.5.2 This type of study is called a:

- A) Prospective study
- B) Case-control study
- C) Cohort study
- D) Randomized, controlled study

Answer 28.5.2 The correct answer is “B.” A case-control study, like this one, will look at select subjects who are categorized based on outcome and try to find associations with certain variables. Case-control studies do not follow subjects over time and therefore are not prospective (but rather retrospective). Cohort studies (“C”) look at groups starting at time zero and following them for a specified amount of time to find an association between a variable and an outcome. The variable in question is not under the researcher's control. An example of a cohort study might be one looking at the association between two different diets (e.g., high-protein vs. high-carbohydrate) and the development of type 2 diabetes. The highest quality evidence is produced by a randomized, double blind, controlled trial (“D”), in which the researcher has control over exposure to a variable and studies its effect on an outcome. In general, the strength of trial design goes: experimental study > cohort study > case-control study > cross-sectional study. Unfortunately, it is not possible to design randomized controlled studies for all conditions. So, a well-done cohort study may be the best we can do.

You are concerned about numerous confounding variables in your study population. Never fear!

Question 28.5.3 Your trusty statistician recommends the following in order to minimize confounding:

- A) Multivariate analysis
- B) Careful calculation of *p*-values
- C) Matched controls and cases
- D) A and B
- E) A and C

Answer 28.5.3 The correct answer is “E.” Confounders can be a serious threat to any study. Confounders result from extrinsic factors—things that may affect the outcome and are also associated with the variable but are not accounted for in the study. As an example, a study may find an association between long-haul truck driving and lung cancer. Therefore, it is concluded that long-haul trucking is bad for your health. However, some long-haul truckers smoke. If tobacco use was not accounted for in this

study, the results of the study would be meaningless. Tobacco is a confounder. It is always advisable to look at a study with an eye for what confounder might be missing. Confounding can be limited by a study design that anticipates confounders and matches controls and cases (“C”). It is important to note that if you match your control and cases on a variable, you can no longer study that variable as a potential cause of the outcome. For example, if you match cases and controls on county of residence among the truck drivers, you can no longer explore county of residence as a risk factor for lung cancer. Also, multivariate analysis (“A”) is a statistical method that allows for adjustment of known confounders. “B” is incorrect because *p*-value has nothing to do with confounding but will tell you whether the results should be considered significant or not.

When you review the literature, you find that there are a number of small studies looking at the effect of variable XYZ on stroke victims. You even find a meta-analysis.

Question 28.5.4 If this is a well-done meta-analysis, you should find all of the following EXCEPT:

- A) Statistically confirmed heterogeneity between the included studies
- B) A thorough search for all valid studies
- C) An evaluation of whether estimates change with varying assumptions
- D) The exclusion of poor-quality studies
- E) The studies included measure the same underlying effect

Answer 28.5.4 The correct answer is “A.” Hopefully, a meta-analysis would confirm *homogeneity* between studies. For example, if one study measured NIH stroke scale and another measured patient quality of life (the outcomes are heterogeneous), it would be impossible to combine the studies. Although there is controversy regarding the appropriate use of meta-analyses, they are often used to study various outcomes by combining smaller studies. A meta-analysis is a systematic review that combines the results of previous studies to evaluate the magnitude or direction of an effect or to evaluate the effect on a subgroup. All valid studies looking at similar outcomes should be included; poor-quality studies should be excluded. The Jadad score is one common way that studies are judged as to their appropriateness for a meta-analysis (Table 28-3). Other similar scales exist. Meta-analyses should also include a “sensitivity analysis.” This may consist of excluding large studies and only analyzing smaller studies. It may consist of changing the economic assumptions in a cost-benefit meta-analysis. If the outcome is the same either way, the result is said to be “robust.” If excluding some studies or changing the underlying economic assumption changes the result, one has to wonder about the quality of the studies, etc.

TABLE 28-3 FACTORS IN DETERMINING THE JADAD SCORE FOR META-ANALYSES

Randomization	Withdrawals and dropout numbers	Blinding
---------------	---------------------------------	----------

► **Objectives: Did you learn to ...**

- Define different types of prevention?
- Define different study types?
- Identify and account for confounding variables?
- Describe some characteristics of a meta-analysis?

HELPFUL TIP:

You will see an increasing number of “noninferiority” studies being done. What does “noninferior” mean? Basically, it means that two drugs have *some* overlap in their efficacy. See Figure 28-2. Drugs Y is noninferior to Drug X even though it may not cure as many patients. “Noninferior” does not mean “as good as.” “Biocreep” (which is one of our favorite terms and reminds us of zombies) occurs when drug Z is now compared to drug Y. Drug Z is noninferior to Drug Y, although it clearly cures fewer people than Drug X. Thus, the standard against which new drugs are compared becomes progressively less efficacious (Fig. 28-2). In another concern, researchers can define their own “margin” of noninferiority. For example if the margin is “2” (as in some of the new anticoagulant studies), the new drug could allow up to twice as many events (e.g., pulmonary emboli) as the old drug and still be considered “noninferior.”

QUICK QUIZ: ERROR PREVENTION 1

You are seeing a 46-year-old female with complaints of lower abdominal pain. Looking at her chart, you see that the last several notes (from several different doctors) all list the diagnosis as constipation. The patient has tried multiple medications for constipation but is still having the pain. You smartly order an ultrasound which shows ovarian cancer. You are wondering

Here, drug Y is noninferior to drug X even though it may not actually be as good as the standard treatment.

FIGURE 28-2. The Three Major Factors of the Jadad Score.

why the last three providers all put “constipation” without ruling out other illnesses.

This could be an example of:

- A) Chronology bias
- B) Diagnostic momentum
- C) Availability bias
- D) Framing bias

The correct answer is “B.” Diagnostic momentum occurs when a provider is not sufficiently skeptical of the diagnosis on the chart. It can be a leading source of diagnostic errors. How many times have you seen “migraine” written on the chart and assume it is correct? Always be skeptical of a diagnosis, especially if treatments don’t seem to be helping. You may be a better clinician than the last person to see the patient. “A,” chronology bias, occurs when a historical cohort is used as the control group in a study. The claim may be made that, “The introduction of fuzzy cookies improves outcomes when compared to historical controls.” The problem is that, over time, *other things have changed in medicine besides the introduction of fuzzy cookies* (e.g., sepsis protocols, stroke protocols, early mobilization, other medications for the illness, etc.). If the controls are historical, it may be that one of these other factors is responsible for the improvement in outcomes. “C,” availability bias, means that something that happened recently makes you think the same thing is happening again. For example, if you miss a pulmonary embolus (PE), all of a sudden it seems as though patients with marginal symptoms have a PE and thus get a PE workup. Or, if you see something rare, you think the next three patients with similar symptoms also have this rare disease (even though the rate in the population is only 1 in 10,000). That which has recently happened is more “available” in your thought processes, so it tends to be intrusive in your thinking. “D,” framing bias, occurs when you try to make symptoms and data fit into your preconceived notion of a diagnosis. For example, a patient presents with fever upon return from Africa, and you assume it is due to malaria, so you specifically look for symptoms and lab data to fit your hypothesis.

QUICK QUIZ: ERROR PREVENTION 2

You are looking at the patient with ovarian cancer: She is dressed in ripped jeans (not the expensive kind which we don’t understand) and a somewhat grubby T-shirt. She has a very annoying, whiny voice. You are thinking that the way she is dressed and speaks may have played a role in the mis-diagnosis.

This is an example of:

- A) Affective bias or attribution error
- B) Anchoring bias
- C) Confirmation bias
- D) Probabilistic diagnosis

The correct answer is “A.” Ok, be honest now. How many of you like to have other healthcare providers or “VIPs” as a patient?

Probably none of us. If you are like the editors, you treat those patients differently. You might defer painful or embarrassing tests (like a rectal exam or an LP) because you don’t want to cause them pain or risk embarrassment. Or, you might do too many tests “just to be sure.” Either approach is wrong. These are examples of “affective bias.” We let our feelings (“affect”) about the patient modify our diagnostic or treatment plan. In the example above, we may (unconsciously) dismiss the patient’s complaints because we don’t like her, because of the way she dresses, or because she presents as a negative stereotype (strange, unwashed, and somehow slightly dazed—thank you, David Bowie). We tend not to believe patients with whom we don’t identify. It is hard to be objective when you really like—or really don’t like—the patient. This is one reason we don’t treat family members. “Attribution error” is similar. We let negative stereotypes about how the patient looks, etc., change our probability of a diagnosis. For example, we look at the “love and hate” tattoos on the knuckles of a patient who smells strongly of tobacco smoke and has had a couple of beers and assume the patient is not a reliable historian and is (more likely) just looking for narcotics.

“B,” anchoring bias, occurs when we hold on too tightly to a piece of information even if other information contradicts it. For example, we may see an infiltrate on x-ray and think, “pneumonia.” We may continue to inflate the significance of the positive x-ray as being suggestive of pneumonia even in the presence of other facts (such as eosinophilia... maybe it isn’t pneumonia but rather pulmonary filariasis). “D,” confirmation bias, occurs when we give excessive weight to data that confirms what we already believe. This is operative in a major way in politics and social media recently. We are in our “bubble” and look only at news sources that confirm our bias. We do the same in medicine: we ignore information that does not fit our hypothesis about the patient’s diagnosis. Finally, “D.” Essentially, “all” diagnoses and treatments are probabilistic. We make the best guess we can. A good example of this is appendicitis. If you tell a parent that their child has appendicitis, but the surgical pathology is negative, they aren’t going to be happy with you. But if you tell them there is a 10% to 15% chance the surgery will yield a normal result, but it is still important to do, they may be more forgiving. *Another way to put this is that there are false-positive and false-negative tests, physical exams, etc.* We can’t be sure of a diagnosis until the “gold standard/criterion standard/reference standard” test is done (in the case of appendicitis this is surgery and surgical pathology).

HELPFUL TIP:

Differential diagnosis checklists have been shown to increase diagnostic accuracy. You can find a set of these at: <https://www.healthcare.uiowa.edu/familymedicine/fpinfo/> under “Ely Checklist.”

CASE 28.6

Uh, oh... Here comes the math. This section is important, especially the concepts of positive and negative predictive values (PPV and NPV) and the concepts of sensitivity and

specificity. We are using cookies as an example in the calculations. Hopefully this will help you visualize and understand it better than if we used a disease. If you don't want to do the math, just get yourself a real cookie. But at least read the summary.

Sensitivity: How often the test will pick up the disease if it is there. $\text{Sensitivity} = \text{true positives} / (\text{true positives} + \text{false negatives})$. Note that the sum of true positives + false negatives represents all of the people **with** disease.

Specificity: Specificity is defined as the proportion of patients **who do not** have the disease and who will test negative for it. $\text{Specificity} = \text{true negatives} / (\text{true negatives} + \text{false positives})$. Note that the sum of true negatives + false positives represents all of the people **who do not** have disease.

Positive predictive value: The probability that someone with a positive test *actually has* the disease. This takes the prevalence of a disease into account. For example, an individual with a positive HIV test who is an IV drug user is more likely to really have the disease than a clean-living nun with a positive HIV test. In the nun, the test is more likely to be a false positive. So for nuns, the number of true positives might be zero but false positives 3 which makes for a PPV of “0.” For an IV drug abuser, the number of true positives may be 10 with 1 false positive. The $\text{PPV} = 90\%$

$$\text{PPV} = \frac{\text{Number of true positives}}{\text{Number of true positive} + \text{Number of false positives}}$$

Negative predictive value: The probability that someone with a negative test *actually does not* have the disease. Again, this takes the prevalence of the disease into account. For example, a negative HIV test in an IV drug user from Sub-Saharan Africa with a CD4 count of $150/\text{mm}^3$ and PCP is likely to be a false negative. Conversely, a negative HIV test in the risk-averse nun, for example, is likely to be a true negative.

$$\text{NPV} = \frac{\text{Number of true negatives}}{\text{Number of true negatives} + \text{Number of false negatives}}$$

HELPFUL TIP:

A test that has a negative predictive value of 99% may sound good. But if only 1% of the population has the disease, doing no test will have a 99% negative predictive value.

Cookie Monster has a dilemma: He has a stack of cookies in front of him. He would like to eat them but there are also round brownies mixed in. Cookie Monster hates brownies. Sure, he could just take a bite, but he hates brownies so much that this is not an option. Luckily, Cookie Monster has developed a new test called the “cookie-o-meter.” It can tell whether a round thing is a cookie or a brownie. When compared with the gold standard of tasting and deciding whether or not it is a brownie or a cookie, the new test has a sensitivity

of 90% (it will detect 90% of the cookies) and a specificity of 95% (thus, 95% of the time when the cookie-o-meter says it is not a cookie [negative test], it will be a brownie).

So, how can you tell if this is a good test or if the Sesame Street Baker is pulling a fast one? You need to know the positive predictive value (PPV) of the test. In order to calculate the PPV, you need three pieces of data: the sensitivity of the test (how often the test will pick up the “disease/cookie” if it is there), the specificity of the test (how often you will get a false positive... that is a brownie is mistakenly called a cookie), and the prevalence of the condition (how many total cookies (vs. brownies) there are in the bowl in front of Cookie Monster).

Let's apply the cookie-o-meter test.

You are currently in Los Angeles, attending a CME course where they really like cookies and the claim is that 99% of the objects in the bowl in front of you are cookies with only 1% brownies. You check your “cookie-o-meter” and it says you have a cookie. But does this mean you have cookie?

In order to answer this question, you can use Bayes theorem or set up 2×2 tables. Here's the 2×2 table method. Begin by drawing a 2×2 table and filling in what you know. See Tables 28-4 and 28-5.

So this makes it easy.

$$\begin{aligned}\text{Sensitivity} &= a/(a + c), \\ \text{Specificity} &= d/(b + d), \\ \text{PPV} &= a/(a + b), \\ \text{NPV} &= d/(c + d)\end{aligned}$$

If we have 100 cookies, the data will look like that above. Now, let's add actual numbers to the table (above). Let's use a total of 10,000 cookies. We multiply by the prevalence of cookies to get the subpopulation totals. Ninety-nine percent of the objects are cookies (99% prevalence). So, $99\% \text{ prevalence} \times 10,000 = 9,900$ are cookies; $1\% \times 10,000 = 100$ are brownies. Once we have these numbers, we simply multiply by the sensitivity and the specificity to get the exact cell numbers to plug into the table above: $9,900 \times 90\% \text{ sensitivity} = 8,910$ for cell A (“true positives”); $9,900 - 8,910 = 990$ for cell C (“false negatives”); $100 \times 95\% \text{ specificity} = 95$ for cell D (“true negatives”); $100 - 95 = 5$ for cell B (“false positives”). See Table 28-6.

Once the table is filled in, these numbers can then be used to calculate the PPV, using the equation above. In this case, $a/(a + b) = 8,910 / (8,910 + 5) = 99.9\%$.

For those who prefer the Bayes theorem method, here's how this approach is done. Bayes theorem shows the relationships between sensitivity, specificity, prevalence, PPV, and NPV. The

TABLE 28-4 SAMPLE TABLE

Test	Disease	
	+	–
+	a (true positive)	b (false positive)
–	c (false negative)	d (true negative)
Total	a + c	b + d

equation for PPV, derived from Bayes theorem, is shown, as is the calculation based on the numbers from the question:

$$PPV = \frac{\text{Number of true positives}}{\text{Number of true positive} + \text{Number of false positives}}$$

$$PPV = \frac{\text{Sensitivity} \times \text{prevalence}}{(\text{Sensitivity} \times \text{prevalence}) + [(1 - \text{specificity}) \times (1 - \text{prevalence})]}$$

$$= \frac{0.9 \times 0.99}{(0.9 \times 0.99) + [0.5 \times 0.01]} = 99.9\%$$

Question 28.6.1 What would the likelihood of not having a cookie if the “cookie-o-meter” had said you did not have a cookie (what is the NPV)?

- A) 95%
- B) 90%
- C) 50%
- D) 9%
- E) None of the above

Answer 28.6.1 The correct answer is “D.” The question asks for the NPV, or the likelihood of not having a cookie if the

cookie-o-meter is negative. This also can be derived from Bayes theorem or calculated using a 2×2 table.

$$NPV = \frac{\text{True negatives}}{\text{False negatives} + \text{True negatives}} \text{ or } \frac{d}{c + d}$$

$$= \frac{95}{990 + 95} = 8.7\% \text{ (round to 9\%)}$$

You are now in San Francisco where they try to sneak in kale brownies. Cookie Monster hates kale brownies. Here the number of “real” cookies is 10% with 90% kale brownies. You check your “cookie-o-meter” and it says you have a cookie. Do you trust it?

Question 28.6.2 What is the likelihood that you actually have a cookie if the “cookie-o-meter” says you have a cookie (and not the dreaded kale)?

- A) 91%
- B) 83%
- C) 67%
- D) 16%
- E) None of the above

Answer 28.6.2 The correct answer is “C.” You can use the 2×2 method or the Bayes theorem methods. Here’s what our 2×2 table looks like. See Table 28-7.

To convert to 10% prevalence, we start with a large baseline population and multiply by the prevalence to get the subpopulation totals (10% prevalence \times 10,000 = 1,000 cookies; 90% \times 10,000 = 9,000 kale brownies [yuck!]). Once we have the subpopulation totals, we multiply by the sensitivity and the specificity to get the exact cell numbers (1,000 \times 90% sensitivity = 900 for cell “a”; 1,000 – 900 = 100 for cell “c” [or alternately 1,000 \times 10% will get the same result for cell “c”]; 9,000 \times 95% specificity = 8,550 for cell “d”; 9,000 – 8,550 = 450 for cell “b”).

These numbers can then be used to calculate the PPV, using the equation above. In this case, $a/(a + b) = 900/(900 + 450) = 66.7\%$ (rounds to 67%). Using Bayes theorem, the equation is as follows:

$$PPV = \frac{\text{Sensitivity} \times \text{prevalence}}{(\text{Sensitivity} \times \text{prevalence}) + [(1 - \text{specificity}) \times (1 - \text{prevalence})]}$$

$$= \frac{0.9 \times 0.1}{(0.9 \times 0.1) + [0.05 \times 0.9]} = 66.7\%$$

Question 28.6.3 Still in San Francisco, we ask: What would the likelihood of having a cookie be if the “cookie-o-meter” said you did not have a cookie (but rather had a kale brownie)?

- A) 50%
- B) 40%
- C) 30%
- D) 1%
- E) None of the above

TABLE 28-5 COOKIE-O-METER SENSITIVITY AND SPECIFICITY

		Actual Cookie	
		+	–
Cookie-o-meter Test Result	+	90 (true positive)	5 (false positive)
	–	10 (false negative)	95 (true negative)
Total		100	100

After Adding Actual 99% Prevalence			
		Actual Cookie	
		+	–
Cookie-o-meter test result	+	8,910	5
	–	990	95
Total		9,900	100
		(99% prevalence)	

TABLE 28-7 EXAMPLE OF A COMPLETED 2 × 2 TABLE FOR QUESTION 28.6.2

Before Adding Actual Prevalence				After Adding Actual Prevalence			
		Actual Cookie				Actual Cookie	
		+	−			+	−
Cookie-o-meter Test	+	90	5	Cookie-o-meter Test	+	900	450
	−	10	95		−	100	8,550
Total		100	100	Total		1,000	9,000
				(10% prevalence)			

Answer 28.6.3 The correct answer is “D.” Again, you can use the 2 × 2 method or Bayes theorem. The 2 × 2 table for this question is the same as it was for the previous question (see Table 28-7). However, unlike previously, you are asked for the likelihood of a cookie if the “cookie-o-meter” says it is not a cookie and instead a dreaded kale brownie. In other words, you have been asked to calculate the false negative rate (FNR) for this scenario. The equation for the FNR is below.

$$\begin{aligned} \text{FNR} &= \frac{\text{False negatives}}{\text{False negatives} + \text{true negatives}} \text{ or } \frac{c}{c + d} \\ &= \frac{100}{100 + 8,550} = 1\% \end{aligned}$$

You were not asked to calculate it, but there is also a false-positive rate (FPR), which is shown below.

$$\begin{aligned} \text{FPR} &= \frac{\text{False positives}}{\text{False positives} + \text{true positives}} \text{ or } \frac{b}{a + b} \\ &= \frac{450}{450 + 900} = 33\% \end{aligned}$$

Clinical Pearls

- A highly sensitive test helps to rule OUT disease; a highly specific test helps to rule IN disease.
- A treatment that is statistically significantly superior to placebo (or to a comparison drug) may not offer a clinically significant benefit. Use clinical judgment when interpreting study results.

- Compare number needed to treat (NNT) with number needed to harm (NNH) when considering therapies, rather than relying on relative risk reduction. The same calculation can be done for screening tests (e.g., number of women needed to screen to avoid one breast cancer death).
- Do not draw conclusions from subgroup analyses. The only conclusion that can be drawn is, “This must be studied.”
- Recognize that the utility of a test is contingent upon the sensitivity and specificity of the test and the prevalence of disease in the population being tested. Therefore, a sensitive and specific test may have a low predictive value in a population with very low disease prevalence.
- When evaluating a noninferiority study, look for the “margin” used by the investigators. This is the maximum extent of clinical difference that will be considered noninferior (e.g., a margin of 2 means twice as many events can occur in the experimental group and still be considered noninferior).

Patient-Centered Care

29

Denise A. Martinez

Note: This chapter deals with culturally responsive care and patient safety. Because not all Black patients identify as African-Americans, the authors have elected to use the term Black in this chapter as inclusive of African-Americans as well as those individuals who are of African descent but may be from another country. The authors have also elected to use the term Latinx when referring to individuals of “Hispanic” descent realizing that many individuals identify strongly with their country of origin. We also use the term “race” understanding that this is a social and not biological construct. We understand the sensitivity of this terminology and ask your understanding.

▶ CASE 29.1

You are doing a locum tenens job in Arizona on the Navajo reservation. You are seeing a lot of patients with diabetes, which reminds you that Native Americans, Latinxs, and Blacks all have a greater prevalence of diabetes compared to the general US population.

Question 29.1.1 Which of the following is TRUE about the age-adjusted prevalence of diabetes in adults?

- A) All Alaska Native and Native American tribes have a higher prevalence of diabetes than non-Hispanic Whites (NHW)
- B) Cuban Americans and South Americans have a higher prevalence of diabetes than NHW
- C) Mexican Americans and Puerto Ricans have close to 90% higher prevalence of diabetes than NHW
- D) Pima Indians in Mexico have the same high prevalence of diabetes as the Pima Indians in Arizona
- E) Non-Hispanic Blacks have a lower prevalence of diabetes than Latinxs in the United States

Answer 29.1.1 The correct answer is “C.” Mexican Americans and Puerto Ricans have a higher prevalence of diabetes compared with NHW (“non-Hispanic White” being the term used by the US Census Bureau). The other statements are false, and

here’s how they break down. Although their diabetes prevalence is increasing rapidly, Alaska Natives historically had a 5.5% age-adjusted prevalence of diabetes compared with 7.1% for NHW. Cubans and South Americans actually have the same prevalence as NHW. The Pima Indians in Mexico whose lifestyle is not sedentary and who eat a more traditional diet actually have a diabetes prevalence of about 7%, while those in Arizona have a prevalence of 38%. Non-Hispanic Blacks have a prevalence higher than those of Latinxs and NHW but not quite as high as the Mexican Americans and Puerto Ricans.

HELPFUL TIP:

Ethnic and cultural groups are not uniform from an epidemiological or cultural belief standpoint. Hence, there are often large differences between individuals and subgroups. This is complicated further by the fact that we all belong to, and are influenced by, multiple different cultural groups. Although there are cultural patterns within healthcare, try not to adopt those patterns as stereotypes for the individuals and groups.

You are seeing a 57-year-old Navajo male with poorly controlled type 2 diabetes. You are trying to understand why his hemoglobin A_{1C} is so high since he has access to healthcare, medicines, supplies, and an amazing doctor (if you do say so yourself). You remember a lecture on culturally responsive patient-centered medicine where they talked about investigating a person’s health problem using both disease and illness models.

Question 29.1.2 The difference between disease and illness is:

- A) Disease is the biomedical explanation of the health condition; illness is the patient’s experience and understanding of their health condition
- B) Disease is chronic; illness is acute
- C) Diseases have known causes; illnesses do not

- D) Disease is more serious and frequently needs treatment; illness will resolve without medical intervention
- E) Disease versus illness ... really? Aren't we just into some phony semantics here?

Answer 29.1.2 The correct answer is “A.” Simply put, “disease” is the way that physicians understand a health problem and “illness” is the way the patient experiences it. The culturally responsive patient-centered model looks not only at the pathophysiology of disease, which is the focus of most of our early medical training, but also at what the patient is experiencing, how it impacts him or her, and what is the larger cultural-social-personal context of that health condition. The patient-centered physician weaves back and forth between the disease and illness model, diagnosing and treating both the disease and the illness.

You want to focus on your patient's illness in the larger context of his life and avoid just discussing glucose metabolism, diet, exercise, lab results, and medication adherence. (Your usual approach of explaining diabetes and its complications has not improved his control.) You ask him, “What has your experience with diabetes been like?” And he looks at you strangely and answers that it has been tough.

Question 29.1.3 One way to help get an understanding of his beliefs about diabetes would be to:

- A) Ask if family members or tribal medical personnel are willing to share information about the intersection of cultural beliefs and care, specifically diabetes; if they share information on their cultural beliefs, listen with understanding and gratitude
- B) Do a literature search on Navajo health beliefs with respect to diabetes to help formulate questions to ask him about his potential cultural beliefs
- C) Ask about his experiences and beliefs about diabetes so you can have a greater understanding about his beliefs to communicate with him about care in a way to meet his needs
- D) All of the above

Answer 29.1.3 The correct answer is “D.” Any of these options may help you understand this patient's health beliefs. Community members can be a good source of cultural patterns. Having a general idea of a cultural belief system makes it easier to ask questions about whether those beliefs apply in this case and how. Asking the right questions will help to get more useful information. There are some canned questions that can be of assistance, including those listed here from a series of questions developed by a psychiatrist–anthropologist named Arthur Kleinman:

- What do you call your problem?
- What do you think caused your problem?
- What do you think is going on with your body?
- How have you treated this?
- What do you think helps?

- Why do you think it started when it did?
- What does your sickness do to you?
- How severe is it?
- What do you fear most about your problem?
- What are the biggest concerns that your sickness has caused for you?
- What kind of treatment do you think would be helpful?
- What are the most important results you hope to receive from the treatment?

HELPFUL TIP:

Don't feel as though you need to memorize all these specific questions. Rather, focus on asking questions that elicit information about the patient's own health beliefs in a nonjudgmental way. Another useful mnemonic that can be applied in many different contexts is “ICE,” which stands for Ideas, Concerns, and Expectations. For “ideas” you might ask what the patient thinks is causing his/her problem. For “concerns” you might ask what he/she is worried is causing the problem. For “expectations” you might ask what they think will happen with their problem and what they are expecting from the visit or healthcare system.

This same patient develops severe osteomyelitis of his right leg and is admitted to your inpatient service. He has not responded to several weeks of appropriate IV antibiotics and debridement. The infection is gradually spreading proximally, and a decision has been made with the patient that you will proceed with a below-the-knee amputation. Although you are confident that this is the right clinical decision, you worry about the fact that Native Americans, Latinxs, Blacks, and people from lower socioeconomic backgrounds all have disproportionately higher rates of limb amputation, even when adjusting for incidence of diabetes (with Navajos having the highest rate of all). The surgeon you are working with asks you to obtain informed consent from the patient. You have heard that Navajos believe that talking about something bad happening (i.e., informing them of the procedural risks) makes those adverse events more likely to occur.

Question 29.1.4 What is the most appropriate approach to gaining informed consent from your patient?

- A) Proceed with the informed consent with the full explanation of the benefits and risks of the procedure.
- B) Just tell him he needs the surgery and avoid the risk/benefit discussion.
- C) Share with him the percentage chance of a good outcome and do not talk about the possible risks and complications.
- D) Explain the information to a tribal leader and let the tribal leader decide what to communicate with the patient.
- E) Explain the process of informed consent to the patient and allow him to opt out of any part of the process he desires to avoid.

Answer 29.1.4 The best answer is “E.” This is a challenging situation since this patient’s belief system is counter to modern Western medical practices. In order to create a culturally responsive plan of care for the patient, we should try to align our guiding medical principles with the patient’s cultural beliefs. Using the four guiding principles of medical ethics (autonomy, beneficence, nonmaleficence, and justice) is one way to work through this dilemma. Some would argue for “A” because the patient cannot make an informed decision without knowing the potential risks and benefits (autonomy), and, “it’s the law.” However, if the patient has traditional Navajo beliefs, proceeding with the full informed consent may deter the patient from undergoing a beneficial or even life-saving procedure, which presents conflict with the principles of beneficence and nonmaleficence. “B” and “C” rely on stereotypes without making sure of the patient’s beliefs. Asking a tribal leader and/or someone from the tribe who works in medicine is an excellent way of obtaining a cross-cultural perspective. However, ultimately, we need to respect the patient’s autonomy.

Your patient consents to the surgery but with a request that makes you uneasy—he wants to take the amputated limb home with him after the surgery. He shares with you his cultural belief that his body needs to be buried whole in order to cross over to the next world after he dies (note that this belief is also common among orthodox Jews and others).

Question 29.1.5 How should you NOT explain to him the potential health hazards of taking an infected limb home?

- A) Explore how other people in the community who have had amputations have managed this
- B) Explain to him that you understand his concerns; however, the health risk of him taking the limb home far outweighs any other consideration so the limb will have to be disposed of by standard hospital practice
- C) Allow family members and community leaders to participate in the discussion if the patient wishes
- D) Negotiate a way where as much as possible his wishes could be met, personal and public health and safety preserved, and community and hospital regulations followed

Answer 29.1.5 The correct answer is “B.” The underlying concern is that the patient’s wishes are in direct conflict with traditional medical practices. Although hospital policy may limit your options, there is usually enough flexibility to allow you to accommodate the patient’s wishes at least to some degree. You can use the LEARN mnemonic (Listen, Explain, Acknowledge, Recommend, Negotiate) to help approach this cultural conflict. First, you Listen to the patient’s perspective. Often you have to probe with nonjudgmental questions to elucidate this. “C” can provide some cultural context for both the Listening and Negotiating phases. “A” would be part of Explaining your perspective. Next you Acknowledge both the differences and similarities between the two perspectives. Then you Recommend a plan hopefully where you and the patient both get what you want. Finally, as in “D,” you may need to Negotiate.

► **Objectives: Did you learn to ...**

- Describe some differences in diabetes prevalence among different ethnic groups?
- Define the terms “disease” and “illness”?
- Explore a patient’s personal and cultural reasons for nonadherence to traditional medical advice?
- Develop some tools for providing care to patients who have health beliefs that diverge from those of traditional Western medicine?

► **CASE 29.2**

A young couple that just immigrated to your town from Bosnia comes to your clinic because they are expecting their first baby. The wife is a healthy 23-year-old woman and in her first trimester of pregnancy.

Your scheduler knows that many Bosnians are of the Muslim faith and has heard that female Muslims are supposed to refrain from care by male physicians.

Question 29.2.1 When making the appointment for this patient, the scheduler should:

- A) Schedule her with the first available OB provider, regardless if it is male or female
- B) Schedule her with the first available female OB provider
- C) Schedule her with your only Bosnian-speaking OB provider who is male (this will cut down on the time needed for an interpreter)
- D) Ask if she has a preference from whom she would like to receive care and schedule her within her preferred provider
- E) Schedule her with the OB provider who has the most experience and interest in working with patients from diverse cultures (maybe Dr. Smith since he eats out at a different ethnic restaurant every night)

Answer 29.2.1 The correct answer is “D.” Although many Muslim women would find it inappropriate to have a male provider, this is not universally true. Besides, we are not even sure this patient is of Muslim faith (only about 40% of Bosnians are Muslim)! Cultural characteristics and belief systems are generalizations that may accurately describe a population. However, if you extrapolate these generalized beliefs to the individual, you are engaging in stereotyping and may often come to the wrong conclusion.

HELPFUL TIP:

Use your knowledge of a patient’s culture as a starting point. Ask about any assumptions or suspicions in a nonjudgmental way. Make sure you know how the belief applies in the current context.

When she arrives in your clinic, you realize she speaks no English and her husband speaks only a little. Using his limited English and some hand gestures, you feel that you should

conduct an interview with them. Because you completed a course entitled “Advanced Life Support for Culturally Responsive Care,” you are able to deal with such a situation! Your mind drifts back to that course ... ah, CME on the beach!

Question 29.2.2 You recall that “culturally responsive care” is defined as:

- A) Learning about multiple cultures
- B) Being able to speak multiple languages
- C) Taking diversity classes
- D) Adopting a set of cultural behaviors and attitudes that enable you to deliver effective medical care to people of different cultures
- E) Hiring staff from a variety of different cultures—preferably all good cooks who will provide some excellent ethnic cuisine

Answer 29.2.2 The correct answer is “D.” While the other answers are laudable goals, they do not define culturally responsive care. Culturally responsive care is a set of behaviors and attitudes that aims to help healthcare providers deliver better care to patients from many different cultures.

You rack your brain trying to remember why culturally responsive care is important to you. You now regret skipping some of the lectures to go snorkeling in those beautiful Hawaiian waters.

Question 29.2.3 Which of the following is NOT a benefit of providing culturally responsive care?

- A) It allows efficient use of time and resources
- B) It increases the chance of providing services that are consistent with patient needs
- C) It might improve health outcomes for minority patients
- D) It might improve patient retention
- E) It is less expensive in the long run

Answer 29.2.3 The correct answer is “E.” Culturally responsive care allows you to use your time and resources efficiently to increase the likelihood that you will provide the services your patient actually wants and needs. This can lead to improved health outcomes for your patients, increased patient satisfaction and retention of your minority patients (and perhaps increase your patient satisfaction scores!). Unfortunately, no studies so far have shown that it can reduce your practice costs.

HELPFUL TIP:

The National Center for Cultural Competence at Georgetown University has identified six compelling reasons that healthcare providers should incorporate culturally responsive care into their practice. They are as follows:

1. To respond to current and projected demographic changes in the United States.

2. To eliminate long-standing disparities in the health status of people of diverse racial, ethnic, and cultural backgrounds.
3. To improve the quality of services and health outcomes.
4. To meet legislative, regulatory, and accreditation mandates.
5. To gain a competitive edge in the marketplace.
6. To decrease the likelihood of liability/malpractice claims.

Pondering this, you decide to try and provide culturally responsive care to this Bosnian woman.

Question 29.2.4 Which one of the following is NOT a step in providing culturally responsive care?

- A) Understanding your own culture
- B) Understanding others’ cultures
- C) Being frustrated with having to work with people different than you
- D) Understanding how your patients’ cultural beliefs affect their attitude toward healthcare
- E) Adapting your way of practicing to provide optimal care

Answer 29.2.4 The correct answer is “C.” The goal of culturally responsive care is to provide better healthcare for patients from different cultures. Some of the specific things this goal calls for include:

- Being respectful of *potential* cultural differences
- Learning about other cultures
- Being aware of the health impact of cultural beliefs and practices
- Being sensitive to patients’ needs
- Using interpreters when necessary
- Adapting practices to provide optimal care

An easy way to achieve these goals is by using the Berlin and Fowkes’ LEARN model described earlier.

HELPFUL TIP:

While learning and respecting patients’ different cultural beliefs is vital, *providing good care does not call for accepting practices that are detrimental to your patient’s health.* But beware ... there are many potential ethical dilemmas that can occur when traditional Western medicine intersects with a culture that has radically different health beliefs. Many cross-cultural medical decisions are not as dichotomous as we would like to think. Western medicine may have to bend a little to accommodate belief systems.

Now that you are ready to proceed with caring for your patient, the question of language comes up. Should you use the husband to interpret (he seems to know a bit of English)?

Question 29.2.5 To help guide you, you call your hospital compliance officer who tells you that:

- A) It is Federal Law that you must provide an interpreter for patients who need it, at your own cost if necessary
- B) It is Federal Law that patients must provide their own interpreters at their own expense
- C) Most insurance companies reimburse for interpreter services
- D) Using family and staff to translate rarely reflects current practice standard
- E) There are no privacy concerns when using nonprofessional interpreters

Answer 29.2.5 The correct answer is “A.” The 2010 census found that more than 60.6 million adults (around 21% of the US population) speak a non-English language at home, while almost 13% of the US population is foreign born. When the healthcare professional does not speak the primary language of the patient, there is potential for loss of important information, misunderstanding of physician instructions, and poor shared decision-making. Title VI of the 1964 Civil Rights Act requires healthcare professionals to provide interpreter services for patients who need them, at the physician’s cost if necessary. Failure to do so would qualify as discrimination and could be prosecuted in a court of law. Unfortunately, most insurance companies do not reimburse for these services. Interpreters can be scarce and costly. As a result, many physicians use any help they can get for translation, including staff members and family members who are bilingual (so, “D” is a false statement); but this leaves room for error. Using a family member as an interpreter makes it hard for the patient to disclose private information they do not want known by the family. Professional interpreters have been trained and certified, while ad hoc interpreters often have no formal training and can make translation mistakes.

Question 29.2.6 Regarding provision of healthcare, language barriers may result in:

- A) Increased risk of intubation for children with asthma
- B) Greater nonadherence to medication regimens
- C) Higher resource use in diagnostic testing
- D) Increased risk of drug complications
- E) All of the above

Answer 29.2.6 The correct answer is “E.” Language barriers have been associated with worse health outcomes to include lower likelihood of having a usual source of medical care; lower likelihood follow-up after an emergency room visit; greater nonadherence to medication regimens; increased risk of drug complications; impaired understanding of diagnoses, medications, and need for follow-up; lower patient satisfaction; longer medical visits; higher resource utilization; increased risk of intubation for children with asthma; greater risk of being labeled with psychopathology; and increased risk of leaving the hospital against medical advice.

Question 29.2.7 What is the proper method to use an interpreter?

- A) Address all questions to the interpreter while facing the interpreter
- B) Address questions to the patient while looking at the interpreter
- C) Address questions to the patient while facing the patient
- D) Address questions to the interpreter while facing the patient
- E) Have the interpreter get you coffee while you muddle through using gestures

Answer 29.2.7 The correct answer is “C.” The physician should speak to and look at the patient; in other words, don’t speak about the patient in the third person. Remember that nonverbal communication is important even when common languages are not shared. Be aware that seemingly universal gestures such as the “OK” sign and a “thumbs up” may have different meanings in other cultures. The physician should speak clearly and give the interpreter time to translate questions and answers. The physician should periodically pause and ensure that the patient understands the questions that are being asked. Failure to look at the patient while asking questions impairs the establishment of the physician–patient relationship and should be avoided.

.....

You remember from medical school that there was disagreement as to the degree that a medical interpreter should function as a cultural advocate.

Question 29.2.8 Which of the following would be the most effective pre-encounter instructions for your interpreter to facilitate the best possible communication between you and your patient?

- A) “Translate word-for-word all that the patient and I say. You may repeat phrases, but do not rephrase anything”
- B) “When clarifying, explaining, or culturally translating concepts, make sure that you are transparent (i.e., let both parties know what you are saying and why)”
- C) “Be sure to culturally translate whenever you think it is appropriate”
- D) “If the patient doesn’t seem to understand, go ahead and explain whatever you think that I mean”

Answer 29.2.8 The correct answer is “B.” Ideally, an interpreter would do an exact translation. However, many concepts do not translate literally or have very different meanings depending on the context that surrounds them. Good interpreters are often aware when the healthcare provider and the patient do not have the same understanding of an event, concept, or plan. In this case, the translator should be sure to let each party know exactly what has been communicated. This feedback to each party is important so that the interpreter’s moral values don’t get projected onto the patient and unduly influence decisions made by the patient. Transparency is thus critical.

.....

You remember that low literacy is associated with poor outcomes.

Question 29.2.9 Which of the following is FALSE?

- A) Patients with low literacy have a 50% increased risk of hospitalization
- B) Only about half of all patients take medications as directed
- C) Low literacy is a stronger predictor of a person's health than race
- D) Low literacy is only an issue among minorities and immigrants

Answer 29.2.9 The correct answer is “D.” Poor health literacy skills are a stronger predictor of health status than a person's race, age, income, socioeconomic status, or employment. This relationship holds across different racial and cultural groups. Unfortunately, up to 90 million people in the United States have low literacy skills and many are ashamed to share this with their physicians. This can lead to “non-compliance” because patients cannot read prescriptions and other instructions. It is not surprising, then, that low-literacy patients have an increased risk of hospitalization. Make sure that patients ask and understand the answers to three simple questions: *What is my main problem? What do I need to do? Why is it important for me to do this?* Other suggestions to improve communication include (1) asking the patient to repeat instructions back to the physician (known as the “teach back”); (2) using basic, nonmedical language when talking to patients; and (3) allowing patients to talk uninterrupted at the beginning of the visit.

**HELPFUL TIP:**

Between 10% and 40% of low-income children have no books at home. A quarter of college-educated parents do not read to their young children daily. Reach Out and Read is a program designed to increase reading at home. You can employ this program to help with literacy by using the SAFER mnemonic: **S**how the book early in the visit, **S**hare the book with the child yourself (modeling the reading for the parents), **A**sk the parents about reading; **A**ssess the child's development and the parent-child relationship; give **F**eedback about what you've observed the child do and about parents' attitudes and interactions with the child, **E**ncourage the parents to read daily to the child; **E**xplain about literacy development. **R**efers to the library and literacy programs, and **R**ecord in the chart what you did. Other than giving a book and briefly reading to the child, you need not do all the activities at each visit. If your clinic is not involved in the program, you can get started at www.reachoutandread.org.

► Objectives: Did you learn to ...

- Describe ways in which you inquire about a patient's culturally related health beliefs?
- Define culturally responsive care and understand its importance?
- List some complications that can occur as a result of language barriers?

- Use interpreter services effectively and appropriately?
- Describe the state of health literacy in the United States and its impact on population health?

► CASE 29.3

You are seeing a 67-year-old Black male for the first time in your clinic. He claims to be healthy but has not seen a physician for over three decades. He says, “Doctors ... I try to avoid them. My wife made me come today.” You tell him you are going to take a history and then perform a physical examination on him. After you are done, you tell him you recommend age-appropriate screening examinations for colon and prostate cancers. The patient politely declines both. You try to explain the importance of screening to him.

Question 29.3.1 Which of the following statements about screening is INCORRECT?

- A) Prostate cancer is a leading cause of death among Black men
- B) Colon cancer is a leading cause of death among Black men
- C) There is clear evidence that screening for colon cancer reduces mortality in Black men
- D) There is clear evidence that screening for prostate cancer among Black men saves lives
- E) Prostate cancer disproportionately affects Black men

Answer 29.3.1 The correct answer is “D.” There is conflicting evidence for screening for prostate cancer and its effect on mortality (see Chapter 16). Prostate cancer is the fourth leading cause of cancer death overall in the United States, and the burden of prostate cancer varies among different racial and ethnic groups. Black men have about a 60% higher incidence and a 2.4-fold higher mortality rate from prostate cancer compared with White men. Compared with White men, mortality from prostate cancer is 17% lower in Latinxs and 55% lower in Asian Americans and Pacific Islanders.

Your patient now agrees to colon cancer screening but still declines prostate cancer screening (which you decide is fine because the evidence is conflicting and especially sparse for Black males). Your examination also revealed an elevated blood pressure (BP) of 160/90 mm Hg with no abnormal cardiac, lung, or other organ system findings.

Question 29.3.2 Assuming you confirm this elevated BP reading at subsequent visits, which of the following antihypertensives would you recommend?

- A) Hydrochlorothiazide
- B) Ramipril
- C) Minoxidil
- D) Atenolol
- E) Losartan

Answer 29.3.2 The correct answer is “A.” While thiazide diuretics are a good choice for most patients with hypertension, they are an especially good choice in Blacks, who tend to have extremely salt-sensitive hypertension. Blacks are more likely than other patients with hypertension to have low renin levels, which make them less likely to respond to ACE inhibitors. β -Blockers also tend to be less effective in Black patients. A reasonable second-line therapy in this patient would be a calcium channel blocker such as amlodipine.

.....
Your patient agrees to your medication choice, but he wants to know if the research on which you based your choice included Black people. You can confidently say yes, knowing that the ALLHAT trial specifically addressed the issue of generalizability by making sure that about a third of the 33,357 subjects were Black. However, you know this has not always been true in scientific research. In fact, you know that minorities are very underrepresented in research data on which we base our treatment choices.

Question 29.3.3 Which of the following is NOT a reason why there are few minorities in research studies?

- A) Past history of abuse leading to mistrust of the healthcare system
- B) Lack of representation of minorities in the medical profession
- C) Discrimination
- D) Overrepresentation of minorities in lower socioeconomic status
- E) Minorities are more likely to volunteer for studies but are generally excluded

Answer 29.3.3 The correct answer is “E.” Minorities’ contact with the medical system has been fraught with abuse in the past. Possibly the most egregious example of this is the Tuskegee Syphilis Study where Black men with syphilis were recruited for a naturalistic study of the disease in the 1930s. Over 400 Black men with syphilis were recruited with 200 men without syphilis as controls. There was no informed consent, and they were told the lie that spinal taps (done for research) were a form of treatment. It was soon apparent that the death rate among those with syphilis was about twice as high as it was among the controls. When penicillin was found to be effective as a cure for syphilis in the 1940s, the participants were neither informed nor offered treatment, so the naturalistic study could continue.

These and other examples of past mistreatment by the medical community may constitute a significant source of distrust (“A”) by minority patients, who are less likely to participate in research. There have also been overt and subtle discriminatory (“C”) barriers against minority participation in clinical trials. Minorities are more likely to come from lower socioeconomic groups and have less education (“D”), while research subjects are generally more educated and of higher socioeconomic status. Finally, there is a significant underrepresentation of minorities in the medical profession (“B”). For example, even though Blacks comprise 13% of the population, they are only about 6% of the physician population (and only about 7% of medical students are Black). All these problems lead to difficulties recruiting minority participants for research trials.

Question 29.3.4 As of 2010, what percentage of Americans belong to a minority group?

- A) 15%
- B) 20%
- C) 25%
- D) 36%
- E) 62%

Answer 29.3.4 The correct answer is “D.” According to the 2010 US Census estimates, 36% of Americans are ethnic minorities, up from 31% in 2000 and 24% in 1990. Yet, only 10% of physicians are from underrepresented minority groups. This is problematic. The lack of minority physicians leads to a discrepancy in healthcare access. Data shows that minority physicians are more likely to serve minority patients and are more likely to serve in urban, underserved areas.

HELPFUL TIP:

Patients of all ethnicities consistently rate their relationships with their physician better when their physician is of the same race/ethnic background (*JAMA* 1999;282(6):583–589).

So, everybody’s racist? Probably not—this phenomenon appears to be related to patient–physician communication and the patient’s perception of participation in their care.

We do need to be aware of “implicit bias”; however. We all have unconscious stereotypes and beliefs about groups that effects our patients treatment and relationships.

Question 29.3.5 Which of the following is NOT true?

- A) Patients living in a low socioeconomic neighborhood have an increased incidence of coronary artery disease
- B) Patients living in low socioeconomic neighborhoods have an increased incidence of asthma
- C) Patients of the same minority group with a low socioeconomic status have the same incidence of disease as those with a high socioeconomic status
- D) Very low-income Black children have a higher incidence of asthma than White children of the same socioeconomic status
- E) Patients from disadvantaged neighborhoods have a higher risk of developing most cancers and are less likely to receive aggressive treatment once diagnosed

Answer 29.3.5 The correct answer is “C.” Patients living in low socioeconomic neighborhoods have increased incidences of coronary artery disease, most cancers (lung, colon, cervical), diabetes, arthritis, accidents, adverse birth outcomes, and asthma. They are also likely to obtain overall less care, less aggressive care (except for limb amputations in diabetics), and are less likely to have evidence-based care. Minority patients with higher socioeconomic statuses tend to have better health when compared to their race-matched peers from lower socioeconomic statuses.

Question 29.3.6 In taking care of Black patients, all of these cultural patterns (not stereotypes) are helpful to keep in mind EXCEPT:

- A) Family relationships are extremely important
- B) Religion often has a role in the patient's life
- C) It is expected that physicians will call patients by their first name
- D) Food has important cultural significance
- E) Nonverbal communication is often as important as what is verbally communicated

Answer 29.3.6 The correct answer is “C.” People in the Black community often maintain extended family ties and view healthcare as a family responsibility (“A”). Therefore, physicians should consider enlisting the family's help in taking care of an ill family member.

Religion (“B”) is often an important aspect in Black culture and members of the clergy are highly respected in the community. Churches are often very helpful for community outreach efforts. Evidence exists that the use of churches to conduct preventive care services, such as immunizations and screening programs for illnesses, leads to better patient compliance with preventive guidelines. Some patients may view illness as a test of one's faith, and it is prudent for the physician to acknowledge and respect the patient's beliefs and perception of illness to the extent that it influences their seeking or receiving healthcare. People from lower socioeconomic backgrounds have little choice but to eat what is available at a low cost. This means our advice to patients to eat a well-balanced diet with fresh fruit, lean meat, and fresh vegetables may be met with some challenges due to access to these resources and familial and cultural traditions (“D”). Advising simple changes in diet including substituting fish or chicken for red meat in dishes, eating inexpensive raw vegetables, modifying cooking techniques, and changing to a vegetable-based rather than a meat-based diet may be more likely to be successful.

Communication is important, with individuals in the Black community being particularly attentive to nonverbal aspects of communication such as body language and voice inflection (“E”). Respect is also emphasized in the culture, and patients often like to be addressed by their formal titles and not their first names. Asking patients' permission to call them by their first names can be appreciated.

Information using real-life examples can be a useful communication tool, instead of cold, dry data, or written messages (this actually holds true for most patients of a variety of cultures!). A useful summary of general principles to keep in mind when caring for Black patients is found in an article on Preventive Care for African Americans by Witt et al. (2002). They are as follows:

- Gaining trust and understanding the historical distrust of the healthcare system.
- Understanding and employing the kinship web in decisions regarding screening and treatment.
- Involving the church in developing and delivering prevention and care messages.

- Asking patients about the meaning of words or phrases.
- Asking patients about the use of alternative medicines and herbs.
- Tailoring messages about prevention to depictions of real-life situations.
- Paying attention to body language and other nonverbal communication.

You have learned in medical school about the importance of behavior change in the management of chronic diseases like hypertension, heart disease, and diabetes, yet are frustrated that you have less success in patients who come from low socioeconomic backgrounds or from minority racial or ethnic groups.

Question 29.3.7 Which of the following behaviors or attributes is most strongly associated with your patient's health status:

- A) Physical activity level
- B) Health insurance coverage
- C) Dietary choices
- D) Socioeconomic status
- E) Tobacco use

Answer 29.3.7 The correct answer is “D.” All of the other choices do have an impact on overall health. However, socioeconomic status has the highest correlation with a patient's overall health. It's like U2 says in their song *God Part II*, “The rich stay healthy; the sick stay poor.” Socioeconomic status is a key driver of health status.

HELPFUL TIP:

Fresh produce is often not available or quite expensive in low socioeconomic neighborhoods (and good luck finding sustainably caught Copper River salmon). Predominantly White neighborhoods have four times as many supermarkets as predominantly Black and Latinx neighborhoods. These areas that are relatively devoid of grocery stores and/or stores with healthy foods are called “food deserts.” This makes dietary modification especially difficult.

► Objectives: Did you learn to ...

- Identify the impact of race on prevention and management of chronic diseases such as colon cancer screening and hypertension?
- Describe barriers to minority participation in research studies?
- Explain the impact of socioeconomic status on a patient's healthcare?
- Relate cultural patterns to the provision of healthcare education and services?

CASE 29.4

Your next two patients are a couple of Cuban friends who present to your office seeking a family physician to take care of their general health needs. They are both of Cuban descent, but one looks White and the other looks Black.

Question 29.4.1 Which of the following assumptions is correct?

- A) Latinx people are of one race
- B) Latinx people can all speak English
- C) Latinx people come from many different countries and can look different from one another
- D) Latinx people are not American
- E) Latinx people all like to be called Hispanic

Answer 29.4.1 The correct answer is “C.” The term “Latinx” denotes an ethnic group who shares some cultural practices but not necessarily other characteristics. Latinxs comprise a significantly diverse group who may or may not speak Spanish or English, may be of any race, hail from different countries of origin, have differing histories, socioeconomic status, and cultural identities. Further, some feel the term “Hispanic” is derogatory, suggesting European ancestry, and may prefer the term Latinx. Thirteen percent of the overall US population now identifies as Hispanic or Latinx, which makes this population the largest ethnic group in the United States. Latinxs come from a broad spectrum of socioeconomic backgrounds and a variety of living conditions in the United States, which has an enormous impact on immigrant and public health.

Despite the diversity represented within the Latinx culture, there exist shared values such as strong family ties, with families often tending to be large and extended. Families frequently serve as the main source of support and share in decision-making. Physicians with a warm bedside manner who demonstrate appropriate respect (especially to the elderly) are appreciated.

HELPFUL TIP:

Despite alarmist paranoia from some parts of our political spectrum, second-generation Latinx immigrants are as likely to speak English as were prior waves of immigrants from European countries. Don't even get us started on the absurd idea of building a wall. Ever hear of ladders?

Question 29.4.2 Which of the following is FALSE regarding health issues affecting the Latinx community?

- A) Infectious diseases are common
- B) Fear of deportation prevents some from seeking healthcare
- C) Latinxs are less likely to obtain preventative healthcare in comparison to Whites or Blacks
- D) Moving to the United States can paradoxically raise the risk for habits that lead to illness such as obesity and diabetes
- E) Elderly Latinxs have a higher mortality than their White counterparts

Answer 29.4.2 The correct, and false, answer is “E.” Recent immigrants are often prone to infectious diseases (“A”) due to inadequate housing, sanitation, and/or immunizations. Many reasons exist why patients may not get vaccinated. These include disbelief in the need for the vaccine, being unaware of the vaccine, lack of patient education by a healthcare provider, lack of transportation, and financial restrictions.

Immigrating to the United States can result in worse nutrition, obesity, a sedentary lifestyle, and an increase in smoking and risky sexual behavior in Latinas (women) (“D”). This translates, in part, into a twofold increased incidence of diabetes in Latinas. For Latinos (males), there is an increased risk of drug abuse, alcohol abuse, tobacco use, and driving under the influence. These risks increase the longer the patient lives in the United States.

Latinxs often fail to get preventive healthcare (“C”). For example, they have a lower rate of screening for diabetes and hypertension than Blacks or Whites. Some avoid presenting for healthcare because they fear being discovered by immigration authorities (“B”). Complementary and alternative practices are also common. Even though they are less likely to access healthcare, older Latinxs seem to have a similar or greater life expectancy than same-age Whites in the United States and enjoy lower mortality rates from cardiovascular diseases, cancer, and chronic illnesses. The risk of diabetes, however, is higher. This phenomenon has been described as “selective immigration” and implies a predilection for healthier individuals to immigrate to this country.

You get into a discussion on race with your new Cuban patients, and they point out several things to you that you had not thought of before.

Question 29.4.3 Which of the following is true about race?

- A) It is a valid biological construct
- B) It is interchangeable with ethnicity
- C) All members of a certain culture are the same race
- D) It is a purely social construct

Answer 29.4.3 The correct answer is “D.” Race is a much politicized and emotionally charged topic in the history of the United States. Since the late 18th and early 19th centuries, attempts have been made to validate race as being biologically based to justify discriminatory practices. However, the Human Genome Project demonstrated conclusively that there is NO biological basis for race. Humans share over 99.9% of their DNA, and one cannot tell a member of one “race” from another on the basis of genetics alone. To add a wrinkle: commercially available DNA tests can place a patient in an ancestral group and clarify geographic backgrounds of ancestors, but they cannot provide the context required to identify race. “B” is incorrect. While race and ethnicity are often used interchangeably, they are not necessarily equivalent. Race is an arbitrary social construct that is given to people based on visual appearance, while ethnicity refers to people with a common country of origin, a shared ancestry, or a common history. Culture refers to a specific set of values, beliefs, and customs shared by members of a community. “C” is obviously incorrect. People from the same

culture can be of different races, so one can see White and Black Latinxs from Cuba, for example.

Question 29.4.4 Which of the following health outcome disparities is FALSE?

- A) White Latinxs have a higher incidence of breast and colorectal cancer than Blacks and Non-Hispanic Whites
- B) Clinicians may order fewer diagnostic tests if they do not understand a patient's description of symptoms
- C) Clinicians may over-compensate by ordering more tests when they do not understand what their patients are saying
- D) Minority children are more likely to be evaluated and reported for suspected abuse even after controlling for likelihood of abusive injury
- E) Blacks have the highest colorectal cancer mortality rates of any group in the United States

Answer 29.4.4 The correct answer is "A." The incidence of colorectal and breast cancer is actually lower in White Latinxs than in other Non-Hispanic Whites and Blacks. However, this does not always translate into less significant disease. There are significant disparities in healthcare quality and outcomes for minorities compared with nonminorities, even when controlling for possible confounding factors, such as income, education, and insurance. So even though Latinxs have a lower incidence of the above-named cancers, they have a similar mortality when compared with non-Latinxs. All of the rest of the statements are correct. Of particular note, Blacks have the highest colorectal cancer mortality rates. Also, of note is the fact that when toddlers of different races present with similar fractures, minority toddlers are significantly more likely to be reported for suspected abuse, even after controlling for age, insurance status, and likelihood of abuse. This is a reflection of biases and stereotyping.

HELPFUL TIP:

Minority patients are significantly less likely to receive appropriate pain medication, even after surgery and for long bone fractures. Additionally, there are often few, if any, pharmacies in poor, inner city areas that have opioids available for patients with a prescription. This adversely affects the pain management of minority patients even further.

In general, mortality rates among racial and ethnic minorities are higher for cancer, heart disease, diabetes, stroke, kidney failure, and HIV/AIDS. Minority groups are also disproportionately affected by asthma, lead poisoning, accidents, homicides, and other environmental health concerns. Some minorities experience higher infant mortality rates and are less likely to receive timely prenatal care. There are numerous other examples of healthcare disparities that exist between majority and minority groups. These include but are not limited to:

- Infant death rates for Blacks are twice that of Whites.
- Heart disease mortality rates are 40% higher in Blacks as compared with Whites.

- Latinxs are almost twice as likely as Whites to die from diabetes and are more likely to be obese and have high blood pressure than are Non-Hispanic Whites.
- Blacks are 13% less likely to undergo coronary angioplasty and one-third less likely to undergo bypass surgery than are Whites.
- Only 7% of Black and 2% of Latinx preschool children hospitalized for asthma are prescribed routine medications to prevent future hospitalizations compared with 21% of White children (not in itself a good reflection on our profession).
- The length of time between an abnormal screening mammogram and follow-up diagnostic testing is more than twice as long for Asian American, Latinxs, and Blacks compared with Whites.
- Minorities are less likely to get immunizations, mammograms, and other preventive care, even when paid for by Medicare.
- There are higher rates of uninsured and lack of physicians in minority communities, leading to reduced access to primary care.
- Minorities are less likely to get heart catheterizations, bypass grafting, dialysis, lung cancer surgery, and organ transplants.
- Blacks have 55% higher mortality rate and 6-year shorter life expectancy than Whites.
- Several studies show the deleterious effect of discrimination on health outcomes, including increasing the risk of diabetes, hypertension, depression, and preterm birth independent of other risk factors.

HELPFUL TIP:

Although perhaps not overtly racist, there is data that suggests that unconscious biases can affect our care of patients. A well-known study in the NEJM in 1999 found that, all things being equal, physicians were **60% less likely** to refer Black women for cardiac catheterization than men and Whites. Hopefully, by being made aware of this unconscious bias, its effect can be mitigated and better care provided to all patients.

► **Objectives: Did you learn to ...**

- Describe some health disparities based on race, culture, and ethnicity?
- Delineate the differences between the terms race, culture, and ethnicity?

► **CASE 29.5**

A 35-year-old comes to your office today to establish care with you. You see the first name of "Jennifer" is on the medical record. The patient is wearing a suit and tie and has a male style haircut. The gender listed on the medical record for this patient is female. Clearly the gender identity of this patient does not match the patient's gender designated at birth.

Question 29.5.1 How do you establish rapport with this patient and use correct terminology?

- A) Ask the patient first thing, "Are you a man or a woman?"
- B) Use the name Jennifer as well as female pronouns she/her/hers
- C) Introduce yourself and your preferred pronouns, and ask the patient for their name and preferred pronouns
- D) Say that you are glad they are here and that you have never had a patient "like them" before
- E) Ask if he is from Iowa as you have heard Iowa is actually a pretty progressive state (or was until our conservative legislature overturned many of the gains made)

Answer 29.5.1 The correct answer is "C." Biological gender, gender identity, and gender expression are all different. Biological gender is defined by one's chromosomes, hormones, and reproductive organs. The assignment of gender is generally done at birth based on the appearance of external genitalia. Some newborns might be born with ambiguous genitalia but are assigned a sex at birth of either male or female. Gender identity is a person's innate, deeply felt psychological identification, which may or may not correspond to the sex assigned to them at birth. Gender expressions are the external characteristics and behaviors that are socially defined such as dress, grooming, mannerisms, and speech patterns. These can widely vary and are accepted as masculine, feminine, or neutral. Transgender is an umbrella term for people whose gender identity is incongruent from the sex assigned to them at birth. It is important to maintain respect for patients who identify as transgender in order to establish rapport and better care for the patient. Using preferred names and pronouns is extremely important in helping to establish respect. A good way to introduce yourself to a patient would be: "My name is Dr. X, my preferred pronouns are she/her/hers or he/him/his (or other); what are your name and preferred pronouns?"

**HELPFUL TIP:**

Transitioning is the process that some transgender people go through to begin living their affirmed gender identity. This may or may not include changing physical appearance and dress, initiating hormone therapy, and undergoing gender confirmation procedures and/or surgery. Treatment for transgender persons, including hormone therapy and surgery, has been deemed medically necessary to treat gender dysphoria. As with every community, there is a great deal of diversity within the transgender community, and each transgender person's transition is unique and may or may not include everything listed.

Jennifer indicates she actually prefers to go by female pronouns as she is of the female *biological sex*. However, she also prefers to identify and express herself as male *gender* at times. She returns to your office for an annual physical examination. She discloses on her intake form that she is in a long-term, monogamous relationship, but the sex of the partner is

not asked on your intake form (which needs updating!) and thus isn't specified for you. She has regular periods and is not currently on birth control.

Question 29.5.2 Which of the following questions should you ask the patient:

- A) "Are you using condoms with sexual activity?"
- B) "What does your boyfriend/husband do for a living?"
- C) "Would you like a pregnancy test today?"
- D) "Are you sexually active with men, women, or both?"
- E) You don't address the subject as you assume she is sexually active and already using protection to prevent pregnancy as she is in a stable relationship

Answer 29.5.2 The correct answer is "D." It can be very uninviting to patients when assumptions are made about the gender of the patient's sex partner(s). Knowing the patient's sexual identity (gay/lesbian, bisexual, heterosexual) as well as their past, current, and anticipated future sexual partner(s) and behavior is essential to providing comprehensive preventative screening and guidance. It is important to not assume the sexual identity or behavior of the patient, but rather ask a complete sexual health history prior to offering treatment or care to the patient.

► Objectives: Did you learn to ...

- Describe the differences between biological sex, gender identity, and gender expression?
- Establish rapport by eliciting preferred pronouns?
- Obtain an appropriate sexual history without making assumptions regarding the patient's gender and sexual identities?

► CASE 29.6

You are on the board of your hospital's quality and safety committee and you have been asked to address the issue of a medication error. Ms. Jones, a 72-year-old patient with diabetes who was hospitalized for an acute myocardial infarction, died from what seems to be a sudden cardiac event. This was unexpected as she was recovering rather well. One of the nurses on the floor had told her supervisor that your partner, Dr. McTremble, had written an order for 6.0 U of insulin; but the new nurse, fresh out of nursing school, had misread this as 60 U of insulin and had proceeded to give the poor lady that amount, precipitating the hypoglycemic event that led to her death. The nurse is distressed as she thought she was only following orders. Around your office, Dr. McTremble's handwriting is a thing of legend: many pharmacists have had to call to double-check his prescriptions on more than one occasion. Time to move to electronic prescribing...

Question 29.6.1 Which of the following would have been an effective way to prevent the type of error that occurred?

- A) The nurse should have called to confirm the dose of insulin before giving it
- B) Writing out "units" rather than "U" and "6" instead of "6.0"

- C) Use of computerized physician order entry
- D) Having a clinical pharmacist as part of the team
- E) All of the above

Answer 29.6.1 The correct answer is “E.” It is estimated that between 44,000 and 98,000 deaths annually are attributable to medical errors, most of which are preventable. Although the numbers have been challenged, it is indisputable that medical errors continue to contribute to adverse outcomes in our patients. One of the most significant contributors to serious errors is mistakes in dosing and administering medication. One of the leading causes of medication errors is the use of potentially dangerous abbreviations and dose designations. The use of “U” as above has been reported in the literature to be problematic as it can easily be misread as a zero or a four, leading to up to 10-fold overdoses that can often have terrible consequences in patients using insulin. A decimal point may not be seen, leading to a factor 10 error (60 units of insulin being given rather than 6).

Question 29.6.2 Which of these would NOT be recommended as a way to prevent prescription errors (we will give you this one)?

- A) Computerized order entry systems
- B) A brief notation of the purpose for the prescription
- C) Metric system for all therapies except those like insulin and vitamins that use standard units
- D) Inclusion of age, and when appropriate, weight of the patient
- E) A trailing zero after a decimal

Answer 29.6.2 The correct answer is “E.” Nurses and pharmacists may not see the decimal point and thus give an order of magnitude higher dose of medication. All of the other options are recommended to help decrease medication errors and, thus, adverse patient events.

► **Objective: Did you learn to ...**

- Recognize some causes of medication errors and ways to prevent them?

QUICK QUIZ: HIPAA, HIPAA, HOORAY!

Which of these is prohibited by Health Insurance Portability and Accountability Act (HIPAA)?

- A) Calling out patients' names in the waiting room
- B) Leaving a message on a patient's answering machine or voicemail
- C) Releasing health information to a specialist without patient authorization if that information is to be used for purposes of treatment, payment, or health operations
- D) Faxing patient information
- E) None of the above

The correct answer is “E.” Since the HIPAA went into effect, many physicians have been confused as to what they can and

cannot do under the HIPAA law. Providers can still call out patients' names in the waiting room (“A”) as long as you do not go into particulars of their presenting complaint in front of other people (e.g., don't say to the whole waiting room, “Ms. Smith, I'm ready to check on your herpes infection”). You may leave a message on a patient's voicemail (“B”) if the patient has authorized you to do so. You may fax information (“D”) once you verify the fax number is correct—but you can only fax to persons the patient designates or consents to. If you fax health information to a wrong number, you are responsible and could be violating HIPAA. Finally, HIPAA gives physicians broad leeway in sharing information with other physicians, provided the information is used for treatment, payment, and healthcare operations (“C”). You must give a notice of your privacy practices to the patients and ask them to sign a form acknowledging receiving the notice or make a good-faith effort to get them to sign it.

Clinical Pearls

- Always offer interpreter services to a patient if you do not speak their language. When using an interpreter, maintain eye contact with and address questions to the patient.
- Do not overestimate the legal authority of the Health Insurance Portability and Accountability Act (HIPAA). Transmission of protected information is allowable for ongoing patient care.
- Do not make assumptions about sexuality or gender. Simply ask. Same goes for race, ethnicity, etc.
- Everyone possesses unconscious biases. Unconscious biases affect the care of patients. Simply recognizing these biases may mitigate their detrimental effects on patient care.
- Gender identity and gender expression are affected by but are separate from sex assigned at birth. Ask transgender patients their preferred pronouns.
- In addressing nonadherence, consider a patient's cultural background and enquire into how their cultural beliefs may conflict with those of traditional Western medicine.

Final Examination

Mark A. Graber, Jason K. Wilbur, and Brigit E. Ray

This is your final examination. See how you do. ...

1) Which of the following IS NOT an *absolute* contraindication to cardiac exercise testing?

- A) Unstable angina
- B) Recent pulmonary embolism
- C) Active pericarditis
- D) Left bundle branch block

See question 2.2.2.

2) Which of the following is the preferred antiplatelet drug for treating chest pain in the emergency department?

- A) Aspirin 81 mg PO
- B) Aspirin 325 mg PO
- C) Clopidogrel 75 mg PO
- D) Clopidogrel 300 mg PO
- E) Abciximab (ReoPro, a glycoprotein 2B/IIIa inhibitor)

See question 2.1.4.

3) This ECG, shown in Figure 30-1, represents a(n):

- A) Inferior wall MI
- B) Anterior wall MI
- C) Inferolateral MI
- D) Normal ECG
- E) Pericarditis

See question 2.17.3.

4) The most appropriate initial treatment of this rhythm in a stable patient, shown in Figure 30-2, is:

- A) Amiodarone
- B) Adenosine
- C) Diltiazem
- D) Lidocaine

See question 2.3.5.

5) You admit a patient to the hospital after an episode of chest pain. The patient has a history of chronic kidney disease stage 4, type 2 diabetes mellitus, hypertension, hyperlipidemia, and obesity. At time of admission, troponin is elevated at 0.06 (normal <0.03). The medical student rotating with you on her family medicine clerkship asks the significance of the elevated troponin. You tell her which of the following?

- A) An elevated troponin is always indicative of cardiac ischemia/infarct
- B) Troponin rises after creatine phosphokinase (CPK) and stays elevated for a longer period of time
- C) Pulmonary embolism and renal failure are two causes of an elevated troponin
- D) CPK is overall the most sensitive (but not specific) cardiac marker for cardiac ischemia

See question 2.1.2: Helpful Tip.

6) Which of the following is true in a patient with known coronary artery disease?

- A) A coronary calcium score will help to risk stratify this patient
- B) The LDL goal is 90 mg/dL or less
- C) A high sensitivity CRP (hsCRP) will help to risk stratify this patient
- D) There is no LDL goal. Just start a maximal dose of a statin at time zero; there is no need to titrate the statin up

See questions 2.22.3 and 2.22.6: Helpful Tip.

7) Which of the following IS NOT a contraindication to the use of tPA in MI?

- A) Blood pressure of >180/110 mm Hg
- B) Noncompressible vascular puncture (e.g., subclavian line)
- C) Major surgery within 3 weeks
- D) Menstrual bleeding

See question 2.1.10 and Table 2-1B.

FIGURE 30-1. Figure for Question 3.

FIGURE 30-2. Figure for Question 4.

8) Which of the following IS NOT necessary for a class 1 indication for tPA in a patient with an acute myocardial infarction?

- A) Greater than 1 mm ST elevation in 2 or more contiguous leads
- B) Pain for less than 2 hours
- C) Age <75
- D) New complete left bundle branch block and typical history suggestive of MI

See question 2.1.10 and Table 2-1A.

9) Your patient has an elevation of his liver function tests (LFTs) after starting an HMG-CoA reductase inhibitor (i.e., statin). When would you consider stopping this patient's HMG-CoA reductase inhibitor?

- A) Doubling of LFTs
- B) Tripling of LFTs
- C) Quadrupling of LFTs
- D) Only when there is biopsy evidence of bridging fibrosis

See question 2.22.7.

10) Which medication(s) is (are) indicated in a patient with atrial fibrillation and a CHA2DS2-VASC score of 3?

- A) Aspirin
- B) Warfarin, rivaroxaban, dabigatran, or apixaban
- C) Aspirin-dipyridamole (Aggrenox)
- D) Clopidogrel

See question 2.4.1 and Table 2-6B.

11) Which of the following DOES NOT improve cardiovascular mortality in systolic heart failure (heart failure with reduced ejection fraction or HFrEF)?

- A) Digoxin
- B) Spironolactone
- C) ACE inhibitors
- D) Beta-blockers

See question 2.7.7.

12) Which statement is true regarding gastric lavage in a patient with a toxic ingestion?

- A) Gastric lavage is of benefit even if it has been more than 1.5 hours, but less than 4 hours, since the ingestion
- B) Gastric lavage should be done until the returned material is clear (maximum of 10 L)
- C) Gastric lavage is associated with esophageal injury and aspiration
- D) Gastric lavage is indicated for petroleum distillates within 1 hour of ingestion

See question 1.1.2.

13) Human papilloma virus (HPV) vaccine is indicated for all of the following EXCEPT:

- A) All otherwise healthy 11- to 12-year-olds (boys and girls)
- B) A 47-year-old female who has never been sexually active
- C) An 18-year-old male with known HPV
- D) Immunosuppressed 15-year-old female who is HIV positive
- E) A 22-year-old female with cervical dysplasia

See question 14.5.3.

14) Topical tretinoin (Retin-A) is most effective in what kind of acne?

- A) Cystic/nodular
- B) Inflammatory papular
- C) Pustular
- D) Comedonal

See question 17.8.3: Helpful Tip.

15) In a study of drug A, 50% of patients in the treatment arm benefit versus 25% in the placebo group. What is the number needed to treat?

- A) 2
- B) 4
- C) 6
- D) 8

See question 28.3.1.

16) You are seeing a 27-year-old male in your clinic for evaluation of a rash which began about 2 days ago and is erythematous and macular with a pale center. He notes the rash itches. He denies any new lotions or creams. He has had recent cold-like symptoms including a sore throat. He has a past history only notable for chicken pox as a child. He is sexually active with several female partners. You diagnose him with erythema multiforme. He asks what could have triggered this. You counsel him that the *most* common cause of erythema multiforme is:

- A) Herpes zoster
- B) Streptococcal pharyngitis
- C) Genital herpes
- D) Rhus exposure ("poison ivy")

See Chapter 17 Quick Quiz: Erythema Multiforme.

17) "Sensitivity" is best defined as:

- A) True positive rate/(true positive rate + false negative rate)
- B) True positive rate/(prevalence of disease)
- C) True positive rate/(true positive rate + true negative rate)
- D) True positive rate/(true positive rate + false positive rate)

See Case 28.6.

18) Which of the following is true regarding isotretinoin (Accutane)?

- A) Women should be on one form of birth control before using this drug
- B) Pregnancy should be avoided for 3 months after discontinuation of this drug
- C) Monthly pregnancy tests should be done on all women of reproductive age
- D) Isotretinoin may increase the HDL

See question 17.8.4: Helpful Tip.

19) In general, what will happen with an innocent flow murmur during a Valsalva maneuver?

- A) It gets louder
- B) It gets softer
- C) It is unchanged in volume
- D) The sound becomes more harsh
- E) It disappears entirely

See question 14.3.1.

20) What blood level of morphine is the most appropriate when treating pain from a terminal cause?

- A) 1 µg/dL
- B) 5 µg/dL
- C) 10 µg/dL
- D) Blood levels are irrelevant in determining the appropriate dose of morphine

See question 27.2.4: Helpful Tip.

21) Which of the following is NOT seen with an anticholinergic overdose?

- A) Dry, flushed skin
- B) Miosis
- C) Confusion
- D) Low-grade fever

See Chapter 1 Quick Quiz: Toxidromes and Table 1-1.

22) Which of the following IS NOT a cause of an elevated anion gap acidosis?

- A) Methanol and other ingestions (e.g., salicylate)
- B) Diabetic ketoacidosis
- C) Uremia
- D) GI bicarbonate loss

See question 1.4.3 and Table 1-3.

23) Reperfusion of extremities in hypothermia can cause all of the following EXCEPT:

- A) Acidosis
- B) Hypokalemia
- C) Paradoxical central temperature drop
- D) Arrhythmia

See question 1.12.3.

24) What is the appropriate course of action after treating a child with croup with inhaled epinephrine?

- A) Admission for observation
- B) Admission if room air oxygen saturation is less than or equal to 95%
- C) Observation for 12 hours followed by discharge if stable
- D) Observation for 2 hours followed by discharge if stable

See question 1.24.5.

25) Which of the following is NOT included in the “Coma Cocktail” for the unconscious patient?

- A) Glucose
- B) Thiamine
- C) Naloxone (Narcan)
- D) Flumazenil (Romazicon)

See question 1.20.1.

26) Which of the following is indicated in the child with croup (laryngotracheobronchitis) presenting to the emergency department?

- A) Amoxicillin
- B) Azithromycin
- C) Dexamethasone
- D) Oral theophylline

See question 1.24.4.

27) You are evaluating a 22-year-old woman in the ED who presents with left-sided pelvic pain. She is sexually active with men and does a poor job of remembering her oral contraceptive; condom use is only sporadic. Her last menses was 6 weeks prior. You are concerned about a possible ectopic pregnancy. Which of the following is true?

- A) A negative pregnancy test effectively rules out ectopic pregnancy
- B) Absence of an adnexal mass effectively rules out ectopic pregnancy
- C) Every woman of reproductive age with a uterus in the ED with abdominal pain is pregnant until proven otherwise
- D) The hCG should double every 5 days early in a normal pregnancy. Any less than this is indicative of an ectopic pregnancy

See questions 1.19.1 and 1.19.4.

28) Which of the following is the one best drug indicated for dyspnea in the terminally ill patient?

- A) Buccal scopolamine
- B) Lorazepam or other benzodiazepine
- C) Morphine or other opiate
- D) Nebulized lidocaine
- E) Albuterol via inhaler

See question 27.1.6.

29) What is the one best drug to reduce headache and confusion secondary to CNS tumor with surrounding edema?

- A) Acetaminophen
- B) Dexamethasone
- C) Morphine
- D) Sumatriptan

Chapter 27 Quick Quiz: More than a little headache.

30) You are called by an anxious mother about her 3-year-old daughter who accidentally ingested lemon-lime smelling household cleaner at her grandparent's house thinking it was soda. Mom has been instructed by her parents, who were born in the late 1950s, that she should give ipecac to induce vomiting of the substance. You counsel her that ipecac:

- A) Should not be used
- B) Can be used if the ingestion may cause mental status changes
- C) Is effective if used within 30 minutes of an ingestion
- D) Is available over the counter in American pharmacies

See questions 1.1.1 and 1.22.5.

31) How frequently should methadone be dosed when used for pain control in the terminally ill?

- A) Once daily
- B) Every 8 to 12 hours
- C) Every 4 to 6 hours
- D) Methadone should not be used for pain management in the terminally ill

See question 27.2.6: Helpful Tip.

32) A 46-year-old male presents to clinic for evaluation of left shoulder pain. He has been taking over-the-counter ibuprofen 600 mg every 8 hours for the last 4 weeks. He is wondering if there are any possible long-term side effects of taking this medication. Most notably, he is concerned, as his wife has told him that ibuprofen can "tear up the gut." You tell him that NSAIDs, such as ibuprofen, can cause ulceration in:

- A) The stomach
- B) The duodenum
- C) The colon
- D) All of the above

See question 7.4.5: Helpful Tip.

33) What is true about the treatment of gastroesophageal reflux disease (GERD)?

- A) Treatment of *Helicobacter pylori* is effective in curing GERD
- B) Treatment should always start with a proton pump inhibitor
- C) Surgical options (e.g., fundoplication) are often suboptimal with patients still requiring medication
- D) Esomeprazole is vastly superior to omeprazole

See questions 7.1.3 and 7.1.4.

34) Which of the following is true regarding Barrett esophagus?

- A) All patients with GERD should have an endoscopy to stage their disease vis-à-vis Barrett esophagus
- B) Barrett esophagus is a change from the normal columnar epithelium to squamous epithelium
- C) Barrett esophagus is present in >50% of patients with GERD
- D) Barrett esophagus can regress with adequate treatment of GERD

See questions 7.1.2 and 7.1.5.

35) Which of the following lesions is considered premalignant on colonoscopy?

- A) Inflammatory polyps
- B) Hyperplastic polyps
- C) Tubular adenoma/adenomatous polyps
- D) Hamartomatous polyps

See question 7.5.4: Helpful Tip.

36) Which of the following histories in a patient with GERD is most concerning for serious underlying disease?

- A) Food bolus impaction on two separate occasions
- B) Dysphagia to solids followed in several months with dysphagia to liquids
- C) Reflux of undigested food at night
- D) Halitosis

See question 7.1.1.

37) Which of the following is NOT an appropriate test of cure for *H. pylori*?

- A) Stool antigen test done 1 month after finishing treatment
- B) Serum antibody test done 3 months after finishing treatment
- C) CLO test done 1 month after finishing treatment
- D) Breath urea test done 1 month after finishing treatment

See question 7.4.5.

38) Which of the following is true about a gastric feeding tube in the demented elderly?

- A) It increases the patient's quality of life
- B) It reduces the risk of pneumonia
- C) It reduces mortality
- D) It does nothing to improve quality of life but can cause complications

See question 21.5.14.

39) Which of the following is NOT a component of CREST syndrome?

- A) Calcinosis
- B) Renal failure
- C) Esophageal dysmotility
- D) Sclerodactyly
- E) Telangiectasia

See question 11.10.4.

40) Which of these drugs is indicated for control of an acute flare of Crohn disease?

- A) Any 5-ASA moiety
- B) Oral prednisone
- C) Sulfasalazine
- D) Thalidomide
- E) Metronidazole

See questions 7.6.4 and 7.6.5.

41) Which of the following is a contraindication to use of sulfasalazine in Crohn disease?

- A) Aspirin allergy
- B) Heme-positive stools
- C) Fever
- D) Platelet count <100,000

See question 7.6.6.

42) Which of the following is the best screening test for hepatitis C virus (HCV)?

- A) Quantitative HCV PCR
- B) Hepatitis C antibody
- C) Recombinant Immunoblot Assay (RIBA)
- D) Qualitative HCV PCR

See question 7.10.1.

43) Which of the following is the most specific test for gluten enteropathy (nontropical sprue)?

- A) Antiendomysial IgA antibody
- B) Tissue transglutaminase antibody
- C) Antigliadin antibody
- D) Hydrogen breath test

See question 7.8.4.

44) *C. difficile* colitis has been linked to all of the following EXCEPT:

- A) Hospitalization
- B) Use of fluoroquinolones
- C) Use of PPIs
- D) Use of H₂ blockers
- E) Use of metronidazole

See question 8.2.3: Helpful Tip.

45) You are seeing a 25-year-old female who works at a day care where there was a recent *Giardia* outbreak. She has been experiencing diarrhea, malaise, and nausea. You are concerned she may have contracted *Giardia*. Which of the following is recommended for treating *Giardia*?

- A) Metronidazole
- B) Vancomycin
- C) Ciprofloxacin

- D) Azithromycin
- E) Mebendazole

See question 7.8.2: Helpful Tip.

46) You recently diagnosed a 30-year-old female with celiac disease. She is wondering what foods she should avoid. Which of the following foods DOES NOT contain gluten?

- A) Wheat
- B) Rye
- C) Sticky (glutinous) Rice
- D) Barley

See question 7.8.6.

47) Which of the following tests is the most sensitive for the diagnosis of bacterial overgrowth syndrome (of the GI tract)?

- A) Urea breath test
- B) D-Xylose breath test
- C) Hydrogen breath test
- D) CLO test

See question 7.8.3.

48) Treatment of hepatitis C with interferon is indicated as primary therapy for which of these patients?

- A) Genotype 1
- B) Genotype 2
- C) Genotype 3
- D) Interferon is no longer recommended as a primary therapy

See question 7.10.6.

49) Routine prenatal screening in the first trimester includes all of the following EXCEPT:

- A) Blood type and antibody screen
- B) Hepatitis B surface antigen
- C) HIV antibody
- D) MSAFP (maternal serum alpha-fetoprotein)
- E) Rubella antibody

See question 15.1.7: Helpful Tips.

50) A 22-year-old G2 P2 female is ready to leave the hospital on postpartum day 2 after a normal spontaneous delivery, but she develops lower abdominal pain and fever. She denies urinary symptoms. She reports constipation and moderate lochia. Her temperature is 38.8°C. She had prolonged rupture of membranes and prolonged labor, and the placenta was removed manually. The most appropriate course of action now is:

- A) Discharge with acetaminophen for fever and follow-up in 2 days
- B) Discharge with amoxicillin and follow-up in 2 days

- C) She likely has endometritis. Keep the patient in the hospital and obtain cultures for gonorrhea and chlamydia. Start oral penicillin
- D) She likely has endometritis. Keep the patient in the hospital and start IV gentamicin and clindamycin
- E) Manual exploration of the uterus for retained placenta

See question 15.2.9.

51) A 21-year-old G0 female presents for a physical examination and her first Pap smear. She has recently become sexual activity and has one lifetime partner. The results of the Pap smear show low-grade squamous intraepithelial lesion (LSIL). In accordance with guidelines, you recommend:

- A) Immediate colposcopy
- B) Immediate referral for excisional procedure
- C) Return in 12 months for Pap smear
- D) Do HPV on current sample and if negative, return in 3 years for Pap smear
- E) Return in 6 months for colposcopy and Pap smear

See question 15.12.8: Helpful Tip.

52) A 48-year-old female presents with menopausal symptoms. She has had a total hysterectomy but her ovaries are intact. She would like to know the benefits and risks of taking estrogen-only hormone replacement therapy (HRT). You tell her that estrogen-only HRT is associated with:

- A) Decreased risk of myocardial infarction
- B) Decreased risk of ovarian cancer
- C) Increased risk of colon cancer
- D) Increased risk of osteoporosis
- E) Increased risk of stroke

See question 15.14.3.

53) A 25-year-old G5P4 female at 28 weeks of gestation presents to labor and delivery with abdominal pain. The pain is sharp or tearing and located in her lower abdomen. She has not had any contractions. She just began to have a little vaginal spotting before she came in. Her pregnancy has been complicated by tobacco use and hypertension. What is the most likely diagnosis?

- A) Cervical cancer
- B) Normal labor
- C) Placenta previa
- D) Placental abruption
- E) Uterine rupture

See question 15.2.1: Helpful Tip.

54) The USPSTF recommends screening for osteoporosis in:

- A) All adults aged 65 and older
- B) All men aged 75 and older
- C) All women aged 65 and older

- D) All women at onset of menopause
- E) Women who smoke at age 50 and older

See question 21.2.3.

55) A 79-year-old male presents with his wife who complains that he has been more forgetful over the past month. The patient agrees and complains of forgetting where he put things, where the car is parked, and names of acquaintances. Also, he is more irritable and angers easily. He has trouble sleeping, and he has lost 5 lbs. He is healthy and takes no medications. He has poor eye contact, a blunted affect, and poor concentration. Neurologic exam is intact. His vitals and physical examination are otherwise normal. He can recall three items and draw a clock with no difficulty. The most likely cause of his symptoms is:

- A) Delirium due to metastatic carcinoma
- B) Delirium due to underlying systemic infection
- C) Delirium due to Alzheimer disease
- D) Dementia due to stroke
- E) Depression

See question 21.5.2.

56) You are considering treating a 65-year-old male with supplemental testosterone due to low serum testosterone levels associated with fatigue, muscle weakness, and mild depression. After initiating testosterone, it is most important to check which of the following?

- A) Creatinine
- B) Hemoglobin
- C) Potassium
- D) Sodium

See question 16.7.3.

57) Delirium in the hospitalized elderly patient can be prevented by implementing all of the following interventions upon admission EXCEPT:

- A) Assuring patient has access to usual aides (hearing aids, glasses, etc.)
- B) Early mobilization
- C) Lorazepam 1 mg QHS
- D) Noise reduction at night
- E) Orientation stimuli

See questions 21.3.4 and 21.3.5.

58) A 75-year-old male with mild dementia, atrial fibrillation (not on anticoagulation), osteoarthritis, and depression presents after sustaining a fall in his home 1 week ago. His son states, "He is a little banged up but otherwise fine." Your routine evaluation should include all of the following EXCEPT:

- A) Asking about potential neglect and abuse
- B) CT scan of the brain

- C) Medication review
- D) Neurological examination
- E) Observation of the patient ambulating

See questions 21.4.1 and 21.4.2.

59) A 75-year-old female fell and injured her hip. She did not fracture it but has significant pain. She has a remote history of peptic ulcer disease. She takes lisinopril for hypertension and phenytoin for a seizure disorder. Which analgesic medication will be safest to initiate in this patient for her moderate pain?

- A) Aspirin
- B) Meperidine
- C) Acetaminophen
- D) Piroxicam
- E) Fentanyl transdermal patch

See question 21.6.2.

60) An 80-year-old female nursing home resident with dementia recently started refusing medication and slapping at the staff when they try to bathe her. The nurse at the care center calls to request “something for her agitation.” As the safest and most effective intervention, you recommend:

- A) A behavior log to track when the agitation occurs and what might be causing it
- B) Haloperidol 1 mg IV prior to bathing and medication administration
- C) Haloperidol 1 mg PO BID
- D) Restraints with bathing
- E) Alprazolam 1 mg PO TID

See question 21.6.9.

61) The most appropriate next step for a 60-year-old male with a PSA level 12.5 ng/mL (normal range <4.0) is:

- A) One month of a fluoroquinolone followed by repeat rectal examination and PSA
- B) Referral for prostate biopsy
- C) Repeat PSA in 6 to 12 months
- D) Transrectal ultrasound of the prostate
- E) Treatment of benign prostatic hyperplasia with terazosin

See question 16.8.3.

62) A 33-year-old male with depression had been taking paroxetine 60 mg daily for a year for depression. Due to sexual problems, he decided to try another medication, and his doctor prescribed bupropion. He stopped the paroxetine one day and started bupropion the next. He comes in 5 days later feeling dizzy, nauseated, and fatigued. He complains of myalgias, feelings of “electric shocks,” and insomnia. These symptoms are most likely due to:

- A) Adverse effects of bupropion
- B) Hyperthyroidism
- C) Major depression

- D) Serotonin syndrome
- E) Discontinuation of paroxetine

See question 23.9.1 and Table 23-1.

63) Concussion is defined as:

- A) A disturbance in brain function caused by trauma
- B) A traumatic event resulting in the loss of consciousness
- C) A neurologic symptom that does not resolve within the first 24 hours of a traumatic injury
- D) Absolutely any trauma involving the head and/or neck

See question 14.8.1: Helpful Tip.

64) A 17-year-old female runner with secondary amenorrhea should be further evaluated with all of the following EXCEPT:

- A) Assessing calcium intake
- B) MRI of the pituitary
- C) Screening for eating disorders
- D) Urine beta-hCG

See questions 14.2.2 and 14.2.4.

65) Gynecomastia in an adolescent male occurs as a response to which of the following mechanisms?

- A) Excessive dehydroepiandrosterone
- B) Excessive estrogen compared with testosterone
- C) Excessive growth hormone
- D) Excessive progesterone compared with testosterone
- E) Rapidly developing obesity

See question 16.5.2.

66) Treatment of a patient in diabetic ketoacidosis (DKA) includes all of the following EXCEPT:

- A) Aggressive volume replacement
- B) Frequent glucose monitoring
- C) Insulin
- D) Potassium
- E) Sodium bicarbonate

See questions 10.9.1 and 10.9.4.

67) A 30-year-old male presents with difficulty obtaining an erection sufficient for penetration. He has acid reflux and takes cimetidine. He reports a good relationship with his wife and denies depression. He does not smoke and rarely drinks alcohol. The most appropriate intervention at this time is:

- A) To order a testosterone level
- B) To perform cardiac stress testing
- C) To refer him to a urologist
- D) To replace cimetidine with omeprazole
- E) To send him to a psychologist

See question 16.10.3.

68) Of the following, the *most* frequent side effect of metformin is:

- A) Diarrhea
- B) Hypoglycemia
- C) Lactic acidosis
- D) Renal failure
- E) Weight loss

See question 10.10.7.

69) A 40-year-old male presents with generalized weakness for 1 month. He has lost some weight, perhaps 10 lb. He briefly lost consciousness yesterday while getting out of bed. He denies depression, drug or alcohol use, and any significant medical history. He is hypotensive but not tachycardic. He has orthostatic hypotension as well. Lab tests reveal mild anemia, low sodium, elevated potassium, and normal TSH, BUN, creatinine, and glucose. He is surprisingly tan for being a Caucasian farmer in the winter. (Did he just return from Cancun? No. He's not traveled. Good question.) To confirm your presumptive diagnosis, you order (which is the *best* test):

- A) 24-hour urine catecholamines
- B) Free T4 and T3
- C) Cosyntropin stimulation test
- D) Serum cortisol and adrenocorticotropic hormone (ACTH)
- E) Serum testosterone

See question 10.8.2: Helpful Tips.

70) A 62-year-old female presents to the emergency department with a sudden "hole" in her right visual field developing today. She also has a right temporal headache present for the last 2 weeks, shoulder and neck pain for a month, and weight loss of 5 lbs. She is slightly hypertensive and has a prominent tender vessel at the right side of her head. Her CBC is normal but the ESR is 85 mm/hr. What is the most appropriate course of action?

- A) Administer IV methylprednisolone and admit for further evaluation
- B) Admit for cardiac monitoring and rule out myocardial infarction
- C) Discharge to home with oral antibiotics
- D) Discharge to home with referral to an ophthalmologist in the next week
- E) Perform a CT scan of the brain and discharge to home if normal

See question 11.2.7.

71) You find a new and suspicious skin lesion in a patient who has had a liver transplant for hepatitis C and is on immunosuppressive therapy. You plan to perform a biopsy. If the skin lesion turns out to be malignant, it will most likely be:

- A) Basal cell carcinoma
- B) Distant metastasis from liver cancer
- C) Melanoma

- D) Squamous cell carcinoma
- E) Kaposi sarcoma

See question 17.3.2.

72) The fractional excretion of sodium (FENa) is useful for determining:

- A) If the patient has true hyponatremia
- B) Whether the patient has oliguric or anuric renal failure
- C) Whether the renal failure is due to acute tubular necrosis or another cause
- D) Whether the renal failure is due to intrinsic renal disease or a prerenal cause
- E) If the patient has pseudohyponatremia

See question 5.6.3.

73) The *major* Jones criteria for rheumatic fever include all of the following EXCEPT:

- A) Carditis
- B) Fever
- C) Polyarthritides
- D) Subcutaneous nodules
- E) Sydenham chorea

See Chapter 11 Quick Quiz: An Ill Child.

74) A 29-year-old female daycare teacher presents with a severely pruritic rash that started at her wrists and has progressed to the web spaces of her fingers, under her arms, around her waist, and around her nipples. On examination, she has multiple excoriations and few small, erythematous papules. The most appropriate next step is:

- A) Biopsy of normal-appearing skin
- B) Biopsy of one of the papules
- C) Empiric treatment with topical clotrimazole
- D) Empiric treatment with topical lindane 1%
- E) Empiric treatment with topical permethrin 5%

See questions 8.6.1 and 8.6.2.

75) A 60-year-old female with diabetic nephropathy is hospitalized with chest pain, and a cardiac catheterization is planned. Which one of the following is the best option to reduce her risk of contrast-induced nephropathy?

- A) Administer ketorolac and IV saline
- B) Administer mannitol and IV saline
- C) Administer IV saline alone
- D) Administer N-acetylcysteine

See question 5.1.7.

76) A 58-year-old man with hypertension, diabetes, heart failure, and chronic kidney disease (stage 4, GFR ~25 mL/min/1.73 m²) presents for follow-up. His current medications are insulin, aspirin, metoprolol, and lisinopril. His blood pressure is 142/86 mm Hg and he has significant dependent

edema. His labs reveal serum potassium of 5.3 mEq/L. To achieve his blood pressure to goal (<130/80) while avoiding adverse events, the best initial step is:

- A) Discontinue lisinopril
- B) Furosemide 20 mg PO daily
- C) Hydrochlorothiazide 12.5 mg PO daily
- D) Increase lisinopril
- E) Losartan 25 mg PO daily

See questions 5.1.10 and 5.6.6.

77) Which of the following is most likely to cause hypokalemia?

- A) Excessive use of “lite” salt
- B) Hypoaldosteronism
- C) Hypomagnesemia
- D) Overdose of propranolol
- E) Renal tubular acidosis type 4

See question 5.5.2.

78) A patient presents with thickened, yellowish, dystrophic toenails. What is the most appropriate next step?

- A) Recommend that the patient return for toenail removal
- B) Send nail scrapings for KOH stain and/or fungal culture
- C) Start treatment with a topical antifungal
- D) Start treatment with an oral antifungal
- E) Start treatment with an IV antifungal

See question 17.3.4.

79) All of the following are consistent with a diagnosis of syndrome of inappropriate antidiuretic hormone secretion (SIADH) EXCEPT:

- A) High urine osmolality
- B) Low plasma osmolality
- C) Low urine sodium
- D) Normal adrenal function
- E) Normal thyroid function

See questions 5.7.2 and 5.7.3.

80) A 21-year-old male is brought in the emergency department by his girlfriend after he overdosed on aspirin. He took “a bottle, maybe 100 pills or so,” but he denies other ingestions. He complains only of nausea. He becomes more somnolent during the evaluation. He is slightly tachycardic and febrile with a normal blood pressure. His blood gas shows: pH 7.38, PaCO₂ 20 mm Hg, PaO₂ 98 mm Hg, HCO₃ 15 mEq/L. His creatinine, CBC, and electrolytes are normal, except for low potassium. What is the best description of this patient’s blood gas?

- A) Metabolic acidosis and metabolic alkalosis
- B) Metabolic acidosis and respiratory alkalosis
- C) Metabolic alkalosis and respiratory acidosis
- D) Pure metabolic acidosis
- E) Normal blood gas (no acidosis or alkalosis)

Chapter 5 Quick Quiz: Acid-Base Disorder.

81) A 19-year-old college student presents to the emergency department with fever, headache, myalgias, and confusion. She has had a splenectomy but is otherwise healthy. The examination is notable for somnolence, fever, and nuchal rigidity. Due to her inability to follow directions, the neurological examination is difficult to complete, but it appears to be non-focal. There are several other seriously ill patients in the ED to triage. Which of the following interventions should not wait an hour and must be done now?

- A) Administer ceftriaxone, vancomycin, and dexamethasone
- B) Consult a neurosurgeon
- C) Perform lumbar puncture
- D) Obtain blood cultures
- E) Order CT of the brain

See questions 8.3.1: Helpful Tip and 8.3.3.

82) You perform joint aspiration on a patient with a painful, swollen knee. Microscopic examination of the fluid shows rhomboid-shaped, positively birefringent crystals. Which one of the following is the most likely to alleviate the patient’s acute symptoms?

- A) Acetaminophen daily
- B) Allopurinol daily
- C) Ceftriaxone IM
- D) Corticosteroid injection into the knee
- E) Topical anti-inflammatory cream

See question 11.5.2.

83) A 23-year-old male with HIV stopped taking all of his medications 3 months ago due to cost. He was feeling fine until 3 weeks ago when he developed a cough. He now has daily fevers around 101°F, a non-productive cough, dyspnea on exertion, fatigue, chills, and tightness in his chest with inspiration. His examination is notable for fever, diaphoresis, bilateral crackles with inspiration, and mild tachypnea. Chest x-ray shows diffuse bilateral interstitial infiltrates. Which of the following is the most likely causative agent for this pulmonary infection?

- A) Adenovirus
- B) *Cryptococcus neoformans*
- C) *Mycobacterium tuberculosis*
- D) *Pneumocystis jiroveci* (PCP)
- E) *Toxoplasma gondii*

See questions 9.1.9 and 9.1.10.

84) Which of the following is not useful in the treatment of hepatic encephalopathy?

- A) Oral lactulose
- B) Polyethylene glycol (Golytely)
- C) Oral rifaximin
- D) Lactulose enemas for acute encephalopathy

See question 7.13.2.

85) An otherwise-healthy 70-year-old female is admitted and started on ceftriaxone and azithromycin for pneumonia. On hospital day 3, her serum creatinine is found to have tripled from admission. She is mildly nauseated and has an erythematous, macular rash on her trunk and arms. Her CBC shows that her white cell count has declined from admission, but she now has a prominent eosinophilia. Urinalysis shows 1 + protein, and urine sediment shows white cell casts and eosinophils. The most appropriate next step is:

- A) Add metronidazole to her antibiotic regimen
- B) Bolus with IV 0.9% saline
- C) Consult a nephrologist for possible renal biopsy
- D) Discontinue ceftriaxone and consider an alternative antibiotic
- E) Start furosemide to improve urine output

See question 5.13.3: Helpful Tip.

86) Each of the following patients is found to have asymptomatic bacteriuria. Who should be treated with a course of antibiotics?

- A) An 88-year-old female nursing home resident
- B) A 20-year-old pregnant patient
- C) A 75-year-old male with an indwelling Foley catheter for obstructive BPH
- D) All of the above

See questions 8.4.1 and 8.4.2: Helpful Tip.

87) In a patient with ascites, which of the following will cause a low serum-ascites albumin gradient (SAAG)?

- A) Carcinomatous peritonitis
- B) Portal hypertension
- C) Budd–Chiari syndrome
- D) Cirrhosis

See question 7.12.4: Helpful Tip.

88) A patient comes to the emergency department after sustaining a needle stick. She is a nurse who had just finished drawing blood for culture on a patient with AIDS, and somehow she stuck herself through her glove. She bled a little. She washed the area copiously. What is the most appropriate next step?

- A) Prescribe antiretrovirals for 4 weeks
- B) Prescribe single-dose antiretroviral prophylaxis
- C) Reassure the patient as her risk of contracting HIV is negligible
- D) Test her for HIV and treat based on the results

See question 9.3.2: Helpful Tip.

89) About half of patients with portal hypertension have esophageal varices, and one-third of these will experience a gastrointestinal bleed. Patients with varices may benefit from preventative therapy aimed at reducing bleeding risk. Which of the following IS useful in the prevention of variceal

bleeding in patients with portal hypertension due to alcoholic cirrhosis?

- A) Pentoxifylline (Trental)
- B) Nadolol
- C) Vitamin K
- D) Cilostazol (Pletal)

See question 7.13.5.

90) Which of the following is generally true in alcohol-related liver disease?

- A) AST is two times greater than ALT
- B) ALT is two times greater than AST
- C) Both ALT and AST are elevated to the same degree
- D) The GGT is specific for liver disease and higher than either the ALT or AST

See question 7.15.2: Helpful Tip.

91) Appropriate antibiotic treatment of diverticulitis includes all of the following EXCEPT:

- A) Ciprofloxacin + metronidazole
- B) Amoxicillin clavulanate
- C) Trimethoprim/sulfamethoxazole + metronidazole
- D) Clindamycin + metronidazole

See question 7.17.3: Helpful Tip.

92) Which of the following is true about the treatment of pancreatitis?

- A) Antibiotics should be used in most cases of pancreatitis
- B) Oral feedings is the preferred method of nutrition if tolerated
- C) Pseudocysts must be drained for pancreatitis to resolve
- D) The Ransom criteria can be used at the time of admission to accurately predict mortality

See questions 7.15.8 to 7.15.12 as well as Helpful Tips.

93) Which of the following does NOT promote gastric emptying in gastroparesis?

- A) Erythromycin
- B) Metoclopramide
- C) Amoxicillin
- D) Cisapride

See question 7.16.2.

94) Of the following, the most common cause of acute pancreatitis in the United States is:

- A) Hypertriglyceridemia
- B) Biliary Tract Disease
- C) Thiazide diuretics
- D) Viruses

See question 7.15.7.

95) All of the following are causes of non-alcoholic fatty liver disease EXCEPT:

- A) Statin use
- B) Hypothyroidism
- C) Diabetes
- D) Obesity

See question 7.14.3.

96) The most common cause of the development of drug resistance in HIV is:

- A) Failure to include zidovudine in the treatment regimen
- B) Failure to initiate treatment until the patient has a known AIDS defining illness
- C) Poor compliance with medications
- D) Failure to include a protease inhibitor in the treatment regimen

See question 9.1.3.

97) At what CD4⁺ level should one initiate prophylactic treatment of *Pneumocystis jiroveci* (previously *Pneumocystis carinii*)?

- A) CD4⁺ ≤ 50 cells/mm³
- B) CD4⁺ ≤ 75 cells/mm³
- C) CD4⁺ ≤ 100 cells/mm³
- D) CD4⁺ ≤ 200 cells/mm³

See question 9.1.4.

98) Which of the following recommendations regarding Pap smear screening in an HIV positive woman is true?

- A) Start screening with a PAP smear 1 year after onset of sexual activity regardless of age
- B) It is CD4⁺ dependent. If the CD4⁺ count is normal and the patient has two normal Pap smears at 1-year intervals, you can continue to do yearly PAP smears
- C) It is CD4⁺ dependent. If the patient has a CD4⁺ count <200 cells/mm³, screening should be done every 6 months regardless of whether or not the patient has had negative Pap smears
- D) Pap smears can be suspended in HIV-positive patients since they will likely die from HIV before they die from cervical cancer

See question 9.2.14.

99) Which of the following statements best reflects the current thinking about treating influenza?

- A) Rimantadine and amantadine are the most effective drugs for influenza B
- B) Treatment with oseltamivir (Tamiflu) is highly effective, thus negating the need for influenza vaccine
- C) Oseltamivir must be started within 48 hours of symptom onset to be of any benefit
- D) There is no resistance of influenza A to oseltamivir

See question 8.1.3.

100) Assuming each of these patients has a negative chest x-ray, which of the following patients needs isoniazid treatment?

- A) A patient with no risk factors who has a PPD reaction of 5 mm
- B) A patient with recent exposure to TB and a PPD reaction of 5 mm
- C) A healthcare worker with a PPD reaction of 5 mm
- D) A patient with a PPD reaction of 10 mm 1 year after treatment for latent TB

See questions 8.4.4, Table 8-4, and 8.4.5.

101) The recommended empirical antibiotic treatment of meningitis in an immunocompetent adult age 40 is:

- A) Ceftriaxone
- B) Ceftriaxone + vancomycin
- C) Ceftriaxone + ciprofloxacin
- D) Ceftriaxone + TMP/SMX

See question 8.3.1 and Table 8-3.

102) The most common bacterial organism causing meningitis in adults is:

- A) *Pneumococcus*
- B) *Meningococcus*
- C) *Haemophilus*
- D) *Listeria*

See questions 8.3.1, 8.3.2, and Table 8-3.

103) All of the following can be used for malaria prophylaxis EXCEPT:

- A) Doxycycline
- B) Mefloquine
- C) Azithromycin
- D) Atovaquone/proguanil (Malarone)

See question 8.8.4.

104) Which of the following is true regarding the diagnosis of urolithiasis?

- A) Over 95% of patients will have blood in their urine at the time of diagnosis
- B) Urolithiasis may be difficult to differentiate from aortic dissection at the initial time of presentation
- C) Hematuria will reliably differentiate urolithiasis from aortic dissection
- D) A negative "FAST" ultrasound scan is considered the standard and if negative, rules out urolithiasis

See question 5.3.5: Helpful Tip.

105) Which of the following profiles are you likely to see in a patient with a pre-renal cause of elevated creatinine?

- A) Urine sodium <20 mEq/L, fractional excretion of sodium <1%
- B) Urine sodium <20 mEq/L, fractional excretion of sodium >2%

- C) Urine sodium >40 mEq/L, fractional excretion of sodium <1%
 D) Urine sodium >40 mEq/L, fractional excretion of sodium >2%

See questions 5.6.3 and 5.13.1.

106) Aldosterone resistance (such as occurs with diabetic nephropathy) or hypoaldosteronism will present with which of the following?

- A) Hypokalemia
 B) Hyperkalemia
 C) Hyperphosphatemia
 D) Hypophosphatemia

See question 5.1.9.

107) Which of the following regimens IS NOT recommended for treatment of a simple cystitis in an otherwise healthy, non-pregnant adult female?

- A) Amoxicillin 500 mg PO TID for 3 days
 B) Fosfomycin 3 grams once
 C) Nitrofurantoin macrocrystals 100 mg PO BID for 5 days
 D) TMP/SMX 1 PO BID for 3 days

See Chapter 5 Quick Quiz: Dysuria.

108) Which of the following drugs is LEAST LIKELY to reduce the progression of proteinuria?

- A) Enalapril
 B) Losartan
 C) Verapamil
 D) Nifedipine

See question 10.10.5.

109) The definition of nephrotic syndrome requires all of the following EXCEPT:

- A) Hypoalbuminemia
 B) Urine albumin excretion >3 g per day
 C) Edema
 D) Renal biopsy showing appropriate changes

See question 5.4.5.

110) Which of the following patients should have a carotid endarterectomy based on all current U.S. guidelines?

- A) A 60-year-old female with a unilateral *symptomatic* 70% carotid plaque
 B) A 60-year-old male or female with an *asymptomatic* 69% carotid plaque
 C) Patient of either gender with bilateral 50% carotid plaque, *symptomatic* or *asymptomatic*
 D) None of the above meet current qualification criterion

*See Chapter 18 Quick Quiz: Carotid Artery Disease:
 When to Cut?*

111) If cost were NOT an issue, which of the following drugs/drug combinations would be the ideal regimen for the secondary prevention of stroke?

- A) Aspirin + clopidogrel
 B) Aspirin + dipyridamole
 C) Aspirin alone
 D) Clopidogrel alone
 E) Warfarin

See question 18.1.5.

112) Which one of the following entities presents with reflexes preserved?

- A) Guillain-Barré
 B) Amyotrophic lateral sclerosis
 C) Charcot-Marie-Tooth disease
 D) Diabetic neuropathy

See question 18.6.4: Helpful Tip.

113) Which one of the following agents is most effective for controlling the pain of peripheral neuropathy?

- A) Tricyclic antidepressant (TCA)
 B) Gabapentin
 C) Oxycodone or other narcotic
 D) Carbamazepine or other traditional antiepileptic

See question 18.3.6: Helpful Tip.

114) Which of the following drugs IS NOT associated with rebound headaches?

- A) Acetaminophen
 B) Dihydroergotamine (DHE)
 C) Nortriptyline
 D) Sumatriptan

See question 18.4.6.

115) The risk of developing a seizure disorder after a single febrile seizure is:

- A) 1% to 5%; the same as the rest of the population
 B) 6% to 10%; slightly higher than the general population
 C) 11% to 15%; significantly higher than the general population
 D) Unknown

See question 18.14.4.

116) You determine that a 77-year-old female has Parkinson disease that is interfering with her daily life. The best drug or drug combination to alleviate her symptoms and improve her function is:

- A) A COMT inhibitor (e.g., Entacapone)
 B) A dopamine agonist (e.g., Requip)
 C) Levodopa/carbidopa (e.g., Sinemet)
 D) Apomorphine

See question 18.10.6.

117) The PRESENCE of a RAPD (relative afferent pupillary defect) can be indicative of:

- A) Cataracts
- B) Large retinal detachment
- C) Bleed into the anterior chamber
- D) Severe refractive error

See Chapter 19 glossary and question 19.2.1.

118) Which of the following patients has an indication for cataract surgery?

- A) Vision 20/100 bilaterally in a patient who has no visual complaints or functional impairment
- B) Vision 20/20 OD and 20/200 OS in a patient who can see well enough to do everything she desires
- C) Vision 20/30 OD and 20/30 OS in a patient who is bothered by her inability to quilt
- D) Vision unknown in a patient who can carry out all ADLs to her own satisfaction

See question 19.14.3.

119) All of the following intraocular muscles are innervated by cranial nerve III EXCEPT:

- A) Inferior oblique
- B) Inferior rectus
- C) Lateral rectus
- D) Medial rectus
- E) Superior rectus

See question 19.15.1.

120) Skinner, “politically correct” Santas are in vogue this year (bearing gifts of celery, no doubt). Your patient is in a tizzy: he has played Santa for years without the need for pillows. He wants to keep up his tradition as St. Nick. What can you tell him about weight reduction surgery?

- A) “Sorry, even though you may lose weight, it will not help your overall health.”
- B) “You must have a BMI >40 kg/m² before qualifying for bariatric surgery regardless of other underlying weight-related conditions.”
- C) “You must have a BMI of 35-39 kg/m² AND significant reversible disease (e.g., hypertension, diabetes) to qualify for bariatric surgery.”
- D) “The reindeer union says it’s members won’t work if Santa’s weight is under 300 lb—they need to keep 8 reindeer working the sleigh at all times.”

See question 22.5.1.

121) A 70-year-old male patient complains of severe unilateral visual loss. He has no other symptoms. Here is a picture of his fundus (Fig. 30-3) that you took with your smartphone jerry-rigged to a direct ophthalmoscope. His diagnosis is:

- A) Acute glaucoma
- B) Acute venous disruption

- C) Acute arterial occlusion
- D) Diabetic retinopathy

See question 19.12.1.

122) What is the general course of rheumatoid arthritis during pregnancy?

- A) Worsening during pregnancy
- B) Worsening during pregnancy but only if methotrexate is used
- C) It may remit during pregnancy and methotrexate is contraindicated
- D) Morning sickness is worse in those with rheumatoid arthritis
- E) Pregnancy has no effect on rheumatoid arthritis and vice versa

See question 11.1.8.

123) A diagnosis of rheumatoid arthritis can be made after symptoms have been present for at least:

- A) 15 minutes
- B) 2 weeks
- C) 6 weeks
- D) Duration of symptoms is no longer a criterion for diagnosing rheumatoid arthritis

See question 11.1.2: Helpful Tip.

124) You make a diagnosis of rheumatoid arthritis based on laboratory and clinical criteria. The best time to begin disease-modifying antirheumatic drugs (DMARDs) is:

- A) At the time of diagnosis
- B) After failure of 2 NSAIDs
- C) After the failure of prednisone
- D) When complications of rheumatoid arthritis occur
- E) After waiting 6 months to see a rheumatologist

See question 11.1.3: Helpful Tip.

125) You are seeing a 57-year-old male in your practice who is complaining of bi-temporal headache. He checked the web and decided that he has giant cell (temporal) arteritis. The only problem is that his ESR is only 30 mm/hr. The CRP is not much more edifying. You appropriately respond to him:

- A) “You may still have temporal arteritis since 15% or more will have normal ESR and CRP.”
- B) “You seem to be displaying drug seeking behavior since you came in to the ED with the same complaint 1 month ago.”
- C) “You may still have temporal arteritis, but we need to perform a temporal bone biopsy.”
- D) “You may still have temporal arteritis, but we will need to submit your head to the state lab for formal testing ... You don’t mind ... do you?”

See question 11.2.2.

126) When treating gout, which one of these drugs for gout will be *ineffective* in those with renal insufficiency?

- A) Allopurinol
- B) Probenecid
- C) Prednisone
- D) Colchicine
- E) Indomethacin

See question 11.4.6.

127) Regarding therapy for giant cell arteritis, which of the following statements best describes the appropriate relationship of aspirin, prednisone, and giant cell arteritis?

- A) ASA (81 mg/day) can be used as adjunctive therapy for those on prednisone
- B) ASA (325 mg/day) can be used as adjunctive therapy for those on prednisone
- C) High-dose ASA (650 mg/day) can be used in those who do not tolerate prednisone
- D) ASA has no role in the treatment of giant cell arteritis

See question 11.2.3.

128) The one best, first-line drug treatment of osteoarthritis pain is:

- A) Acetaminophen
- B) Celecoxib (Celebrex)
- C) Ibuprofen
- D) Naproxen
- E) Morphine

See Chapter 12: General Note, at the start of the chapter.

129) Of the following options, the best initial pharmacologic therapy for fibromyalgia pain is:

- A) Duloxetine
- B) Ibuprofen
- C) Nortriptyline
- D) Tramadol

See questions 11.8.2 and 11.8.3: Helpful Tip.

130) Which of the following should NOT go into the calculus of what antibiotic to use for a patient with community acquired pneumonia?

- A) Appearance of infiltrate on chest x-ray (lobar vs. “atypical”)
- B) Comorbid medical conditions
- C) Likelihood of resistant organisms (based on prior cultures)
- D) Patient age
- E) Medication allergies

See question 3.12.1: Helpful Tip, 3.12.2, and 3.12.3.

131) Regarding depot medroxyprogesterone (Depo-Provera), which of the following is true?

- A) Depo-Provera can cause bone mineral loss. However, recent data suggest that bone remineralization is possible after stopping
- B) It is associated with an increase in breast cancer
- C) More than 2 years of Depo-Provera is never indicated because of weight gain and other metabolic effects
- D) It is a frequent cause of depression

See question 15.1.1: Helpful Tip.

132) Bleeding in a non-pregnant, amenorrheic patient in response to a “progesterone challenge” (e.g., medroxyprogesterone given for 10 days and then stopped) indicates that the patient has sufficient endogenous:

- A) Follicle stimulating hormone (FSH)
- B) Luteinizing hormone (LH)
- C) Progesterone
- D) Estrogen

See Chapter 15 Quick Quiz: Amenorrhea.

133) You get the following results on a vaginal wet prep: pH 5 and a positive “whiff” test. Wouldn’t you know it, the rest of the results got lost. With the information available, the most likely diagnosis is:

- A) Vulvovaginal candidiasis
- B) Bacterial vaginosis
- C) Vaginal trichomoniasis
- D) Physiologic vaginal discharge

See Chapter 15: Table 15-13.

134) When is screening for Group B *Streptococcus* (GBS) in the pregnant female recommended?

- A) Between 30 and 32 weeks of gestation
- B) Between 32 and 34 weeks of gestation
- C) Between 35 and 37 weeks of gestation
- D) Intrapartum only

See question 15.1.8.

135) Which of the following is the most appropriate treatment of chronic menorrhagia in a 42-year-old female hypertensive smoker?

- A) Low androgenic progesterone oral contraceptive
- B) Levonorgestrel-containing IUD (e.g., Mirena, Liletta, Kyleena, or Skyla)
- C) Copper IUD (Paraguard)
- D) Low estrogen oral contraceptive

See questions 15.8.2: Helpful Tip and 15.9.4.

136) You are called to see a partner's patient who is G3P2 at 32 weeks gestation and is having regular contractions. After monitoring and an examination, you suspect that she is in labor. The SINGLE most important step, and the first step to take, at this point is:

- A) Administration of corticosteroids to hasten fetal lung maturation
- B) Administration of a tocolytic such as terbutaline
- C) Insertion of a cervical cerclage to delay delivery
- D) Antibiotic therapy (ampicillin) from now until delivery

See questions 15.4.2 and 15.4.4.

137) This fetal tracing, shown in Figure 30-3, is:

- A) Reassuring
- B) Worrisome
- C) An indication for immediate C-section
- D) An indication for the addition of Pitocin

See Chapter 15: Table 15-4 and question 15.2.7.

138) Which of the following *must* be present to make the diagnosis of pelvic inflammatory disease?

- A) Adnexal pain
- B) Elevated WBC count
- C) Elevated CRP
- D) Temperature of $>38^{\circ}\text{C}$

See question 15.13.2: Helpful Tip.

139) A NEGATIVE fetal fibronectin suggests that:

- A) The fetal lungs are immature
- B) There is little likelihood that the patient will deliver within the next 7 days
- C) There is an amniotic fluid leak
- D) Is not helpful. A positive fibronectin suggests imminent delivery

See question 15.4.1.

140) Which of the following is true about tocolytics for pre-mature labor?

- A) They are effective at stopping labor and can arrest labor for an average of 1 week
- B) They have very few side effects and should be used routinely in premature labor
- C) Their use is mostly to buy time for antenatal steroids to work for those pregnancies between 24 and 34 weeks
- D) Terbutaline is the only FDA-approved tocolytic

See question 15.4.3: Helpful Tip.

141) As you start a patient on fluoxetine for depression, you counsel him about the adverse effects of this class of

medications. All of the following are common adverse effects of SSRIs EXCEPT:

- A) Anxiety
- B) Diarrhea
- C) Headaches
- D) Hypersexuality
- E) Insomnia

See question 23.1.8.

142) A 12-month-old female presents to the emergency department after 24 hours of vomiting, diarrhea, and fever. She is lethargic, tachycardic, and hypotensive with poor skin turgor. What is the most appropriate initial method of providing her fluids?

- A) Half-normal saline, 20 mL/kg bolus
- B) Half-normal saline with 5% dextrose, 10 mL/kg bolus
- C) Normal saline, 100 mL/kg bolus
- D) Normal saline, 20 mL/kg bolus

See question 13.3.3.

143) A 15-month-old male is brought to the clinic by his parents. Like everyone else at his home, he has had some rhinorrhea and diarrhea in the last week. However, 4 hours ago the patient developed episodes of inconsolable crying accompanied by lying in "the fetal position" for 15 to 20 minutes at a time. At first his parents were puzzled but not too worried, but these episodes have occurred six to seven times now and he has become more lethargic. Finally, he had a bloody bowel movement, so they decided to bring him in to the office. On examination, he is afebrile, lethargic but arousable, and well hydrated. His abdomen appears benign. What is your leading diagnosis?

- A) Cholecystitis
- B) Gastroenteritis
- C) Intussusception
- D) Volvulus

See question 13.4.1.

144) Which of the following screening tests is recommended universally for all children in the United States?

- A) Eye examination at 3 to 5 years
- B) Hearing testing at 1 or 2 days old
- C) Hemoglobin at 12 months
- D) Lead level at 12 months

See Chapter 13 Quick Quiz: Congenital Infections, Helpful Tip.

145) During a visit for a physical examination, you note that this 33-year-old female has checked "depression" on her health-screening questionnaire. You ask her more about this and find that she has felt that her mood has been depressed

FIGURE 30-3. Figure for Question 137.

for 15 years or more. She generally feels fatigued and has low self-esteem, but she denies suicidal ideation and feelings of guilt and worthlessness. What diagnosis best characterizes her symptoms?

- A) Avoidant personality disorder
- B) Borderline personality disorder
- C) Persistent depressive disorder
- D) Major depressive disorder

See Chapter 23 Quick Quiz: Sad All the Time.

146) Which of the following symptoms would be LEAST likely to be due to a panic attack and therefore would prompt further investigation in a patient with known panic disorder?

- A) Chest pain
- B) Dyspnea
- C) Palpitations
- D) Syncope

See question 23.6.4.

147) A 23-year-old male presents with symptoms suggestive of panic attacks, an underlying anxiety disorder, and possibly panic disorder. You refer him for counseling services and recommend starting a medication. Which of the following drugs is LEAST effective for treating panic disorder?

- A) Bupropion
- B) Nortriptyline
- C) Sertraline
- D) Venlafaxine

See question 23.6.8.

148) All of the following are part of the CHA₂DS₂-VASC score EXCEPT:

- A) Age
- B) Sex/Gender
- C) History of stroke, thromboembolic disease, etc.
- D) Active cancer
- E) Heart failure

See Chapter 2: Table 2-6A.

149) According to the USPSTF and CDC, hepatitis C screening is recommended for all of the following groups EXCEPT:

- A) All individuals born between 1955 and 1975
- B) Hemodialysis patients
- C) Patients with a history of incarceration
- D) Users of illicit injection drugs
- E) Migrants from an endemic area (e.g., Southeast Asia)

See question 7.10.3: Helpful Tip.

150) Which of the following patients does NOT need a head CT scan per the PECARN rules?

- A) A child with a GCS of 14 and no other symptoms or signs of intracranial injury
- B) A 3-month-old with an occipital bruise after a fall of 3 ft
- C) A 3-year-old with an occipital bruise and a fall of 3 ft
- D) A 1-year-old child with a palpable skull fracture who is otherwise neurologically intact
- E) A 1-year-old child with a scalp hematoma

See Chapter 1: Table 1-6.

151) Because _____ is the major unmeasured anion in the serum, the anion gap needs to be adjusted for the _____ level in the serum.

- A) Albumin
- B) Calcium
- C) Phosphate
- D) Total protein
- E) Chloride

See question 1.4.2.

152) Your patient has just returned from Mexico where she sustained an ankle bite from a suspect dog. Rabies vaccine and immunoglobulin are not likely to be effective after:

- A) 10 days
- B) 20 days
- C) 30 days
- D) 90 days

See question 1.6.2.

153) Dislocation of which of the following joints is associated with the highest risk of arterial injury?

- A) Wrist
- B) Elbow
- C) Shoulder
- D) Knee
- E) Ankle

See Chapter 1: Quick Quiz: Orthopedic Emergencies.

154) The Women's Health Initiative revealed which of the following statistically significant correlations?

- A) Combined estrogen/progesterone therapy reduced breast cancer risk
- B) Combined estrogen/progesterone therapy increased breast cancer risk
- C) Estrogen monotherapy did not affect breast cancer risk
- D) Estrogen monotherapy increased breast cancer risk

See question 15.14.3.

155) A 2-year-old child presents having missed his routine vaccines at 12 and 15 months. The patient should:

- A) Restart all vaccines

- B) Spread out the interval for his remaining vaccines to reduce the risk of side effects
- C) Receive all of his missed doses of vaccines right now
- D) Receive the vaccines due at age 12 months and continue on the “catch-up” schedule

See question 13.2.6: Helpful Tip.

156) A 12-month-old female infant presents for her routine well-child examination. She has some nasal congestion and her temperature is 100.4°C. She looks otherwise great. You should:

- A) Administer her routine 12-month vaccines
- B) Administer half her routine 12-month vaccines now and half in 2 weeks
- C) Have her return for vaccines when she is afebrile for 24 hours
- D) Never give her any more vaccines as she clearly has a febrile reaction just being close to them

See question 13.2.6.

157) A 20-year-old female with asthma presents to the ED wheezing and dyspneic. Within 5 minutes of a treatment with nebulized albuterol, her wheezing improves but she still feels dyspneic. The most appropriate next step is:

- A) Prepare for imminent intubation
- B) Administer IV magnesium
- C) Administer IV ceftriaxone
- D) Administer another dose of nebulized albuterol
- E) Discharge her with a prescription for cough syrup

See question 1.14.4.

158) The diagnosis of chronic obstructive pulmonary disease is secured by:

- A) Cough and sputum production in a smoker
- B) Two or three of the following symptoms over the last 6 months: cough, dyspnea, sputum production
- C) FEV₁/FVC ratio of <0.7
- D) FEV₁ <70% predicted
- E) FVC >FEV₁

See question 3.3.3 and Table 3-1.

159) A 16-year-old male with asthma and seasonal allergies presents for follow-up. His only asthma medication is an albuterol inhaler. In the past few months, he has needed the medication more and more, and is now using his albuterol inhaler one to two times per day. The most appropriate next step is to:

- A) Add a low-dose inhaled corticosteroid (e.g., triamcinolone) twice daily
- B) Add a long-acting bronchodilator (e.g., salmeterol) twice daily
- C) Schedule his albuterol inhaler 4 times per day
- D) Add a low-dose systemic steroid (e.g., prednisone) daily
- E) Add a leukotriene inhibitor (e.g., montelukast) daily

See question 3.3.6 and Figure 3-1.

160) According to the USPSTF, the most appropriate modality and frequency for lung cancer screening is:

- A) Posteroanterior and lateral chest radiographs annually
- B) Low-dose CT of the chest annually
- C) Low-dose CT of the chest every 3 years
- D) Sputum cytology annually
- E) None is recommended as the evidence is insufficient

See question 3.11.6.

161) A 30-year-old male is found unconscious, slumped in a chair outside the ED. You arouse him briefly with a sternal rub. He has pinpoint pupils and a respiratory rate of 8 per minute. The drug most likely to causing his current symptoms is:

- A) Methamphetamine
- B) Cocaine
- C) Heroin
- D) Ecstasy
- E) Alcohol

See Chapter 1: Table 1-1.

162) You admit a 45-year-old male with cirrhosis for alcohol withdrawal. He meets criteria for complicated withdrawal. Which of the following medications will be safest and most effective at treating his withdrawal symptoms?

- A) Chlordiazepoxide
- B) Clonidine
- C) Lorazepam
- D) Metoprolol

See question 25.2.7.

163) You are admitting an 88-year-old male to a care facility with hospice due to declining overall health. In the last year, he has started to require total functional dependence in most activities of daily living. He has moderate-to-severe dementia, ischemic cardiomyopathy and heart failure with a left ventricular ejection fraction of 20%. When he was healthier, he had an implanted cardiac defibrillator (ICD) placed, which has fired once a year ago and caused him significant pain and distress. His daughter is his durable power of attorney and agrees with the patient that hospitalization, procedures, and CPR are not desired. He has made these same goals clear in past conversations with other care providers, documented in the medical record. When his daughter asks about his ICD, you recommend which of the following?

- A) Deactivate the ICD
- B) Change the settings so the ICD only fires for ventricular tachycardia
- C) Surgically remove the ICD
- D) Leave the ICD as it is

See questions 27.1.1 and 27.1.2.

164) A 58-year-old male tobacco connoisseur presents for increasing cough, dyspnea, and sputum production. He is afebrile. Oxygen saturation on ambient air is 88%. Lung examination demonstrates poor air movement and diffuse expiratory wheezing. His chest x-ray is consistent with COPD and shows no infiltrates. You decide to admit him. Which of the following drug regimens would be the best choice for this patient?

- A) Nebulized albuterol every 4 hours as needed and IV methylprednisolone 125 mg daily
- B) Tiotropium inhaler 1 puff daily, levofloxacin 500 mg PO daily, and nebulized albuterol every 4 hours as needed
- C) Prednisone 50 mg PO daily, doxycycline 100 mg PO BID, and nebulized albuterol every 4 hours as needed
- D) Morphine 5 to 10 mg IV every 2 hours to palliate his breathlessness

See question 3.4.1: Helpful Tip.

165) A 35-year-old male presents for follow-up, after an admission for pneumonia. Blood cultures grew *Streptococcus pneumoniae*. Over the past 10 years, he reports having several bouts of pneumonia and numerous sinus infections. Also, he has developed an autoimmune hemolytic anemia. What is the most useful test in making the diagnosis of an immune deficiency in this patient?

- A) Complement levels
- B) Immunoglobulin levels
- C) CBC and differential
- D) Bone marrow biopsy
- E) Lymph node biopsy

See Chapter 4: Table 4-2.

166) You are evaluating a 70-year-old male for abdominal pain that you suspect may be due to mesenteric ischemia. You believe the best test would be a CT angiogram of his abdomen, but he has a contrast allergy. When you inquire about the allergy, he reports rash and shortness of breath. The most appropriate next step in the care of this patient is to:

- A) Perform a non-contrast CT scan of the abdomen and pelvis
- B) Perform a contrast-enhanced CT scan of the abdomen and pelvis and pre-treat the patient with prednisone and diphenhydramine
- C) Perform a contrast-enhanced CT scan of the abdomen and pelvis and pre-treat with IV normal saline boluses and N-acetylcysteine
- D) Consult a vascular surgeon or an interventional radiologist for an angiogram
- E) Consult a surgeon for an exploratory laparotomy

See Chapter 4: Quick Quiz: Contrast Allergy.

167) A 12-year-old male presents with his mother for concerns about diplopia, which began two days ago. On examination, he has normal visual acuity when each eye is tested

individually, normal pupillary reflexes, and esotropia. What is the best next step to take in the care of this patient?

- A) Reassurance that this is a normal, age-related change that will improve with time
- B) Refer to an optometrist for corrective lenses
- C) Refer to a physical therapy for “eye training”
- D) Order an MRI of the brain
- E) Order an EEG

See question 19.1.4: Helpful Tip.

168) A 3-year-old female returns for continued problems with hearing. Her parents are concerned about another ear infection. She has had three episodes of otitis media that you have treated over the last 6 months. Her hearing is diminished, per parents, and she indeed tests positive for hearing loss bilaterally. On examination, you note bulging tympanic membranes with clear, bubbly fluid in the middle ears, but no signs of inflammation. The intervention most likely to help this patient improve her hearing and prevent another infection is:

- A) Eustachian tube exercises
- B) Tympanostomy tubes
- C) Prolonged antibiotics
- D) Nasal steroids
- E) Systemic decongestants

See question 20.1.9.

169) Which of the following findings is diagnostic of acute otitis media?

- A) Child pulling at ears and fussing in the examination room
- B) Child with fever and injected tympanic membrane on examination
- C) Child with fever and an injected tympanic membrane that does not move when ear canal is insufflated
- D) Child with history of acute otitis media whose tympanic membrane is clear but does not move when ear canal is insufflated

See questions 20.1.1 and 20.1.3.

170) A 72-year-old male presents with hearing loss. He has no other symptoms. He spent much of his life working in a machine shop after he was discharged from the army where he was assigned to an artillery unit. His real passion has been music: he continues to serve as a back-up vocalist and bass guitar player in a rock band. On examination, he has normal ears to inspection but high frequency hearing loss. Which of the following is the most likely diagnosis?

- A) Presbycusis
- B) Otosclerosis
- C) Acoustic neuroma
- D) Ménière disease
- E) Otitis media with effusion

See question 20.4.2.

171) A 40-year-old obese female walks into the office requesting a refill on her oral contraceptives and asks to be seen for acute onset of shortness of breath. She reports that she just got back from a 3-week road trip when she developed dyspnea. She wonders if it could be related to her smoking. On examination, she is tachypneic and mildly tachycardic with an oxygen saturation of 92%. She has a tender, swollen lower leg on the left. Her lungs are clear to auscultation. The most appropriate next step in the care of this patient is to:

- A) Order a d-dimer
- B) Prescribe an albuterol inhaler
- C) Order a contrast-enhanced chest CT scan
- D) Prescribe a course of antibiotics
- E) Order pulmonary function testing

See question 3.5.6.

172) A 65-year-old female presents for follow up after hospital discharge 8 days ago. She underwent laparoscopic cholecystectomy that was complicated by intra-abdominal hemorrhage and repeated surgical exploration. She was in the hospital for 10 days. Now, she complains of coughing fits that hurt her surgical wounds. She produces yellow sputum. She is currently febrile, tachypneic and tachycardic on examination. Chest x-ray shows a right middle lobe infiltrate. You decide to admit her and order the following antibiotic regimen:

- A) Cefepime and vancomycin
- B) Ceftriaxone and azithromycin
- C) Linezolid
- D) Clindamycin and metronidazole
- E) Doxycycline

See question 3.12.5: Helpful Tip on HCAP.

173) A 60-year-old male presents to discuss lung cancer screening via low-dose CT scan. He has smoked 1 pack-per-day of cigarettes for 40 years. Consistent with USPSTF recommendations, you advise him to undergo annual screening with CT until he has quit smoking for:

- A) 1 year
- B) 5 years
- C) 15 years
- D) The rest of his life. There is no end time identified for former smokers

See question 3.11.6.

174) Which of the following medications is/are associated with urticaria?

- A) Aspirin
- B) Lisinopril
- C) Morphine
- D) All of the above
- E) None of the above

See question 17.10.5: Helpful Tip.

175) A 45-year-old female with type 2 diabetes presents for follow-up. On examination, she has two brownish-red patches with yellowish areas through the center on her lower legs. The center of the rash appears shiny and has telangiectasia. When asked, she states the rash has been present for at least a year and is mildly tender if touched. It is not pruritic. Of the following, what is the most likely diagnosis?

- A) Acanthosis nigricans
- B) Atopic dermatitis
- C) Cellulitis
- D) Contact dermatitis
- E) Necrobiosis lipoidica

See question 17.11.1.

176) All of the following are components of the “female athlete triad” EXCEPT:

- A) Low energy availability with or without disordered eating
- B) Recurrent stress fractures
- C) Menstrual dysfunction
- D) Altered bone mineral density

See question 14.2.2.

177) For adolescent athletes, what is the number one cause of sudden cardiac death?

- A) Chest trauma (e.g., baseball hit to the chest)
- B) Anomalous coronary artery
- C) Hypertrophic cardiomyopathy
- D) Patent foramen ovale

See Chapter 14 Quick Quiz: Adolescent Athletes.

178) A 29-year-old male presents with symptoms of fatigue, weight loss, palpitations, and anxiety. On examination, you note tachycardia, lid lag, fine tremor, and diffusely enlarged thyroid gland. Suspecting a hyperthyroid state, you order a TSH and free thyroxine (T4). The TSH is below the normal range but the free T4 is normal. What is the next step in the management of this patient?

- A) Refer to an endocrinologist who can see him in 3 to 6 months
- B) Check a calcium level
- C) Check a thyrotropin-releasing hormone level
- D) Check a free tri-iodothyronine (T3) level
- E) Send for thyroid biopsy

See Chapter 10 Quick Quiz: Thyroid Tests.

179) Thyroid storm is diagnosed by:

- A) History and physical examination findings
- B) Elevated free T3 level
- C) Free T4 level 10 times the upper limit of normal
- D) TSH level immeasurably low
- E) An endocrinologist, preferably a really old one with a long white beard

See question 10.2.6: Helpful Tip.

180) You are seeing a 75-year-old female with progressive memory impairment. In order to diagnose her with a neurocognitive disorder (dementia) according to DSM-V, she must demonstrate impairment in any one of the following EXCEPT:

- A) Apraxia
- B) Anosmia
- C) Aphasia
- D) Agnosia
- E) Impairment in executive functioning

See questions 21.5.1 and 21.5.3.

181) Regarding the treatment of hepatitis C for genotype 1 patients, which of the following therapies has the highest cure rate?

- A) Ledipasvir/sofosbuvir (Harvoni)
- B) Ribavirin
- C) Interferon alpha
- D) Pegylated interferon alpha
- E) Interferon alpha + ribavirin

See questions 7.10.6 and 7.10.7: Helpful Tip.

182) According to the 2018 ADA guideline, which of the following patients should be screened for diabetes mellitus EXCEPT?

- A) A 25-year-old female whose mother is diabetic
- B) A 40-year-old female whose BMI is 29 kg/m²
- C) A 40-year-old female with history of delivering a 9 lb 6 oz infant
- D) A 25-year-old female who really, really likes soft drinks

See question 10.10.1: Helpful Tip.

183) You have diagnosed a 10-year-old child with immune thrombocytopenic purpura (ITP), and his platelet count is currently 10,000/μL. You are considering therapy to improve this patient's platelet count. All of the following are treatments for ITP EXCEPT:

- A) Platelet transfusion
- B) Corticosteroids
- C) IVIG
- D) Splenectomy
- E) Rho(D) immunoglobulin (if he is Rh positive)

See question 6.2.2.

184) You are seeing a 45-year-old male with elevated liver transaminases. His serum bilirubin, alkaline phosphatase, and GGT are normal. He does not drink alcohol. In your evaluation of his liver disorder, you find that a liver ultrasound is unremarkable for anatomic abnormalities, serologic studies for hepatitis A, B, and C are negative for infection, and his ferritin level is 725 ng/mL (upper limit of normal 300 ng/mL). What is the preferred next step in diagnosing his disease?

- A) Bone marrow biopsy
- B) Liver biopsy
- C) Hemochromatosis gene testing
- D) Echocardiogram
- E) Diagnostic and therapeutic trial of phlebotomy

See question 6.18.3: Helpful Tip.

185) Fournier gangrene is caused by infection with:

- A) Virulent, flesh-eating viruses
- B) Methicillin-resistant *Staphylococcus aureus*
- C) Mixed aerobic and anaerobic bacteria
- D) *Yersinia pestis*

See question 22.1.2.

186) Sepsis survival is improved by:

- A) Early central line placement for hemodynamic monitoring
- B) Early recognition with aggressive fluid resuscitation and antibiotic administration
- C) Specific protocols guided by central venous pressures
- D) Early intubation and ventilation
- E) Early palliative care consultation

See question 22.1.5: Helpful Tip.

187) You are seeing a 30-year-old male in the ED. He has survived a motor vehicle collision in which the driver of the other car was killed. He has multiple traumatic injuries but is alert—in fact, he's screaming in pain. His blood pressure is 88/56 mm Hg. What is the best option for managing his pain?

- A) A lollipop and reassurance that the trauma team is on the way
- B) IV morphine
- C) Oral morphine liquid
- D) IV fentanyl
- E) IV ketorolac

See question 22.2.1.

188) A 65-year-old female presents with 6 hours of abdominal pain. She also notes nausea but has not had emesis. She has not moved her bowels today. She has a history of abdominal surgeries, including hysterectomy, appendectomy, and cholecystectomy—all for benign reasons. Her vital signs are normal. Her abdomen is protuberant, tympanic to percussion, and mildly tender diffusely. Her bowel sounds are hypoactive. You suspect a partial small bowel obstruction due to adhesions. Your admission orders include all of the following EXCEPT:

- A) IV fluids
- B) Antiemetics
- C) NPO status
- D) NG tube to continuous suction
- E) Analgesic medication

See question 22.4.3: Helpful Tip.

189) After weight loss surgery, patients are at risk of developing nutritional deficiencies. Which of the following deficiencies are patients NOT likely to experience?

- A) Protein deficiency
- B) Vitamin B1 (thiamine) deficiency
- C) Vitamin B12 deficiency
- D) Copper deficiency
- E) Zinc deficiency

See question 22.5.4: Helpful Tip.

190) By definition, external hemorrhoids are located:

- A) Proximal to the dentate line
- B) Distal to the dentate line
- C) Distal to the anal verge
- D) In the gluteal cleft

See question 22.6.1.

191) A 55-year-old female presents with concern for a new mass she palpated in her left breast. She first noticed it a month ago and it has not changed. Your examination reveals a 2-cm firm mass in the upper outer quadrant of the left breast. The examination is otherwise normal. You find that a screening mammogram, done 6 months ago, was completely negative (BIRADS 1). The best next step in the management of this patient is:

- A) Reassurance, as her mammogram was normal
- B) Repeat a mammogram in 6 months
- C) Have her return in 6 months for a follow-up breast examination
- D) Refer for biopsy of the mass
- E) All of the above are equally appropriate

See question 22.7.3.

192) A surgical colleague consults you on an 80-year-old female who broke her femur after falling. The patient underwent an uncomplicated open reduction and internal fixation. It is now postoperative day 4 and she has developed a fever of 39°C. Potential causes of postoperative fever in this patient include all of the following EXCEPT:

- A) Atelectasis
- B) Wound infection
- C) Venous thrombosis
- D) Pneumonia
- E) Drug-induced fever

See Chapter 22: Table 22-3 and Question 22.8.3.

193) A patient with a history of heparin-induced thrombocytopenia and thrombosis syndrome CAN have:

- A) Low-molecular-weight heparin for any reason
- B) Bivalirudin and argatroban
- C) Heparin or low-molecular-weight heparin for prevention of venous thromboembolism

D) No heparin products for the rest of his or her life

See question 22.8.9.

194) Which of the following tests has the highest sensitivity (i.e., misses the fewest) for appendicitis?

- A) CBC
- B) CRP
- C) CT scan of the abdomen and pelvis
- D) Ultrasound of the right lower quadrant
- E) All of the above have equivalent sensitivity for appendicitis

See question 22.9.4.

195) A hysterical mother runs into the ED with her 2-year-old daughter in her arms, screaming, "She got scalded!" After a moment she is able to recount the story. The child was by the stove playing when she pulled on a pot handle and dumped hot water on herself. You find that the dorsum of her right hand and most of her dorsal right arm are covered in second- and third-degree burns. Using the "Rule of 9s," you estimate that she has burned:

- A) 1% of her body surface area
- B) 5% of her body surface area
- C) 10% of her body surface area
- D) None of the above. The "Rule of 9s" should not be used in children

See question 22.11.4: Helpful Tip.

196) A new test has been developed to detect pheochromocytoma (not really ... just pretend). The test has a very high sensitivity but a very low specificity for pheochromocytoma. The prevalence of pheochromocytoma in the population is low. If this new test is applied to the general population, which of the following is likely to occur?

- A) The specificity will increase
- B) The sensitivity will increase
- C) The positive predictive value will be low
- D) The negative predictive value will be low

See Case 28.6: Helpful Tip.

197) You are seeing 23-year-old female for a routine physical examination. She tells you that she has a new male partner who has used injectable drugs in the past and has shared needles. His HIV status is not known. They do not always use condoms when sexually active. In addition to recommending consistent condom use, you also recommend pre-exposure prophylaxis (PrEP) with:

- A) Tenofovir
- B) Tenofovir/Emtricitabine (Truvada)
- C) Efavirenz (Sustiva)
- D) Tenofovir/Emtricitabine/Efavirenz (Atripla)
- E) None of the above

See question 9.4.2.

198) A 5-year-old patient presents with “leg pain” that you determine is originating from the right hip joint. An x-ray demonstrates a density at the right femoral head. With your Spidey senses tingling, you order an MRI which shows osteonecrosis of the femoral head. The best next step in the care of this patient is:

- A) Acetaminophen, rest, and physical therapy
- B) Referral to orthopedic surgery for a hip replacement
- C) Systemic steroids (e.g., prednisone)
- D) Steroid injection of the hip joint

See question 12.2.3.

199) A 35-year-old male presents for foot pain one day after an injury. He was playing soccer when he twisted his right foot and ankle and fell. He has trouble bearing weight on the foot due to pain. You order an x-ray of his foot and ankle. The radiologist calls to tell you he has a Jones fracture. When you look at the x-ray, you expect to find a:

- A) Proximal 5th metatarsal fracture (but distal to the tuberosity)
- B) Distal 5th metatarsal fracture

- C) Midshaft 5th metatarsal fracture
- D) 5th metatarsophalangeal joint dislocation

See question 12.19.1.

200) You are watching a really bad grade B movie. Who do you think will win?

- A) Mothra
- B) King Ghidorah
- C) Biollante (a bioengineered Godzilla including the genes of humans and roses)
- D) Godzilla
- E) Mechagodzilla

Never bet against Godzilla.

Index

Note: Page numbers followed by f and t indicate figures and tables, respectively.

A

- Abacavir
 - common adverse effects, 283t
- ABC (airway, breathing, and circulation), 3
- Abdominal aortic aneurysm (AAA) screening
 - older patients, 657
- Abdominal pain, 220
- ABI (ankle-brachial index), 76–77
- Abortion, 770–771
 - threatened, 477
- ABPA (allergic bronchopulmonary aspergillosis), 136–137
- Absence seizures, 558, 578–579
- Abuse and neglect
 - children
 - abusive head trauma (subdural hematomas), 408
 - constipation, abuse may be a triggering event for, 396
 - encopresis, abuse may be a triggering event for, 396
 - nonaccidental trauma, 371
 - in orthopedics, always include child abuse in the differential diagnosis, 370
 - older persons, 653–655
 - risk factors, 654
 - rape, 493–494
- AC (acromioclavicular) sprain, 380–381
- Acamprosate (Campral), 754
 - alcohol, 754
- Acanthosis nigricans, 545, 545f, 732–733
- ACC/AHA staging system for heart failure, 69
- Accelerated junctional rhythm, 86, 87f
- Accommodation, 585
- Accommodative esotropia
 - infants, 586f
- ACE (angiotensin-converting enzyme) inhibitors
 - can cause effects on fetus during pregnancy, 162
 - cause cough in some patients, 121
 - for moderately increased albuminuria, 151
 - preferred over ARBs in patients with
 - hypertension, cardiovascular disease, and/or chronic kidney disease, 103
 - for proteinuria, 161–162, 328
 - in reducing progression of renal disease, 181
 - side effects, 83
 - to treat proteinuria and hypertension in patients with diabetes, 328
- Acetaminophen overdose, 1
- Acid-base disorder, 179
- Acidosis
 - will spuriously elevate a patient's potassium level, 164
- ACL (anterior cruciate ligament) rupture, 384–385
 - Lachman test, 385
- ACLS (advanced cardiac life support)
 - no need to intubate if patient can be easily bagged, 74
 - start with, and don't interrupt, chest compressions, 74
- Acne vulgaris, 540–541
 - do not use systemic antibiotics for first-line treatment, 549
- ACPA (anti-citrullinated protein antibodies), 331
- Acral lentiginous melanoma
 - most common melanoma in people of African descent, 527
- Acromegaly due to growth hormone excess, 327
- Acromioclavicular (AC) sprain, 380–381
- Actinic keratoses
 - precursors to squamous cell carcinoma, 544
- Activated charcoal
 - inappropriate for patients with altered mental status or otherwise unable to protect their airway, 2
 - likely helpful only within first hour after ingestion, 2
 - limited or no effect on outcome of poisonings, 2
 - not indicated for iron overdose, 2
- Acute abdomen, 667, 680
- Acute-angle closure glaucoma, 587–589, 587f
- Acute chest syndrome, 19–20
 - diagnosis, 19
 - exchange transfusion, 20
 - initial treatment, 19–20
 - in sickle cell patients, 197
- Acute coronary syndrome
 - perform ECG and administer aspirin 325 immediately for all patients presenting with symptoms, 103
 - stop all NSAIDs (except for aspirin) when admitting a patient for ACS, 103
- Acute DVT, 206–208
 - Homan sign, 206
 - pregnant women, 208
- Acute interstitial nephritis, 180
 - common drugs associated with, 180t
 - symptoms/signs/laboratory findings in, 180t
- Acute ischemic stroke
 - do not aggressively treat elevated blood pressure, 582
- Acute lead poisoning
 - children, 194–195
 - dimercaprol for, 195
 - lead can be released from bone years after initial exposure, 195
- Acute leukemia, 204
- Acute myeloid leukemia, 188
- Acute myocardial infarction (AMI), 43–46, 45–50
 - aspirin in treatment of, 45
 - categorizing chest pain patients, 44
 - echocardiography, 50
 - enoxaparin for anticoagulation, 49–50
 - HEART calculator, 44
 - lidocaine, 49–50
 - prasugrel (Effient), 45
 - submaximal stress testing, 50
 - thrombolytics, 47–48
 - vorapaxar (Zonivity) should not be used, 45
- Acute otitis media (AOM), 607–609
 - pneumatic otoscopy, 607, 609
- Acute prostatitis, 27–28
- Acute retroviral syndrome
 - testing for with combined HIV-1/2 antibody and antigen test by ELISA, 281
- Acute tubular necrosis (ATN), 165, 167–169
 - infection is most common cause of death, 169
- AD (Alzheimer disease), 646–648
 - drugs to treat, 648–650, 650t
- Addisonian (adrenal insufficiency) crisis
 - start steroids immediately, 328
- Adenocarcinoma, 220
- Adenomatous colon polyps, 221
- ADHD (attention-deficit/hyperactivity disorder)
 - adults
 - presentation, 714, 714t
 - children, 712–715
 - presentation, 714t
 - stimulant effects on, 714t, 715
- Adhesive capsulitis
 - associated with diabetes, 382
- Adjustment disorder, 704
- Adolescent females
 - long-acting reversible contraceptives (LARCs), 449
- Adolescent medicine, 437–450
- Adolescents
 - athletes, 438–441, 443–446
 - dietary supplements, 446–447
 - headache, 447
 - return to play, 447–449
 - sports physicals, 441, 443–444

- Adolescents (*Contd.*)
- sports-related concussion (SRC), 447–449
 - sudden cardiac death (SCD) in, 440–441
 - birth control options, 439–440
 - bone mineral content in females by age 12, 440
 - bulimia nervosa, 439
 - calcium, 440
 - constitutional delay of growth and puberty, 437–438
 - female athlete triad, 438–439
 - herpes gladiatorum (cutaneous herpes), 443
 - hypertrophic cardiomyopathy, 440–441
 - immunizations, 444
 - meningitis vaccines, 444
 - menstrual dysfunction, 438–440
 - mood disorders, 443
 - mortality, leading causes of, 442
 - nonconsented urine drug “screening” should not be performed, 443, 449
 - obesity, 444–446
 - osteopenia, 440
 - post-concussive syndrome, 449
 - puberty, first sign of, 437
 - routinely screen for substance abuse and mood disorders if adequate support resources are available, 449
 - self-harm, 443
 - substance use, 442–443
 - CRAFFT questions, 442
 - substance use disorders, 442–443
 - CRAFFT questions, 442
 - ultraviolet radiation exposure (sun tanning), counseling to minimize, 446
 - Valsalva maneuver, 441
 - vaping, 442
 - weight loss likely leads to decreased cardiovascular disease as an adult, 446
- ADPKD (autosomal-dominant polycystic kidney disease), 165
- Adrenal insufficiency, 309–311
- primary versus secondary, 310
- Advanced cardiac life support (ACLS)
- no need to intubate if patient can be easily bagged, 74
 - start with, and don’t interrupt, chest compressions, 74
- Advance directives, 773
- Advance healthcare planning
- older patients, 639
- Adverse effects
- evidence-based medicine, 793–794
- AEDs (anti-epileptic drugs), 556–557
- all women of childbearing age should be on folate and a prenatal vitamin while on AEDs, 557
- Aeroallergen skin prick, 141
- Aerophagia, 213
- Affective bias
- evidence-based medicine, 796
- Aged cheese
- and MAOIs (monoamine oxidase inhibitors), 63
- Age-related macular degeneration (AMD), 591–592
- AREDS2 vitamins, 592
 - dry form, 592
 - wet form, 592
- Agitated patients
- techniques to calm, 720t
 - warning signs, 720t
- AIDS. *See* HIV/AIDS
- Airway, breathing, and circulation (ABC), 3
- Albuterol metered-dose inhaler with spacer, 23–24
- Alcohol
- acamprosate (Campral), 754
 - brief interventions, 761–762
 - disulfiram (Antabuse), 753–754
 - fetal alcohol spectrum disorder (FASD), 750
 - fetal alcohol syndrome (FAS), 748–750, 749f, 762
 - screen all adults, 762
 - tetratogenic actions, 748–750, 753
 - treating alcohol use disorders, 753–755
 - Wernicke encephalopathy, 748
- Alcohol abuse
- documenting, ethics and, 766
- Alcohol withdrawal, 744–746
- Aliskiren (Tekturna)
- contraindicated with an ARWB or ACE inhibitor, 67
- Allergen immunotherapy, 142
- beta-blockers may increase risk of severe systemic reactions, 142
- Allergic angioedema, 146
- Allergic bronchopulmonary aspergillosis (ABPA), 136–137
- criteria for diagnosis of, 137t
- Allergic contact dermatitis, 530, 530f
- Allergic rhinitis, 141
- versus nonallergic rhinopathy, 137
- Allergy and immunology, 141–149
- clinical pearls, 149
- Allopurinol
- gout, 343–344
- Alopecia areata, 548
- Alpha-blockers
- for urolithiasis, 160
- Alpha thalassemia, 196
- Alport syndrome, 174
- ALT elevations, 234–235, 243
- Alternative therapies, 737–740
- Alzheimer disease (AD), 646–648
- drugs to treat, 648–650, 650t
- AMA (antimitochondrial antibodies), 240
- Amblyopia, 585
- Ambulatory devices, 644–645
- cane goes in hand contralateral to affected side, 645
- AMD (age-related macular degeneration), 591–592
- AREDS2 vitamins, 592
 - dry form, 592
 - wet form, 592
- Amenorrhea, 324–325, 498–499
- American Headache Society
- guidelines for acute treatment of migraines, 563t
- AMI (acute myocardial infarction). *See* Acute myocardial infarction (AMI)
- Amlodipine
- for Raynaud phenomenon, 358
- Amsler grid, 592
- Anal fissures, 671
- Anaphylactic reactions, 142
- Anchoring bias
- evidence-based medicine, 796
- Anemia
- causes, by red cell volume, 192t
 - chronic disease, 194
- Angina, 51–52
- Angiodysplasias, 247
- Angioedema, hereditary (HAE), 145–146
- Angiotensin-converting enzyme (ACE) inhibitors
- can cause effects on fetus during pregnancy, 162
 - cause cough in some patients, 121
 - for moderately increased albuminuria, 151
 - preferred over ARBs in patients with hypertension, cardiovascular disease, and/or chronic kidney disease, 103
 - for proteinuria, 161–162
 - in reducing progression of renal disease, 181
 - side effects, 83
 - to treat proteinuria and hypertension in patients with diabetes, 328
- Angiotensin receptor blockers (ARBs)
- evidently no benefit on mortality, 151
- Angle-closure glaucoma
- definitive treatment of choice: laser peripheral iridotomy, 589
 - drugs used, 588t
- Animal bites, 11
- Anion gap, 7
- acidosis, 7, 7t
- Ankle-brachial index (ABI), 76–77, 546–546
- Ankylosing spondylitis, 359–360
- Annexa, 209
- Anorexia nervosa, 716–717
- high mortality, 718
 - medical complications of, 717t, 718
- Anovulation, 488–489
- Answers to final examination, 838–839
- Antabuse (disulfiram), 753–754
- Anterior cruciate ligament (ACL) rupture, 384–385
- Lachman test, 385
- Anterior talofibular ligament sprain, 386–387
- Anterior uveitis, 599
- Antibiotics
- bacterial meningitis, 582
 - chronic kidney disease (CKD), 155
 - lumbar puncture, do not delay antibiotic therapy to obtain, 35
 - Lyme disease
 - do not treat with prolonged courses of antibiotics, 279
 - symptoms typically improve a few days after starting antibiotics, 348
 - meningitis, do not delay antibiotics in, 279
 - neonates, 35
 - sepsis, presumed
 - start fluids and antibiotics as soon as possible, 279
 - surgery, 664
 - prophylactic antibiotics should be given *before* surgery and *not* continued after surgery, 690
 - viral conjunctivitis
 - do not prescribe antibiotics for, 606
 - viral upper respiratory infections
 - do not treat with antibiotics, 279
- Anticholinergic toxidrome, 5, 5t
- Anti-citrullinated protein antibodies (ACPA), 331

- Anticoagulation
 - in atrial fibrillation, 59
 - bridging warfarin patients with heparin, cautions concerning, 207–208
 - length of, 207–208
 - new anticoagulants, 207
 - warfarin for, 59
 - Antidepressants and birth defects, 708
 - Anti-epileptic drugs (AEDs), 556–557
 - all women of childbearing age should be on folate and a prenatal vitamin while on AEDs, 557
 - Antihypertensive agents
 - when used with PDE5 inhibitors, 59–60
 - Antimitochondrial antibodies (AMA), 240
 - Antiphospholipid antibody syndrome, 354–355
 - Antipsychotics, 724
 - avoid first-line of antipsychotic medication for indications other than psychotic disorders, 727
 - avoid in older patients, 660
 - do not prescribe two simultaneously, 727
 - Antiretroviral agents
 - common adverse effects of, 283t
 - Antiretroviral treatment of HIV/AIDS (HAART), 281, 284
 - begin treatment immediately in pregnant women, 283
 - failing HAART treatment, 285–286
 - frequency of Pap smears, 292, 295
 - if patient is not able to comply fully, it is often better to not take any HAART at all, 292
 - partner notification, 283–284
 - starting, 283
 - Antisocial disorder, 721–722
 - characteristics of, 722t
 - Anxiety
 - and major depressive disorder (MDD), 694
 - Aortic aneurysm, 71–72
 - dissection of, 32, 72
 - percutaneous endovascular stent graft repair compared to open repair, 72
 - screening recommendations, 72
 - in women, 72
 - Aortic regurgitation
 - echocardiogram frequency, 78t
 - Aortic stenosis, 78
 - echocardiogram frequency, 78t
 - repair when it becomes symptomatic, 77–778
 - Aphthous ulcers (canker sores), 622
 - Apixaban (Eliquis), 209
 - Appendicitis, 680–681
 - anorexia will be present in only 75% of patients, 690
 - white count will be normal in 10% of patients, 690
 - ARBs (angiotensin receptor blockers)
 - evidently no benefit on mortality, 151
 - Arthritis and joint involvement, 362
 - Arthrocentesis, 374
 - Aspiration pneumonia
 - multiple definitions of, 677
 - Aspirin, 54
 - acute coronary syndrome
 - perform ECG and administer aspirin 325 immediately for all patients presenting with symptoms, 103
 - acute myocardial infarction (AMI), 45
 - chewed is preferable to swallowed in speed of action, 45
 - colon cancer, 222
 - recommendations, 43
 - sensitivity, 110
 - stop all NSAIDs (except for aspirin) when admitting a patient for ACS, 103
 - stroke, 553
 - Aspirin-exacerbated asthma, 110
 - Assisted reproductive technology, 485
 - AST elevations, 234–235, 243
 - Asthma, 23–24, 106–111
 - albuterol metered-dose inhaler with spacer, 23–24
 - aspirin-exacerbated, 110
 - categorization of severity and stepwise approach to therapy, 108–109, 108t
 - do not use a long-acting beta-agonist in asthma without an inhaled steroid, 138
 - do not use non-targeted IgE testing, 149
 - exacerbation, 23–24
 - expanded therapies for severe asthmatics, 111
 - importance of patient education in, 110–111
 - leukotriene inhibitors add little or nothing to inhaled steroid therapy, 110
 - normal blood gas can be an ominous sign, 107
 - populations at increased risk for, 106–107
 - ratio of forced expiratory volume in 1 second/forced vital capacity, 107
 - risk factors for, 106–107
 - “rule of twos,” 109–110
 - salmeterol associated with increased risk of asthma-related mortality, 110
 - spirometry, 107, 108t
 - stepwise approach to therapy, 109f
 - steroid use in, 24
 - Asymptomatic bacteriuria, 260–261
 - do not treat in most patients, 279
 - Asymptomatic reflux disease
 - does not exacerbate asthma, 121
 - Atazanavir
 - common adverse effects, 283t
 - Athletes, adolescent, 438–441, 443–446
 - dietary supplements, 446–447
 - headache, 447
 - return to play, 447–449
 - sports physicals, 441, 443–444
 - sports-related concussion (SRC), 447–449
 - sudden cardiac death (SCD) in, 440–441
 - Ativan (lorazepam)
 - for tricyclic-induced seizures, 4
 - Atomoxetine (Strattera), 715
 - Atopic dermatitis, 527–529, 529f
 - Atrial fibrillation, 57–58, 57f
 - anticoagulation, 60–61, 60t
 - cardioversion, 59
 - diltiazem to treat, 58
 - spontaneous conversion to normal sinus rhythm, 59
 - Atrial tachycardia with third-degree heart block, 84–86, 85f
 - digitalis intoxication, 86
 - pacemaker for, 86
 - Atropine
 - no longer in ACLS guidelines for asystole, 74
 - Attention-deficit/hyperactivity disorder (ADHD)
 - adults
 - presentation, 714, 714t
 - children, 712–715
 - presentation, 714t
 - stimulant effects on, 714t, 715
 - Attribution error
 - evidence-based medicine, 796
 - Atypical depression, 693
 - Audiogram, 614–615
 - Aura, 562t
 - Auricular hematoma/seroma, 622
 - Autoimmune hypothyroidism, 296–297
 - Autoimmune liver disease, 240
 - Autosomal-dominant polycystic kidney disease (ADPKD), 165
 - Avulsed tooth
 - reinsertion of, 15
 - but not baby teeth, 15
 - transport of, 14–15
 - Avulsion fracture of tuberosity, base fifth metatarsal, 388–389, 388f
 - Axis designation system, 722
- B**
- Babesiosis, 270t
 - Back pain
 - children, 378
 - Bacterial conjunctivitis, 596–597, 597f
 - Bacterial endocarditis, 265
 - Duke criteria for, 265t
 - Bacterial meningitis, 258–260
 - antibiotics and, 582
 - on campus, 260
 - recommended antibiotic therapy, 260t
 - Bacterial overgrowth syndrome, 228
 - Bacterial pneumonia
 - complicating influenza, 255
 - Bacterial sinusitis, 617–618
 - Bacteriuria, asymptomatic
 - do not treat in older patients, 660
 - Bad news, giving, 785–786, 785t
 - by phone, 785
 - phrasing, 786
 - Bag urine versus catheterized urine, 35
 - Balanitis, 514, 515f
 - Baloxavir (Xofluza)
 - influenza, 254
 - Bariatric surgery, 668–670, 734
 - dumping syndrome, 669
 - laparoscopic adjustable gastric banding (LAGB), 668–669
 - multivitamin recommended in patients who have had, 690
 - necessary conditions, 668
 - procedures, 670f
 - Roux-en-Y, 668–669
 - Barrett esophagus, 212–213
 - Basal cell carcinoma, 537
 - Baseline labs
 - do not get preoperatively without an indication in patients without significant systemic disease, 690
 - Bat bites, 11
 - Bayes theorem, 798
 - “Beer potomania,” 170
 - Bee sting, 24–25
 - children, 24–25
 - prophylactic treatment not routinely indicated, 25
 - removing stinger, 25
 - Bell palsy, 622–623

- Benign paroxysmal positional vertigo (BPPV), 619–620, 621t
Epley maneuvers, 620
- Benign prostatic hyperplasia (BPH), 501–502
prostate massage, 504
symptoms, 501
transurethral resection of the prostate (TURP), 504
treatment, 501–504
- Benzodiazepines
alcohol withdrawal, 42, 747
do not prescribe as first-line therapy for anxiety disorders, 727
often overprescribed, 702
seizures caused by drug overdose, 42
- Bereavement, 706, 723
- Beta-blockers
for HFREF, 67
not to be used alone as antihypertensive therapy unless there is another indication, 103
oral, in most patients with an AMI, 46
overdose, treating, 8–9
use with caution in patients with a history of severe anaphylactic reaction, 149
- Beta thalassemia
children, 196
- Biases and problems seen in studies, 789t
- Biceps tendon rupture, 383
- Bile acid sequestrants, 101
- Biliary outlet obstruction, 242–243
- Bioterrorism, 2–3
- Bipolar disorders, 715–716
- Bipolar I disorder, 715
- Bipolar II disorder, 715
- Birth control
for adolescents, 439–440
oral contraceptive pills (OCs), 451–454
 backup method, 452, 454t
 Depo-Provera and bone loss, 451
 headache, 451–452
 nausea and vomiting, 452, 454
- Birth defects and antidepressants, 708
- Birthmark in infants, 537–538, 537f
- Black cohosh, 736
- Black patients, 805–807
- Bleach ingestion, 22
- Bleeding
intrapelvic, 665
upper GI tract, 217–218
- Blood, giving
give only as much as necessary (one unit), 42
- Blood gas
normal can be an ominous sign in asthma, 107
normal CO₂ in dyspneic patient portends declining respiratory status, 138
venous compared to arterial, 138, 164
- Blood in urine, 156–157
gross hematuria more commonly associated with malignancy, 157
kidney stones, 157
microscopic hematuria, benign causes of, 157
- Blood pressure monitoring, 24-hour ambulatory, 79–80
- Blood pressure recommendations, 43
- Blood transfusion, 186–187
indications, 187t
reactions, 187
7 to 8 mg/dL for stable patients, 210
- Blowout fracture, 15–16
- Blueberry muffin appearance from CMV, 535f
- Blue dot sign, 507, 507f
- BNP (brain natriuretic peptide) level, 65
heart failure, 65
- Body Weight Planner, link to, 733
- Bone mineral content in females by age 12, 440
- Borderline personality disorder, 721–722, 721t
- Boxer fracture, 380
- BPH (benign prostatic hyperplasia), 501–502
symptoms, 501
transurethral resection of the prostate (TURP), 504
treatment, 501–504
- BPPV (benign paroxysmal positional vertigo), 619–620, 621t
Epley maneuvers, 620
- Brain natriuretic peptide (BNP) level, 65
heart failure, 65
- Brainstem stroke, 551–553
- Breast cancer, 672–673
BRCA genes, 672
core needle biopsy, 673
different types of, 674
favorable prognostic indicators, 674
fine needle aspiration (FNA), 673
GAIL score, 674–675
scoring radiologic findings, 673
- Breastfeeding
expressed milk
 should only be kept at room temperature for 6 hours, 479
HIV/AIDS, 290
risk of becoming overweight, 446
supplements to breast milk, 731
- Breastfeeding failure jaundice, 397
- Breast growth (gynecomastia) in adolescent males, 512
- Breast lumps, 672
- Breast milk jaundice, 402
- Breath-holding spells
children, 401
- Brief interventions
alcohol, 761–762
- Brief resolved unexplained event (BRUE), 401
- Bromocriptine
can generally be continued during pregnancy, 326
- Bronchiectasis, 134–135
- Bronchiolitis, 36–37
infants, 421–422
- Bronchitis
common cause of hemoptysis, 123
- Brudzinski sign, 259
- BRUE (brief resolved unexplained event), 401
“Bulge sign,” 349
- Bulimia nervosa, 439, 718–719
- Bullosis diabetorum, 546
- Bullous pemphigoid, 538–539, 539f
- BUN/Cr ratio, 152–153, 166–167
greater than 20 generally indicates that acute injury is secondary to extrarenal causes (except in children), 181
- Buprenorphine
alcohol withdrawal, 743
advantages over methadone, 743
- Bupropion (Wellbutrin), 703–704, 706, 714
no withdrawal syndrome (unlike SSRIs), 704, 706
- Burns, 685
Rule of 9's, 685
- Button batteries, swallowed, 38
- C**
- Cabergoline
can generally be continued during pregnancy, 326
- CABG (coronary artery bypass grafting)
management of arrhythmia in postoperative period, 679
- Calcium, 440
for renal osteodystrophy, have patients take it with meals, 175
taken with meals reduces risk of calcium oxalate stones, 181
- Calcium gluconate, 39
- Calcium pyrophosphate dehydrate crystal deposition disease (CPPD) (pseudogout), 345–346
- Campral (acamprosate), 754
- Canker sores, 622
- Cannabidiol, 740
- Cannabis hyperemesis syndrome, 250
- Cannabis intoxication, 759–760
- Capsule endoscopy of the small bowel using a small camera, 247
- Carbamazepine, 746
- Carbohydrates and calories, 324
- Carbon monoxide (CO) exposure, 9–10
carboxyhemoglobin level, 10
pregnancy is an indication for hyperbaric oxygen therapy, 10
“time zero” carboxyhemoglobin level, 9–10
- Carcinoid tumors, 222
- Cardiac catheterization, 53–54
- Cardiac CT scan, 53t, 56
- Cardiac resynchronization, 98
- Cardiac risk factors, 98–99, 99t
ACC/AHA calculator for, 98–99
- Cardiac temponade, 56
- Cardiology, 43–104
clinical pearls, 102–103
- Carotid artery disease
do not screen asymptomatic patients for, 582
- Carotid endarterectomy, 554
- Carpal tunnel syndrome, 391–392
- Case-control study, 794
- Casting, 392
- Cataracts, 603
- CAT scale (COPD Assessment Test), 113
- Cauda equina syndrome, 376, 394, 578
- Cauliflower ear, 622
- Ceftriaxone
do not use in neonates, 435
- Celexa (citalopram), 707, 709
- Cellular immunodeficiency syndromes, 147t
- Central line, placing, 687–688
- Central retinal artery occlusion, 601–602, 601f
- Central venous nutrition, 245
- Cervical cancer screening
in HIV-negative patients, do not begin before age 21, 499
older patients, 660
- Cervical intraepithelial neoplasia, 481–482
- Cervical spine, clearing clinically, 5, 6t
- Cervicitis, 495
- Cesarean section, emergency, 205

- CHA2-DS2-VASC score, 60, 60t–61t
 use when determining need for anticoagulation in atrial fibrillation, 103
- Chantix (varenicline)
 to assist with tobacco cessation, 129
- Charcoal, activated
 inappropriate for patients with altered mental status or otherwise unable to protect their airway, 2
 likely helpful only within first hour after ingestion, 2
 limited or no effect on outcome of poisonings, 2
 not indicated for iron overdose, 2
- CHARCOAL mnemonic, 2
- Cheese
 and MAOIs (monoamine oxidase inhibitors), 63
- Chemical eye injuries, 595–596
 alkali burns tend to be more severe than acid burns, 595–596
 irrigate, irrigate, irrigate!, 606
- Chemical pneumonitis, 676–677
- Chest pain, 51–52
 diagnosis, 32
 with normal ECG does not rule out ACS, 102
- Chest tube management, 690
- Chest wound (open, sucking), 31
- Cheyne-Stokes breathing, 784
- Chickenpox, 417
 children, 373
- Child-Pugh classification, 688, 688t, 690
- Children
 abuse. *See* Abuse and neglect
 acetaminophen overdose, 1
 acute lead poisoning, 194–195
 dimercaprol for, 195
 lead can be released from bone years after initial exposure, 195

- HSV, 506f
- Human granulocytic anaplasmosis, 270t
- Human monocytic ehrlichiosis, 270t
- Humoral immunodeficiency syndromes, 147t
- “Hungry bone syndrome”
- and parathyroidectomy, 306
- HUS (hemolytic uremic syndrome)
- children, 177–178
- Hyperaldosteronism, 82–83
- adrenal adenoma is most common cause, 83
 - treatment, 83, 873
- Hyperalgia, opioid-induced
- end-of-life pain control, 779–780
- Hyperbaric oxygen, 9–10
- Hypercalcemia, 156, 304–305
- causes of, 306t
- Hypercoagulability workup, exhaustive
- avoid in patients with VTE who have a major risk factor, 209
- Hyper IgE (Job syndrome), 147t
- Hyper IgM syndrome, 147t
- Hyperkalemia, 94, 94f
- causes, 94
- Hypernatremia
- causes, 166t
 - in older patients, may be caused by inability to access enough free water, 166
- Hypersensitivity pneumonitis, 105–106
- Hypersensitivity reactions, 143, 543
- Hypertension, 78–82
- avoid NSAIDs, 181
 - blood pressure recommendation in diabetic patients, 57
 - echocardiogram for, 80
 - initial treatment of, 81
 - treating for a patient with symptomatic benign prostatic hypertrophy (BPH), 80–81
 - treating in the elderly, 57
- Hyperthyroidism, 296–302
- can be confused with pheochromocytoma, 300
 - diarrhea is a sign that can presage thyroid storm, 301
 - treating in pregnancy, 299
- Hypertonic left upper extremity
- children, 409
- Hypertrophic cardiomyopathy, 440–441
- Hypocalcemia, 307
- replace calcium in patient who is not responding as expected to treatment, 181
- Hypoglycemia, 323–324
- treating, 320–321
- Hypokalemia, 164–165
- replace magnesium in patient who is not responding as expected to treatment, 181
- Hyponatremia, 311
- Hypotension, 168
- in response to nitroglycerin, may indicate right ventricular infarct, 46
- Hypothermia, 20–21
- determining proper demarcation line for debridement and grafting, 22
 - rewarming for bradycardia, 21
 - risk factors, 21
- Hypothyroidism, 296–298
- outside U.S., iodine deficiency is most common cause of, 297
- Hypovolemic hyponatremia, 169–171
- I**
- IBD (inflammatory bowel disease), 223–225
- NSAIDs are contraindicated, 224
- IBS (irritable bowel syndrome). *See* Irritable bowel syndrome (IBS)

HSV, 506f
infertility, 520–521, 521t

Men's health (*Contd.*)

- Klinefelter syndrome, 521, 521f
 - priapism, 515–516, 515t
 - prostate cancer, 518–519
 - prostate-specific antigen (PSA), 518–519, 523
 - scabies, 506f
 - seminal fluid analysis (SFA), 520
 - sexually transmitted infections, 504–506, 505f
 - syphilis, 505f
 - testicular cancer, 506–507
 - testicular torsion, 508
 - testosterone supplementation, 516–517, 516t
 - trauma
 - routinely screen young patients for high-risk behaviors, 523
 - vasectomy, 509–510
- Menstrual dysfunction, 438–440
- MEN types, 307
- MEN 1, 307
 - MEN 2A, 307
 - MEN 2B, 307
- Meperidine
 - avoid in older patients, 786
- Meralgia paresthetica, 372
- Meta-analyses, 795
- Metabolic acidosis
 - caused by ethylene glycol, methanol, and ethanol, 7
- Metabolic alkalosis, 153, 172–173
 - causes of, 173, 173t
- Metal fume fever (caused by zinc), 105
- Metamucil to reduce serum cholesterol, 102
- Metatarsalgia, 393
- Metatarsus adductus, 372
 - children, 372
- Methadone
 - older patients, 780
 - use and overdose, 755–757
- Methanol ingestions, 7–8
 - ethanol to treat, 8
 - fomepizole (4-MP) to treat, 8
 - hemodialysis for, 8
 - measured serum osmolality to help determine, 8
- Methemoglobinemia, 201–202
- Methicillin-sensitive *S. aureus* (MRSA), 265–266
- Methotrexate (MTX)
 - avoid pregnancy while taking, 333–334
 - ensure that women of child-bearing age have reliable contraception, 362
 - for rheumatoid arthritis, preferably in combination with other drugs, 332
- Methylene blue, 202
- Metoclopramide (Reglan)
 - treatment of GERD, 213
- Metoprolol succinate
 - to reduce mortality with HFrEF, 66–67
- Microalbuminuria, 150–151
 - renamed “moderately increased albuminuria,” 150
- Microcytic anemia, 194
- Microscopic hematuria
 - benign causes of, 157
 - detecting, 157
 - evaluation of, 157t
- Midgut volvulus
 - children, 423
- Migraine
 - neuroimaging, 582

- Migraine headaches, 561–566
 - American Headache Society guidelines for acute treatment, 563t
 - with aura, IHS criteria for diagnosis of, 562t
 - avoid use of narcotics if possible, 41
 - feverfew for, 738
 - neuroimaging not typically recommended in migraine patients with a normal neurologic exam, 564–565
 - prevention, 564
 - without aura, IHS criteria for diagnosis of, 561t
- Minimally invasive valve replacement, 64
- Minute ventilation, 134
- Miscarriage, 497–498
- Mitral regurgitation
 - echocardiogram frequency, 78t
- Mitral stenosis
 - echocardiogram frequency, 78t
- Mitrazapine (Remeron), 707
- Mixed metabolic/respiratory acidosis, 133
- MMRC Dyspnea Scale, 112–113
- MMR vaccine
 - fever and rash side effects are from the measles component and usually 1 week after vaccine is given, 399
- Moderately dehydrated children, 32–33
- Modified Checklist for Autism in Toddlers (M-CHAT), 409–410

 older people, 652
 Tdap (tetanus, diphtheria, and acellular pertussis) 11
 Tekturna (aliskiren)
 contraindicated with an ARWB or ACE inhibitor, 67
 Telangiectasias, 214, 214f
 Tenofovir
 common adverse effects, 283t
 Tenofovir/emtricitabine (Truvada) for pre-exposure HIV prophylaxis in high-risk patients, 295
 Tension pneumothorax, 31
 Tertiary prevention, 794
 Testicles, 25–26
 cancer, 506–507
 cremasteric reflex, 25
 normal lay, 25
 torsion, 25–26, 508
 Testosterone supplementation, 516–517, 516t
 Tetanus boosters, 11
 Tetanus primary series, 11
 Tetatogenic actions of alcohol, 748–750, 753
 Thalassemia
 children, 196
Thermoactinomyces candidus
 cause of “farmer’s lung,” 106
 Thiopurines
 test for thiopurine methyltransferase (TPMT) enzyme prior to starting, 223
 Third nerve palsy, 605–606
 Thoracentesis, 125–126
 Threatened abortion, 477
 Thrombocytopenia, 678
 Thrombocytopenic purpura (TTP), 204–205
 mimics, 2–5
 Thrombolysis generally not indicated for a DVT, 118
 Thrombolytics
 acute myocardial infarction (AMI), 47–48
 Thyroglossal duct cyst, 625
 Thyroid cancer, 302–305
 Thyroid replacement
 initiate at a low dose, 328
 Thyroid-stimulating hormone (TSH), 296–298, 328
 Thyroid storm, 300, 301
 Thyroid ultrasound
 do not order to routinely evaluate abnormal thyroid function tests, 328
 TIA (transient ischemic attack), 553
 ABCD criteria, 553t
 dual antiplatelet therapy, 553
 Ticagrelor (Brillinta), 45
 Tick-borne illnesses, 270t
 Tinel sign, 392
 TIPS (transjugular intrahepatic portosystemic shunt), 240
 Tissue plasminogen activator (tPA), 551–552
 for acute stroke, 552t
 eligibility and contraindications, 552t
 TMJ (temporomandibular joint) syndrome, 624
 Toddler’s fracture, 370, 370f
 Toenail fungal infections, 532, 549
 Toenail removal, 689
 Tolcapone (Tasmarr)
 associated with fatal hepatic necrosis, 573
 Tophaceous gout, 344
 Torsades de pointes, 3, 4f
 Toxic megacolon, 224
 Toxic shock syndrome, 274–275
 Toxidromes, 5, 5t
 tPA (tissue plasminogen activator), 551–552
 for acute stroke, 552t
 eligibility and contraindications, 552t
 Tranexamic acid and hypotensive trauma patients, 32
 Transcatheter aortic valve replacement (TAVR), 64
 mitral valve injury from, 64
 Transferrin receptor, 194
 Transfusion
 for patient with HFrEF, 68–69
 Transient ischemic attack (TIA), 553
 ABCD criteria, 553t
 dual antiplatelet therapy, 553
 Transient toxic synovitis, 364–365
 Transjugular intrahepatic portosystemic shunt (TIPS), 240
 Transsphenoidal pituitary resection, 327
 Transsphenoidal pituitary surgery, 326
 Transurethral resection of the prostate (TURP), 504
 Trapdoor fracture
 children, 16
 Trauma
 abuse. *See* Abuse and neglect
 eye, 606
 primary survey, 31
 routinely screen young patients for high-risk behaviors, 523
 Traumatic hyphema, 593–594, 593f
 Travelers’ diarrhea, 230, 272
 Treating family members
 ethics and, 772–773
Trichomonas vaginalis infection, 495
 Tricyclic overdose, 3
 difference between “entirely asymptomatic” and “asymptomatic,” 4
 sodium bicarbonate to treat arrhythmia, 3
 Trigeminal neuralgia, 578
 Triiodothyronine (T3)
 do not use for hypothyroidism, 328
 Trimethoprim, inhaled, 109
 Troponin
 false-positive readings, 102
 Troponin tests, 44
 TSH (thyroid-stimulating hormone), 296–298, 328
 T3 (triiodothyronine)
 do not use for hypothyroidism, 328
 Tuberculin skin test (TST), 261
 false positives, 261
 interpretation of, 261–262

- Tuberculosis (TB), 261–262
 drug-resistant, multidrug-resistant, and extensively drug-resistant, 263
 latent versus active TB, 262
 older people, 652
- Tularemia, 270t
- Tumor lysis syndrome, 190–191
 rasburicase approved for prevention of, 191
- TURP (transurethral resection of the prostate), 504
- Tylenol overdose, 1

 differentiating from Crohn disease, 225
- Ulcers
 NSAIDs and, 219
- Ultrasound
 as first modality in urolithiasis, 160
- Ultrasound-guided thoracentesis, 126
- Ultraviolet radiation exposure (sun tanning)
 counseling adolescents to minimize, 446
- Ultraviolet (UV) keratitis, 17
- Unconscious biases, 809, 811
- Uncontrolled bleeding
 consider use of tranexamic acid and tourniquet above the injury, 690
- United States Preventive Services Task Force (USPSTF)
 screening guidelines for lipid disorders, 100
 screening recommendation for HIV, 294–295
- Unresponsiveness, 30–31
- Upper endoscopy (EDEGD)
 do not refer patients with typical heartburn and no alarm symptoms, 251
- Uric acid nephropathy, 190
- Urinary incontinence
 older patients, 652–653
- Urinary retention in men, 28
- Urine albumin/creatinine ratio, 150–151
- Urine dipsticks, 161
- Urine drug “screening” of nonconsented adolescents should not be performed, 443, 449
- Urine protein/creatinine ratio, 161
- Urine sediment findings and associated conditions, 162t
- Urolithiasis, 158–160
 alpha-blockers for, 160
 can have same presenting symptoms and signs as abdominal aortic aneurysm, 158
 determining etiology, 159
 hospitalization for, 160
 NSAID as part of pain control regimen, 181
 ultrasound as first modality, 160
- Urologic infections, 26–27
 pregnancy test, 26–27
- Urticaria, 542–544, 543f
 causes of, 544t
- Urticaria pigmentosa, 547
- USPSTF (United States Preventive Services Task Force)
 screening guidelines for lipid disorders, 100
 screening recommendation for HIV, 294–295
- Uterine bleeding, chronic, 473–474
- UTI
 infants, 412–413
 symptoms of, 181
- ## V
- Vaccinations
 between 12 and 15 months of age, 401
 children, 435
 influenza, 253
 older patients, 635
- Vaginal bleeding, 487
- Vaginal dryness, 486
- Vaginitis diagnosis and treatment, 496t
- Valerian root, 709
- Validation set, 790
- Valsalva maneuver, 441
- Valve replacement, minimally invasive, 64
- Valvular disease, 63–64
- Valvular heart disease
 antibiotics
 do not use pre-procedural prophylactic antibiotics in most cases, 279
- Vancomycin
 do not use in patients with methicillin-sensitive *Staphylococcus aureus*, 279
- Vaping, 442
- Varenicline (Chantix)
 to assist with tobacco cessation, 129
- Varicella vaccination, 417
- Vascular dementia, 726
 older patients, 647
- Vascular endothelial growth factor (VEGF)
 inhibitor, 592
- Vasectomy, 509–510
- VDC (vocal cord dysfunction), 141
- Vena caval filters, 118
- Venlafaxine (Effexor), 708
- Venocaval filters
 do not use to prevent a second PE in a patient with a prior history of DVT, 209
- Venous stasis, 531
 do not routinely recommend diuretics as general therapy, 549
- Venous thromboembolism (VTE), 208–209
 perioperative management of patient with recent VTE, 209
 pregnant women, 208
- Ventilation, weaning from, 134
- Ventricular fibrillation, 40–42, 41f
- Ventricular tachycardia, 62
- Vertebral artery dissection, 554
- Vertigo
 causes of, 621t
- Vesicoureteral reflux, grading of
 infants, 413t
- Vestibular migraines, 620, 621t
- Vestibular neuritis/labyrinthitis, 620
- Viagra (sildenafil), 59–60
- Violent patients
 techniques to calm, 720t
 warning signs, 720t
- Viral conjunctivitis, 596–597, 597f
 do not prescribe antibiotics for, 606
- Viral encephalitis, 571
- Viral gastroenteritis, 229–230
- Viral infections
 in children, do not prescribe antibiotics for, 435
- Viral sinusitis, 617
- Viral upper respiratory infections
 do not treat with antibiotics, 279
- Vision loss, 590–591
- Vital signs, intake, and output, 168t
- Vitamin A, 729–731
- Vitamin B, 731, 735, 739
- Vitamin C, 729–731, 739
 for iron deficiency anemia, 193
- Vitamin D, 729–731
 for all breast-fed infants within the first few days of life, 740
- Vitamin E, 729–730
- Vitamin K, 209, 729–730
 and PT in liver disease, 186
- Vitamins and minerals, 729–730
 deficiencies, 735
- Vocal cord dysfunction (VCD), 141
- Von Willebrand disease (VWD), 183–184
 in women with menorrhagia, 192
- VTE (venous thromboembolism), 208–209
 perioperative management of patient with recent VTE, 209
 pregnant women, 208
- Vulvar itching, 496–497
- Vulvovaginal candidiasis, 497
- Vulvovaginitis, 27
- ## W
- Warfarin
 for anticoagulation, 59
 genetic testing for warfarin sensitivity, 209
 reversing, 61–62, 187–188
 vitamins and herbals that interact with, 727, 729t
- Weight
 gain, 731–732
 drugs associated with, 732, 732t
 loss, 733–734
 in adolescents likely leads to decreased cardiovascular disease as an adult, 446
 bariatric surgery, 734
 Body Weight Planner, link to, 733
 diets, 733
 drugs, 734
 exercise, 733–734
 lifestyle modifications, 744
 in older people, 632
 maintaining in end-of-life care, 782
 status by BMI, 731–732, 732t
- Wells criteria for PE, 116, 116t
- Wernicke encephalopathy
 Alcohol, 748
- West Nile Virus (WNV), 278–279
- Wheezing, 23–24
- White coat hypertension, 79
- WHO medical eligibility criteria for contraceptive use, 453f
- Wilson disease, 199
- Wiskott-Aldrich syndrome, 147t
- Wolf-Parkinson-White (WPW) syndrome, 90, 91f
 procainamide as treatment, 90
- Women's health and obstetrics, 451–500
 abuse. *See* Abuse and neglect
 amenorrhea, 498–499
 anovulation, 488–489
 assisted reproductive technology, 485

- cervical cancer screening
 - in HIV-negative patients, do not begin before age 21, 499
 - cervical intraepithelial neoplasia, 481–482
 - cervicitis, 495
 - chlamydia and gonorrhea testing, 492, 496
 - chorioamnionitis, 457–458
 - chronic pelvic pain, 492
 - contraception, 474–475
 - do not require a Pap smear and pelvic examination to prescribe contraception, 499
 - weight gain, 451
 - delivery
 - do not perform elective deliveries (unless medically indicated) prior to 39 weeks of gestation, 499
 - postpartum hemorrhage, 465–466, 466t
 - Down syndrome baby, 469–470
 - dysmenorrhea, 488
 - ectopic pregnancy, 476–477, 485
 - embryonic chromosomal abnormality, 477
 - emergency contraception, 490–491
 - endometrial cancer
 - protective factors for, 488t
 - risk factors for, 487t
 - endometriosis, 491–492
 - episiotomies, 464
 - do not routinely perform, 499
 - estrogen testing, 485
 - fibroids, 475
 - gestational diabetes, 470, 470t
 - group B streptococcus (GBS) culture or PCR, 455
 - gynecologic cancers, 493
 - HPV vaccine, 489
 - irregular menses, 484–485
 - labor, 455, 457, 458, 464, 478–479
 - bleeding during, 455, 457
 - endometriosis, 458, 460
 - fetal heart rate (FHR), 458
 - fetal heart tracing category definitions, 460t
 - inducing or augmenting, 461–462, 463f
 - shoulder dystocia, 479
 - variable deceleration, 462, 464f
 - LEEP, 481–482
 - menopause, 485–488
 - hormone replacement therapy (HRT), 486
 - hot flashes, 487
 - vaginal bleeding, 487
 - vaginal dryness, 486
 - miscarriage, 497–498
 - multifetal gestation, 466–467
 - operative vaginal delivery, 464–465
 - oral contraceptive pills (OCPs), 451–454
 - backup method, 452, 454t
 - Depo-Provera and bone loss, 451
 - headache, 451–452
 - nausea and vomiting, 452, 454
 - ovarian cancer, 493
 - ovarian mass, 492–493
 - Pap smear, 481–483
 - pelvic inflammatory disease (PID), 483–484
 - criteria for admission, 483t
 - placenta previa, 499
 - polycystic ovarian syndrome (PCOS), 495–496
 - hirsutism associated with, 496
 - preeclampsia, 469, 471t, 472
 - pregnancy
 - Bishop score, 460
 - chronic hypertension, 473
 - fetal macrosomia, 478
 - folate supplement, 740
 - guidelines for dating based on ultrasonography, 461
 - headache treatment in, 564
 - HIV/AIDS, 287–290, 295
 - prenatal vitamins, 740
 - size-date discrepancy, 478
 - weight gain in, 498, 498t
 - premenstrual syndrome (PMS), 489–490
 - treatment options, 490t
 - prenatal testing
 - diabetic screening, 454
 - genetic screening, 456f
 - prenatal tests, 454–456
 - preterm birth, 467–468
 - prolapse, 492
 - rape, 493–494
 - Rh-D-negative woman positive for D antibody, 477
 - screening, 469–470
 - Sheehan syndrome, 466
 - stress incontinence, 480
 - teens, screening in, 496
 - threatened abortion, 477
 - Trichomonas vaginalis* infection, 495
 - uterine bleeding, chronic, 473–474
 - vaginitis diagnosis and treatment, 496t
 - vulvar itching, 496–497
 - vulvovaginal candidiasis, 497
 - WHO medical eligibility criteria for contraceptive use, 453f
 - Wounds
 - closure, time for, 12
 - infections, 676–677
 - irrigation, 11–12
 - normal saline and tap water are equally effective, 12
 - WPW (Wolf-Parkinson-White) syndrome
 - procainamide as treatment, 90
 - Wrist drop, 561
- X**
- Xanax, 703
 - X-linked agammaglobulinemia, 147t
 - Xofluza (baloxavir)
 - influenza, 254
- Z**
- Zarelto (rivaroxaban), 209
 - Zenker diverticulum, 215
 - Zetia (ezetimibe), lack of positive evidence for, 101–102
 - Zika, 277–278
 - Zinc, 739
 - Zits, 540
 - Zollinger-Ellison syndrome, 219
 - Zolof (sertraline), 710
 - Z-Pak, 40
 - Zyvox (linezolid), 709

Adult Preventive Care*					
Recommended Screening	Start Age	End Age	Periodicity	Strength of Recommendation	Comments
Alcohol Misuse	18	None	Periodically	B	For populations at increased risk Systems should be in place for treatment and follow-up
Tuberculosis	18	None	Periodically	B	
Depression	18	None	Periodically	B	
Hypertension	18	None	Periodically	A	
Obesity	18	None	Periodically	B	
Tobacco Use/Cessation	18	None	Periodically	A	
HIV Testing	18	None	Periodically depending on risk	A	
Hepatitis B	18	None	Periodically	B	All pregnant women should be screened each pregnancy If at high risk (MSM, etc.)
Syphilis	18	None	Based on risk	A	If at high risk (MSM, etc.), up to every 3 months
BRCA	18		Once	B	If appropriate family history. General screening not recommended (Grade D...harmful)
Chlamydia and Gonorrhea (Women)	18–24		Periodically or with new partner	B	If sexually active
Chlamydia and Gonorrhea (Women)	25	None	Periodically or with new partner	B	If high risk sexual activity
Intimate Partner Violence (Women)	Reproductive age	50	Periodically	B	
Pap Smear (Women)	21	65	Every 3–5 years (see Chapter 15)	A	Q3 years or if >30 every 5 years with HPV Testing
Glucose	40	70	Periodically	B	Earlier if Asian overweight, hypertensive, etc.
Lipids	40	75	Periodically	B	If ASCVD 10-year risk is > 10% (see Chapter 2)
Hepatitis C	18	None	Periodically	B	Once for those born between 1945 and 1965, periodically for others at high risk
Colorectal Cancer	50	75	Depends on method used (see Chapter 7)	A	See chapter 7. Individualize for those 76–85 (grade C)
Breast Cancer (Women)	50	74	Every other year	B	For <50 individualize (grade C), for >75 no sufficient data
Lung Cancer	50	None	Every year CT	B	If 30+ pack-year of smoking unless quit 15 years or more ago. Note that AAFP disagrees (grade I)
Osteoporosis (Women)	65	None	Once	B	Or when FRAX score 10-year risk >9.3%
Abdominal Aortic Aneurysm (Men)	65	75	Once	B	If ever smoker

Select Screenings NOT to do (evidence insufficient or harmful)		Strength of Recommendation	Comments
Bladder Cancer		Grade I	AAFP recommendation
Carotid Screening for Stenosis		Grade D	
Celiac Disease		Grade I	
Chronic Kidney Disease		Grade I	
COPD Screening		Grade D	
Dementia		Grade I	
Genomic Testing for CAD		Grade I	
Glaucoma		Grade I	
Hearing (adults)		Grade I	
Obstructive Sleep Apnea		Grade I	
Osteoporosis in Men		Grade I	
Ovarian Cancer		Grade D	
Pancreatic Cancer		Grade D	
Prostate Cancer		Grade D	
Self Breast Exam for Women		Grade D	
Thyroid Dysfunction		Grade I	
Urinalysis	Any age	Grade D	
*Please see U.S. Preventative Services Task Force website for grade definitions at https://www.uspreventiveservicestaskforce.org/Page/Name/grade-definitions .			

Pediatric Preventive Care				
Note that the recommendations are based on AAP “Bright Futures.” If this differs from AAFP 2017 recommendation, it is noted in comments*				
Age	Test/Screen	Who to Screen	End Age	Comments
3–5 Days	Hearing	All		
	Newborn blood screen	All		
	Blood Pressure	Selective	To 30 months*	If kidney disease, heart disease, family hx congenital kidney disease, transplant, etc.
	Vision	Selective	To 30 months*	Parental concern, family history eye disorders, etc.
1 Month	Maternal Depression	All		Grade B evidence per AAFP
	Hearing if not done	All		
	Review Newborn Blood Screen	All		
	Tuberculosis	Selective		If HIV positive, history of exposure including travel. Not included in AAFP guidelines
2 Months	Maternal Depression	All		
	Hearing	If not done		Grade B evidence per AAFP
	Newborn Blood Review	If not done		
4 Months	Maternal Depression	All		Grade B evidence per AAFP
	Anemia	Selective		If low birth weight, prematurity, low iron diet, Cow’s milk (AAFP disagrees and gives a level I)
	Hearing	Selective	To age 3 years ^T	Caregiver concern, craniofacial abnormalities, etc. AAFP suggests screening once between age 3 and 5
6 Months	Maternal Depression	All		Grade B evidence per AAFP
	Oral Health	All		Oral exam, apply fluoride to erupted teeth
	Lead Level	Selective		Refugees 6 months - 16 years on entry to US, live in house built before 1960 or in poor repair, Medicaid (AAFP disagrees, level I)
9 Months	Tuberculosis	Selective		If HIV positive, history of exposure including travel
	Oral Health	All	Selective after this to 6 years ^Y	Fluoride on erupted tooth, exam, prescribe fluoride if not using fluorinated water
	Developmental Screening	All		
12 Months	Lead Level	Selective		Refugees 6 months - 16 years on entry to US, live in house built before 1960 or in poor repair, Medicaid (Note that AAFP gives lead screening a level of evidence of I)
	Anemia	All		
	Lead Level	All		AAFP disagrees (level of evidence I)
15 Months	Oral Health	Selective	See “Y” below.	
	Tuberculosis	Selective		If HIV positive, history of exposure
	Oral Health	All		In absence of a dental home
18 Months	Autism	All		Note that AAFP disagrees with this recommendation (level of evidence I)
	Developmental Screen			
	Anemia	Selective		AAFP assigns level I
2 Years	Lead	Selective		AAFP assigns level I
	Autism	All		Note that AAFP disagrees with this recommendation (level of evidence I)
	Lead	All		If on Medicaid, high risk housing, etc. (AAFP disagrees (level of evidence I)
3–5 Years	Oral Health	Selective		If no dental home
	Dyslipidemia	Selective	See “***” below.	>95% BMI, strong family history CAD,
	Tuberculosis	Selective		If HIV positive, history of exposure
3–5 Years	Developmental Screening	All		AAFP considers grade I
	Vision Screening	All		AAFP suggests screening once between ages 3 and 5
9 Years	Lipids	All	Once between age 9 and 11	

* Note that many AAP recommendations are not true “screenings.” They are a response to parenteral or other concerns.

** Blood pressure and vision can be done any visit if there are concerns.

^T Hearing can be done at any visit if there are concerns.

^Y Oral screening should be done electively at each visit if the child has no dental home.

** Dyslipidemia elective based on risk factors (noted above) until age 9–11 where it should be checked once.

What NOT to screen for per AAFP and USPSTF*		
Condition	Level of Evidence	Comments
Autism	I	AAP: Recommended at age 18 and 24 months
Celiac Disease	I	
Depression < 11 years old	I	
Formal Development Evaluation	I	
Hypertension	I	AAP: All children at 9, 18 and 30 months AAP suggests at age 3 and every year after. Permissive earlier if kidney disease, heart disease, family history of congenital kidney disease, transplant, etc. Not recommended by any source
Idiopathic Scoliosis	I	
Iron Deficiency	I	
Lead	D for normal risk individuals, I age 1–5 if not at high risk	
Lipids	I	AAP: Permissive from age 2–8 years, if strong family history, BMI>95%, etc. Recommended once from age 9–11 AAP: “Developmental surveillance,” newborn to age 21
Speech and language delay age 5 and younger	I	
Vision < 3 years old	I	
Tuberculosis	I	

*List combined from both sources.

AAFP Recommended Pediatric Screening in Order by Age		
Screening (by Age)	Comments	Grade Recommendation
Hearing Newborn	AAP: Birth and selective to age 3 years	
Oral Health 6 Months		Grade B
On Tooth Eruption	Fluoride supplement, same as AAP Fluoride varnish, same as AAP	Grade B
Vision Age 3–5 Years	At least once	Grade B
Obesity 6 Years and Older	AAP: 24 months and older	Grade B
Depression 12–18 Years	Same as AAP	Grade B
